Rods, 0.5–1.0 × 1.0–3.0 μm, motile by means of a single polar flagellum. Colonies on nutrient agar are 1–5 mm in diameter after 3 d at 25°C, circular, and smooth. No organic growth factors are required. Fluorescent pigment is produced in King B medium. Denitrification is negative. PHB is not accumulated in the cells. Arginine dihydrolase, catalase, and oxidase are positive. Gelatin liquefaction is variable. Only one strain has been observed to produce lipase against Tween 80.

All strains produce acid but not gas from L-arabinose, D-galactose, D-glucose, D-mannose, D-ribose, cellobiose, maltose, melibiose, and D-xylose. In assimilation tests, the last four sugars do not serve as carbon and energy sources. The following carbon compounds are assimilated (number of negative strains from a collection of 60 strains of the species, are given in parentheses): acetate, L-alanine, β-alanine, 4-aminobutyrate, 2-aminoethanol (1), 5-aminopantanoate, L-arabinose (1), L-arginine, L-asparagine, L-aspartate, betaine (2), citrate (1), fructose, fumarate, D-gluconate (4), D-glucose, L-glutamate, L-glutamine, glycerate (1), glycerol (1), heptanoate, L-histidine, *meso*-inositol (6), L-lactate (2), L-leucine (1), L-malate (2), L-ornithine, 2-oxoglutarate, pelargonate, L-phenylalanine, L-proline, propionate, putrescine, pyruvate, succinate, DL-tyrosine and DL-valine (1). Less than 90% of the strains can use D-arabinose, benzoate, carnosine, creatine, deoxycholate, D-galactose, DL-hydroxybutyrate, L-isoleucine, D-malate, D-ribose, sarcosine, and taurocholate. Slow utilization of butyrate, caproate, L-lysine, D-mannose, and trehalose. The main characteristics of the species are summarized in Tables BXII.γ.112 and BXII.γ.113. They refer to the type strain.

Growth occurs between 0 and 33°C, and one-third of the strains are able to grow at 37°C. Optimal growth is at 25°C. No growth at pH below 4.5. Isolated from meat. The strains

correspond to cluster 2 of a previous numerical taxonomic study of psychrotrophic pseudomonads that had been isolated from meat, soil, and water (Molin and Ternström, 1982, 1986). Interestingly, results of numerical taxonomic studies performed independently at about the same time on the fluorescent pseudomonad collection at Berkeley, which included the biotype G of *P. fluorescens*, identified a tight cluster with the same properties as *P. lundensis* (Barrett et al., 1986).

The mol% G + C of the DNA is: 58–60.

Type strain: ATCC 49968 , CCM 3503, DSM 6252.

28. **Pseudomonas luteola** Kodama, Kimura and Komagata 1985, 473^{VP} (*Chryseomonas luteola* (Kodama, Kimura and Komagata 1985) Holmes, Steigerwalt, Weaver and Brenner 1987, 246.)

lu.te′ o.la. L. dim. adj. *luteola* yellowish.

The following description is taken from the original paper.

Rods, 0.8 × 2.5 µm, with rounded ends, occurring singly, rarely in pairs. Motile by means of polar multitrichous flagella. A small number of PHB granules accumulate in the cells. Colonies on 0.5% glucose nutrient agar are smooth or wrinkled, entire or erose, flat or convex, light yellow or pale yellow, 3 mm in diameter after 2 d of growth at 30°C. A pellicle is formed on the surface of 0.5% glucose nutrient broth. A water-insoluble yellow pigment is produced. No water-soluble fluorescent pigment is produced. Catalase positive but oxidase negative. Nitrate is reduced to nitrite, but no denitrification occurs. Production of indole, hydrogen sulfide, and hydrolysis of starch, gelatin, Tween 80, esculin, and ONPG are all negative. No organic growth factors are required. Growth does not occur in a medium with 6.5% NaCl. Growth occurs at 42°C. Cleavage of protocatechuate is of the *ortho* type.

Acid is produced from L-arabinose, D-xylose, D-ribose, D-glucose, D-fructose, D-mannose, D-galactose, L-rhamnose, maltose, trehalose, mannitol, inositol, and salicin, but not from sucrose, lactose, cellobiose, adonitol, sorbitol, or inulin. L-arabinose, D-xylose, D-ribose, D-glucose, D-fructose, D-mannose, D-galactose, maltose, trehalose, mannitol, glycerol, acetate, pyruvate, malonate, DL-β-hydroxybutyrate, fumarate, 2-ketogluconate, gluconate, succinate, *p*-hydroxybenzoate, and glutamate are utilized, but sucrose, lactose, raffinose, inulin, starch, phenol, *o*-hydroxybenzoate, and *m*-hydroxybenzoate are not. Some properties are summarized in Table BXII.γ.116. The fatty acid and ubiquinone composition is typical of that of the genus *Pseudomonas*. Isolated from clinical specimens.

The mol% G + C of the DNA is: 55.4 (T_m).

Type strain: KS0921, DSM 6975 , IAM 13000, JCM 3352.

GenBank accession number (16S rRNA): D84002.

Additional Remarks: This species, originally assigned to the genus *Pseudomonas* (Kodama et al., 1985), was subsequently considered a member of a newly proposed genus, *Chryseomonas* (Holmes et al., 1987). Later studies (Anzai et al., 1997) demonstrated that *Pseudomonas* should be its correct generic allocation.

29. **Pseudomonas mandelii** Verhille, Baïda, Dabboussi, Izard and Leclerc 1999b, 56^{VP}

man.de′ li.i. M.L. gen. n. *mandelii* of Mandel, dedicated to M. Mandel, American bacteriologist.

Colonies on nutrient agar are smooth, circular, and nonpigmented. Fluorescent pigment produced on King B agar medium. Catalase, oxidase, denitrification, and levan formation are positive. Gelatin and starch are not hydrolyzed. Sodium chloride inhibits growth at 5% concentration. Growth occurs at 4°C but not at 41°C. Optimal growth at 30°C. Growth at the expense of many organic compounds, as well as the result of many enzymatic reactions, are listed in the original paper (Verhille et al., 1999b).

DNA–DNA hybridization experiments indicate a relative high DNA similarity with that of biovar IV (*"P. lemonnieri"*) of *P. fluorescens*. Isolated from mineral water.

The mol% G + C of the DNA is: 57.

Type strain: CFML 95-303, CIP 105273.

GenBank accession number (16S rRNA): AF058286.

30. **Pseudomonas marginalis** (Brown 1918) Stevens 1925, 30^{AL} (*Bacterium marginale* Brown 1918, 386; *Phytomonas marginalis* (Brown 1918) Bergey, Harrison, Breed, Hammer and Huntoon 1923, 182; *Phytomonas intybi* Swingle 1925, 730; *Chlorobacter marginale* (Brown 1918) Patel and Kulkarni 1951b, 80.)

mar.gi.na′ lis. L. *margo, marginis* edge, margin; M.L. adj. *marginalis* marginal.

Description taken from Haynes and Burkholder (1957), who cite the original sources.

Rods, motile with one to three polar flagella. Green fluorescent pigment produced in culture. Agar colonies cream to yellowish. Gelatin is liquefied. There is a discrepancy among different authors on nitrate reduction. Feeble hydrolysis of starch. Acid but no gas from glucose, galactose, fructose, mannose, arabinose, xylose, rhamnose, mannitol, and glycerol. Alkali from (indicating utilization of) acetate, citrate, malate, formate, lactate, succinate, and tartrate. Sucrose, maltose, raffinose, and salicin are not degraded. Optimum growth temperature between 25 and 26°C. Minimum, 0°C; maximum, 38°C.

Isolated from marginal lesion on lettuce from Kansas; pathogenic on lettuce and related plants. Strains of this species have been included in biovar II of *P. fluorescens* (Stanier et al., 1966), and it appears under such designation in Tables BXII.γ.112, BXII.γ.113, and BXII.γ.119. Later, the taxon was subdivided by Young et al. (1978) into three pathovars. *P. marginalis* pathovar *marginalis*, which includes the type strain of the species, ATCC 10844; *P. marginalis* pathovar *alfalfa* Shinde and Lukezic 1974b, associated with discolored alfalfa (reference strain PDDCC 5708, NCPPB 2644), and *P. marginalis* pathovar *pastinacae* (Burkholder 1960a), a pathogen of cultivated parsnip (*Pastinaca sativa*) (reference strain ATCC 13889, PDDCC 5709, NCPPB 806). Fatty acid analysis data were taken as the basis for placing this species in a subgroup with other fluorescent phytopathogenic and saprophytic *Pseudomonas* (Stead, 1992). This subgroup also contains the nonfluorescent *P. meliae*.

The mol% G + C of the DNA is: 60 (Bd).

Type strain: ATCC 10844, LMG 2210, NCPPB 667, PDDCC 3553.

GenBank accession number (16S rRNA): Z76663.

31. **Pseudomonas meliae** Ogimi 1981, 382^{VP} (Effective publication: Ogimi 1977, 547.)

me′ li.ae. Gr. n. *Melia* Chinaberry tree, *Melia azedarach*; M.L. gen. n. *meliae* of Melia.

The following description is taken from the original paper.

Rods, 0.4–0.5 × 1.4–2.0 µm (average 0.5 × 1.8 µm). Motile by means of one to two polar flagella. Noncapsulated. Do not accumulate PHB as carbon reserve material. Colonies on nutrient agar very small after 48 h, and 0.3–1.0 mm in 72 h. Circular, smooth, convex, translucent, and white when viewed with reflected light. On potato-sucrose agar, the colonies have a rough surface and irregular shape. The rough colonies revert to the smooth type after transfer to nutrient agar. The following properties are negative: nitrate reduction, gelatin liquefaction, H_2S and indole formation, production of pyocyanine, fluorescein, and other pigments, levan formation on nutrient-sucrose agar, arginine and lysine dihydrase reactions, starch and esculin hydrolysis, production of gluconate, tyrosinase and urease reactions, egg-yolk and lipase (margarine hydrolysis), malonate utilization, phenylalanine deaminase, methyl red, and Voges–Proskauer reactions. The catalase and oxidase reactions are positive. Nicotinate is required as an organic growth factor.

The following carbon compounds are used for growth: ribose, glucose, mannose, galactose, fructose, sucrose, glycerol, citrate, succinate, and malate. No growth is observed at the expense of xylose, rhamnose, arabinose, lactose, maltose, cellobiose, melibiose, trehalose, dextrin, glycogen, starch, inulin, mannitol, sorbitol, inositol, adonitol, dulcitol, salicin, or tartrate. Growth occurs between 4 and 37°C (optimum, 27°C) and between pH 5 and 8 (optimum, pH 7–8). rRNA–DNA hybridization studies have confirmed the allocation of this species in the genus *Pseudomonas* (De Vos et al., 1985). Based on fatty acid analysis, *P. meliae* was placed in the same subgroup constituted by phytopathogenic and saprophytic fluorescent *Pseudomonas* species (Stead, 1992). Isolated from Chinaberry tree (*Melia azedarach* L.) (family Meliaceae), where this pathogen produces the bacterial galls. The galls are formed in the leaf petioles and in branches and trunk.

The mol% G + C of the DNA is: 57.9 (T_m).

Type strain: ATCC 33050, DSM 6759, LMG 2220, NCPPB 3033.

Additional Remarks: See the Additional Remarks at the end of the description of *P. amygdali* in this list.

32. **Pseudomonas mendocina** Palleroni *in* Palleroni, Doudoroff, Stanier, Solanes and Mandel 1970, 220[AL]

men.do.ci′ na. Sp. fem. n. *mendocina* native of Mendoza (Argentina).

Characteristics of the species useful for differentiation from other species are given in Tables BXII.γ.116 and BXII.γ.117. Properties useful for distinguishing the species from some denitrifying pseudomonads are summarized in the chapter on the genus *Burkholderia*. Colonies are yellowish because of production of carotenoid pigment; not adherent or wrinkled in appearance. Optimum temperature, approximately 35°C. For further descriptive information, see Palleroni et al. (1970). Found in soil and water; isolated by enrichment in media with nitrate under anaerobic conditions, especially at 40°C. Ethanol and L(+)-tartrate can be used as carbon sources in the enrichments. It has also been isolated from clinical specimens (Hugh and Gilardi, 1980).

The mol% G + C of the DNA is: 62.8–64.3 (Bd).

Type strain: ATCC 25411, DSM 50017, LMG 1223.

GenBank accession number (16S rRNA): M59154, Z76664.

33. **Pseudomonas migulae** Verhille, Baïda, Dabboussi, Hamze, Izard and Leclerc 1999a, 1570[VP]

mi′ gu.lae. M.L. gen. n. *migulae* of W. Migula, who created the generic name *Pseudomonas*.

The following description is taken from the original paper.

Rods, motile by means of a single polar flagellum. Colonies on nutrient agar are smooth and circular. Fluorescent pigment is produced on King B agar. No phenazine pigments are synthesized. Starch and gelatin are not hydrolyzed. Levan is produced from sucrose and the arginine dihydrolase system is present in the cells. Low concentrations of NaCl (up to 0.8%) are tolerated, and 5% concentration is inhibitory. Growth occurs at 4°C but not at 41°C. The original paper reports the results of a number of enzymatic tests, as well as a list of compounds that can serve as sources of carbon and energy for growth, and a selection of these characters is used for differentiation from other fluorescent species.

DNA–DNA hybridization experiments suggest that this species may be considered as a genomovar of some of the biovars of *P. fluorescens*. Isolated from natural mineral water.

The mol% G + C of the DNA is: unknown.

Type strain: CFML 95-321, CIP 105470.

GenBank accession number (16S rRNA): AF074383.

34. **Pseudomonas monteilii** Elomari, Coroler, Verhille, Izard and Leclerc 1997, 849[VP]

mon.tei′ li.i. M.L. masc. gen. n. *monteilii* of Monteil, in honor of Henri Monteil, a French microbiologist.

The following description is taken from the original paper.

Motile rods. Colonies on nutrient agar are circular and nonpigmented. Fluorescent pigment is produced. No hemolysis on blood agar. The strains are lipase, elastase, lecithinase, and tetrathionate reductase negative. Arginine dihydrolase, catalase, and cytochrome oxidase are produced. Denitrification, formation of levan from sucrose, gelatinase, starch hydrolysis, hydrolysis of esculin and starch, deamination of phenylalanine, exonuclease activity, lysine and ornithine decarboxylase, and the tributyrin and fibrinolysis tests are all negative. Temperature range for growth is 10–36°C; optimal growth at 30°C. Growth occurs in the presence of 3% NaCl but not with 5% NaCl. The original paper by Elomari et al. (1997) includes an extensive nutritional and enzymatic characterization of the species. Part of the available information has been summarized in Tables BXII.γ.112 and BXII.γ.113. The strains have been isolated from clinical specimens.

The mol% G + C of the DNA is: 60 (T_m).

Type strain: CFML 90-60, CIP 104883.

GenBank accession number (16S rRNA): AF064458.

35. **Pseudomonas mucidolens** Levine and Anderson 1932, 344[AL]

mu.ci′ do.lens. L. adj. *mucidus* musty; L. v. *oleo* to smell of; L. part. adj. *mucidolens* musty smelling.

The description below is taken from the original paper.

Rods, rounded ends, occurring singly and in pairs, ac-

tively motile. Filamentous cells are frequently observed. Fluorescent pigment is produced. Gelatin is liquefied. Nitrates reduced to nitrites and gas. Optimum growth temperature 23–25°C; slight growth at 37°C and at 10°C. Acid produced from glucose, rhamnose, arabinose, erythritol, sorbitol, trehalose, galactose, fructose, and mannose. Moderate amount of acid from glycerol, mannitol, dulcitol, glycogen, inulin, maltose, melezitose, pectin, raffinose, salicin, starch, sucrose, and xylan. Lactate, citrate, and urate can be used for growth. Acetate, oxalate, sulfanilate, tartrate, salicylate, and formate do not support growth. A physiologically less active form of this species is described in the same paper under the name " *P. mucidolens* biovar tarda".

P. mucidolens is one of the species causing mustiness in eggs, which were the source for its isolation. The general characteristics as described above roughly conform to those of one of the denitrifying biovars of *P. fluorescens*, but extensive comparative studies of the phenotypic properties have not been done. However, DNA–rRNA hybridization data (De Vos et al., 1989) and rRNA sequence analysis (Anzai et al., 1997) confirm the allocation to the genus *Pseudomonas*.

The mol% G + C of the DNA is: 61.0 (T_m).
Type strain: ATCC 4685, LMG 2223.

36. **Pseudomonas nitroreducens** Iizuka and Komagata 1964a, 214[AL]
ni.tro.re.du′ cens. L. n. *nitrum* nitate; L. v. *reduco* to draw backwards, bring back to a state or condition; M.L. part. adj. *nitroreducens* nitrate reducing.

The following description is taken from the original paper.

Rods, 0.4–0.6 × 1.4–1.8 μm, occurring singly, rarely in pairs; motile with polar flagella. Fluorescent pigment produced. Gelatin is not liquefied. Nitrates are reduced to nitrites and to gas. Oxidase reaction positive. H_2S not produced. Starch is not hydrolyzed. Acid is produced from glucose. Glucose, gluconate, 2-ketogluconate, citrate, succinate, ethanol, *p*-hydroxybenzoate, and protocatechuate can be utilized as sole carbon sources. 5-Ketogluconate, benzoate, salicylate, gentisate, anthranilate, and *p*-aminobenzoate are not utilized. The fresh isolate could utilize kerosene, but the activity was lost after subcultivation in the laboratory. Optimum growth temperature, 25–30°C. No growth at 37°C. The source of isolation was oil brine in Japan.

The species has two characteristics never found in association in any of the fluorescent species described in RNA group I, namely, the capacity for denitrification and the inability to utilize gelatin. Its assignment to the genus *Pseudomonas* has been confirmed by molecular studies (Anzai et al., 1997).

The mol% G + C of the DNA is: unknown.
Type strain: IAM 1439.
GenBank accession number (16S rRNA): D84021.

37. **Pseudomonas oleovorans** Lee and Chandler 1941, 377[AL]
o.le.o′ vo.rans. L. n. *oleum* oil; L. v. *voro* to destroy, consume; M.L. part. adj. *oleovorans* oil consuming.

Description taken from the original paper.

When grown on agar, the cells are almost coccoid (0.5 × 0.8 μm), but the length increases to about 1.5 μm during the exponential phase in broth. The colonies have a typical fluorescence that is not imparted to the medium. Nitrate is reduced to nitrite. Gelatin not liquefied. Starch is hydrolyzed. Isolated from oil-water emulsions used as lubricants and cooling agents in the cutting and grinding of metals. Apparently the organism lives on some normal constituent of the cutting compound, probably the naphthenic acids, which act as emulsifying agents. Consequently, the name *oleovorans* may not be appropriate. Allocation to the genus *Pseudomonas* was confirmed by DNA–rRNA hybridization studies (De Vos et al., 1989) and by 16S rRNA sequence analysis (Moore et al., 1996; Anzai et al., 1997).

The mol% G + C of the DNA is: 63.5 (T_m).
Type strain: ATCC 8062, DSM 1045.
GenBank accession number (16S rRNA): Z76665.

38. **Pseudomonas orientalis** Dabboussi, Hamze, Elomari, Verhille, Baida, Izard and Leclerc 1999b, 303[VP]
or.i.en.tal′ is. M.L. masc. adj. *orientalis* pertaining to the Orient.

Rods, motile by means of a single polar flagellum. Colonies on nutrient agar are circular, smooth, and nonpigmented. Fluorescent pigment is produced on King B agar. Catalase, oxidase, gelatinase, esterase-lipase, urease, and arginine dihydrolase reactions are all positive. Levan is produced from sucrose. Reduction of nitrate to nitrite is positive, but there is no denitrification. All strains liquefied gelatin. Various enzymatic reactions are described in the original paper, but not the ability to liquefy gelatin. Assimilation of various organic compounds, particularly carbohydrates, is described.

DNA–DNA hybridization experiments give low reannealing values with other fluorescent species and biovars. Growth occurs at 4°C. Isolated from Lebanese spring water.

The mol% G + C of the DNA is: 60.
Type strain: CFML 96-170, CIP 105540.
GenBank accession number (16S rRNA): AF064457.

39. **Pseudomonas oryzihabitans** Kodama, Kimura and Komagata 1985, 472[VP] (*Flavimonas oryzihabitans* (Kodama, Kimura and Komagata 1985) Holmes, Steigerwalt, Weaver and Brenner 1987, 245.)
o.ry.zi′ ha.bi.tans. L. fem. n. *oryza* rice; L. fem. adj. *habitans* inhabiting; M.L. fem. adj. *oryzihabitans* rice.

The description is taken from the original paper.

Rods, 0.8 × 2.0 μm, with rounded ends, occurring singly, rarely in pairs. Motile by means of a monotrichous flagellum. Granules of PHB do not accumulate. Colonies on 0.5% glucose nutrient agar are smooth or wrinkled, entire or erose, flat to convex, light yellow, 2 mm in diameter after 2 d incubation at 30°C. A pellicle is formed on the surface of 0.5% glucose nutrient broth. A water-insoluble yellow pigment is produced. No water-soluble fluorescent pigment is produced. Catalase is produced; the oxidase reaction is negative. Nitrate reduced to nitrite, but no denitrification occurs. Urease is produced. Production of indole, hydrogen sulfide, and hydrolysis of starch, Tween 80, esculin, and ONPG are all negative.

Growth occurs in medium containing 6.5% NaCl. No organic growth factors are required. Cleavage of protocatechuate is of the *ortho* type. Acid is produced from L-arabinose, D-xylose, D-glucose, D-fructose, D-mannose, D-galactose, maltose, trehalose, mannitol, sorbitol, and inositol, but

not from L-rhamnose, sucrose, lactose, cellobiose, adonitol, salicin or inulin. L-arabinose, D-xylose, D-ribose, D-glucose, D-mannose, D-galactose, maltose, trehalose, mannitol, glycerol, acetate, pyruvate, malonate, DL-β-n-hydroxybutyrate, fumarate, gluconate, 2-ketogluconate, succinate, *p*-hydroxybenzoate, and glutamate are utilized, but not sucrose, lactose, raffinose, inulin, starch, phenol, *o*-hydroxybenzoate, or *m*-hydroxybenzoate. Hydrogen is not utilized. Some properties are given in Table BXII.γ.116. The cellular fatty acid and ubiquinone composition is the typical type of the genus *Pseudomonas*. Isolated from a Japanese rice paddy.

The mol% G + C of the DNA is: 65.1 (T_m).

Type strain: KS0036, ATCC 43272, DSM 6835, IAM 1568, JCM 2592.

GenBank accession number (16S rRNA): D84004.

Additional Remarks: This species was originally described as a member of the genus *Pseudomonas* (Kodama et al., 1985), but was later assigned to the proposed new genus name *Flavimonas* (Holmes et al., 1987). Further studies (Anzai et al., 1997) demonstrated that the latter should be considered a synonym of *Pseudomonas*.

40. **Pseudomonas pertucinogena** Kawai and Yabuuchi 1975, 318[AL]

per.tu.ci.no′ ge.na. pertucin (coined word), a bacteriocin active against *Bordetella pertussis*; L. v. *gigno* to produce; M.L. fem. adj. *pertucinogena* intended to mean pertucin producing.

The description is from the original paper, referring to two strains of the species.

Rods, 0.4 × 1.1 μm, motile by means of single polar flagellum. Do not accumulate PHB. Oxidase reaction positive. No pigments are produced. Hydrolysis of gelatin, starch, or Tween 80, and arginine dihydrolase reaction are all negative. Acid production from sugars is in general weak or negative (glucose, D-arabinose, and galactose are positive). Pyruvate, succinate, oxaloacetate, β-hydroxybutyrate, and L-alanine are utilized for growth. A number of amino acids, carbohydrates, and alcohols are not utilized. Further details are given in the original paper. The two known strains produce pertucin, a bacteriocin active against *Bordetella pertussis*, and were kept for many years in the American Type Culture Collection as members of this species.

The mol% G + C of the DNA is: ~60.

Type strain: ATCC 190.

41. **Pseudomonas pseudoalcaligenes** Stanier *in* Stanier, Palleroni and Doudoroff 1966, 247[AL]

pseu.do.al.ca.li′ ge.nes. Gr. adj. *pseudes* false; M.L. adj. *alcaligenes* alkali-producing; M.L. adj. *pseudoalcaligenes* false alkali-producing.

Characteristics useful for differentiation from other *Pseudomonas* species are given in Tables BXII.γ.116 and BXII.γ.117, and the chapter on the genus *Burkholderia*, which summarizes information on denitrifying pseudomonads. Optimum temperature, 35°C. Further descriptive information can be found in Ralston-Barrett et al. (1976) and Stanier et al. (1966). The nutritional spectrum is quite narrow (see *P. alcaligenes*). The gelatinase reaction is negative. The species is rather heterogeneous. The collection examined by Stanier et al. (1966) included at least two groups. Strains of one of the groups were capable of PHB accumulation and gave a positive arginine dihydrolase reaction, while the strains of the second group were negative for the two properties and also differed in some nutritional characteristics (Doudoroff and Palleroni, 1974).

Three subspecies were thought to integrate this species, namely, *P. pseudoalcaligenes* subsp. *pseudoalcaligenes* (corresponding to the original description by Stanier et al., 1966), *P. pseudoalcaligenes* subsp. *citrulli* Schaad et al. 1978 (a name given to strains isolated from water soaked lesions on cotyledons of watermelon, *Citrullus lanatus*, and also pathogenic for other plants of the same family) (Schaad et al., 1978), and *P. pseudoalcaligenes* subsp. *konjaci* (the causal agent of bacterial blight of konjac, *Amorphophallus konjaci* Koch) (Goto, 1983b). Nutritional characteristics that were found useful for rapid identification were the utilization of L-arabinose and galactose by the subspecies *citrullus* (subsp. *pseudoalcaligenes* and subsp. *konjaci*, and *P. alcaligenes* are negative), and the utilization of mannitol by subsp. *konjaci* but not by subsp. *pseudoalcaligenes* and subsp. *citrulli*, and *P. alcaligenes* (Goto, 1983b).

The fatty acid composition of *P. pseudoalcaligenes* and its subspecies placed this taxon in one of the subgroups of *Pseudomonas* together with other nonfluorescent species (Stead, 1992). In spite of the above considerations, the results of a numerical analysis supplemented by DNA–DNA reassociation experiments (Hu et al., 1991) were taken as the basis for the conclusion that subsp. *citrulli* and subsp. *konjaci* should be transferred to a different species, *P. avenae*, which had been allocated to rRNA similarity group III (Palleroni, 1984). Consequently, this species should include three subspecies: *P. avenae* subsp. *avenae* Manns 1909 (type strain ICMP 3183), *P. avenae* subsp. *citrulli* (Schaad et al., 1978) comb. nov. (type strain ICMP 7500), and *P. avenae* subsp. *konjaci* (Goto, 1983a) comb. nov. (type strain ICMP 7733) (Hu et al., 1991). Studies by Willems et al. (1992) support the conclusion that these various phytopathogenic pseudomonad taxa should be transferred to the genus *Acidovorax* and the new combinations *Acidovorax avenae* subsp. *citrulli* and *A. avenae* subsp. *cattleyae* as well as the new name *Acidovorax konjaci* have been proposed. *P. pseudoalcaligenes* has been isolated from various natural materials and from clinical specimens.

The mol% G + C of the DNA is: 62.2–63.2 (Bd).

Type strain: ATCC 17440, LMG 1225, NCIB 9946.

GenBank accession number (16S rRNA): Z76666.

42. **Pseudomonas putida** (Trevisan 1889b) Migula 1895a, 29[AL] (*Bacillus putidus* Trevisan 1889b, 18.)

pu′ ti.da. L. fem. adj. *putida* stinking, fetid.

Characteristics of the species (103 strains of biovar A and 9 strains of biovar B) are given in Tables BXII.γ.112 and BXII.γ.113. Other properties of interest are summarized in Tables BXII.γ.108 and BXII.γ.114. The characteristics that are useful for a separation from *P. aeruginosa* and *P. fluorescens* include the inability to liquefy gelatin, to produce any phenazine pigments, to denitrify or to give an egg-yolk reaction, and to grow at 41°C. In this constellation of negative properties, the incapacity to hydrolyze gelatin is the one that has classically defined *P. putida*. Optimum temperature, 25–30°C.

Isolated from soil and water after enrichment in mineral media with various carbon sources. The majority of the strains have been assigned to biovar A (biotype A of Stanier

et al., 1966), which is considered typical. Biovar B differs from biovar A only in a few phenotypic properties: all known strains of this biovar utilize L-tryptophan, kynurenine, and anthranilate, and most use D-galactose as carbon sources. None of the strains of biovar B uses nicotinate. Recent studies on many strains of this species, combining a numerical analysis of phenotypic data with rRNA gene restriction patterns (ribotyping), have indicated the convenience of a revision of its present internal subdivision into biovars (Elomari et al., 1994), as previously suggested by Barrett et al. (1986) and by Stenström et al. (1990) (see also the sections on taxonomic comments and on ribotyping, in particular the contribution by Brosch et al., 1996).

The mol% G + C of the DNA is: 62.5 (biovar A; thermal denaturation); 60.7 (biovar B).

Type strain: ATCC 12633, DSM 291, NCIB 9494.

GenBank accession number (16S rRNA): D37923.

43. **Pseudomonas resinovorans** Delaporte, Raynaud and Daste 1965, 1075[AL]

re.si.no' vor.ans. L. n. *resina* resin; L. v. *voro* to devour, digest; M.L. part. adj. *resinovorans* resin digesting.

The description is taken from the original paper.

Rods, 0.6–0.7 × 2.0–2.5 μm. Motile by means of a polar flagellum. Fluorescent pigment is produced. Gelatin is not liquefied. Nitrate reduction is weak, and denitrification is negative. Oxidase reaction positive. Optimum growth temperature, 28–30°C; no growth at 5°C or 42°C. No acid is produced from arabinose, xylose, rhamnose, glucose, fructose, galactose, mannose, lactose, maltose, sucrose, raffinose, inulin, salicin, dextrin, glycerol, mannitol, inositol, or dulcitol. Starch hydrolysis very weak. Growth occurs at the expense of colophony, Canada balsam, or abietic acid. Phenol, phenanthrene, salicylic acid, *m*-cresol, and naphthalene can also be used as carbon and energy sources for growth. Further information may be found in the original paper by Delaporte et al. (1965). Assignment to the genus *Pseudomonas* is confirmed by results on nucleic acid hybridization (De Vos et al., 1989) and by 16S rDNA sequence analysis (Moore et al., 1996).

The mol% G + C of the DNA is: 63.7 (T_m).

Type strain: ATCC 14235, CCUG 4439, LMG 2274.

GenBank accession number (16S rRNA): Z76668.

44. **Pseudomonas rhodesiae** Coroler, Elomari, Hoster, Izard and Leclerc 1996, 603[VP]

rho.de' si.ae. M.L. fem. gen. n. *rhodesiae* of Rhodes, in honor of M.R. Rhodes, an English microbiologist.

Rods, motile by means of single polar flagella. Colonies on nutrient agar are smooth, circular, and nonpigmented. No hemolysis observed on blood agar. Fluorescent pigment is produced in King B medium. Arginine dihydrolase, catalase, cytochrome oxidase, lecithinase, nitrate reduction to nitrite, formation of levan from sucrose, growth on cetrimide agar, lecithinase reaction, and decomposition of L-tyrosine are all positive. PHB is not accumulated. Phenazine pigments are not produced. Gelatin liquefaction, lipase reaction, esculin and starch hydrolysis, deamination of phenylalanine, and exonuclease production are all negative. A large number of enzymatic properties are described in the original paper. A summary of properties of this species is presented in Tables BXII.γ.112 and BXII.γ.113. A number of additional characteristics can be found in the original paper and elsewhere (Elomari et al., 1995). Isolated from natural mineral water.

The mol% G + C of the DNA is: 59 ± 1 (T_m).

Type strain: CIP 104664.

GenBank accession number (16S rRNA): AF064459.

45. **Pseudomonas savastanoi** (Janse 1982) Gardan, Bollet, Abu Ghorrah, Grimont and Grimont 1992, 611[VP] (*Pseudomonas syringae* subsp. *savastanoi* Janse 1982, 168.)

sa.vas.ta' no.i. L. gen. n.*savastanoi* of Savastano, the first worker who studied olive knot disease.

The description is taken from the above-mentioned paper.

Rods, 0.4–0.8 × 1.0–3.0 μm. Motile by means of one to four polar flagella. Rather slow growing. Colonies are white or cream, smooth, flat, and glistening with entire or erose margins. Strains produce an hypersensitive reaction on tobacco leaves. Other properties of interest are summarized in Table BXII.γ.109. Metabolism is respiratory. Oxidase negative. Nitrates are not reduced. Blue fluorescent pigment is produced on King B medium and can be observed under UV light. Arginine dihydrolase negative. Esculin, gelatin, and starch are not hydrolyzed. Strains assimilate sucrose, L-arabinose, gluconate, caprylate, fumarate, DL-glycerate, L-malate, pyruvate, citrate, D-alanine, and L-proline. They do not assimilate lactose, L-xylose, adonitol, 2-aminobutyrate, DL-lactate, D-β-hydroxybutyrate, D(−)-tartrate, L-cysteine, L-methionine, and L-valine.

Strains have been isolated for many years from members of the family Oleaceae (olive, oleander). These do not produce levan from sucrose. Strains isolated from another species of the same family (*Fraxinus excelsior* L.), *Phaseolus vulgaris*, and *Glycine max* (Leguminosae) do produce levan. The species is now divided into three pathovars. *P. savastanoi* pathovar *savastanoi* causes knots, galls, and cankers on plants of various genera of the family Oleaceae; *P. savastanoi* pathovar *glycinea* causes bacterial blight of soybean; and *P. savastanoi* pathovar *phaseolicola* causes halo blight of bean.

The mol% G + C of the DNA is: 60 (T_m).

Type strain: ATCC 13522, CFBP 1670, ICMP 4352, NCPPB 639.

Additional Remarks: The paper by Gardan et al. (1992) essentially is a proposal to revive the name *P. savastanoi*, which had been created by Stevens in 1913 in a valid publication. This name was omitted from the 1980 approved list of bacterial species, an omission that had its origin in the fact that the name had been included in a list of pathovars of the species *P. syringae*.

The restoration of *P. syringae* pathovar *savastanoi* to its original status as independent species (*P. savastanoi*) after two demotions (one to the subspecies category, and the other to pathovar), has been formulated based on a phenotypic analysis and DNA–DNA hybridization studies (Gardan et al., 1992). In fact the phenotypic properties that differentiate this taxon from other related fluorescent, oxidase negative plant pathogens, are very few. In addition, the conditions of the nucleic acid hybridization used by Gardan et al. (1992) apparently were those used in the original description of the adopted methodology (Crosa et al., 1973b), even to the point of the incubation at 60°C, which is low for organisms of mol% G + C content higher

than *E. coli*. As a consequence, the estimated similarities reported in the paper tend to be high, although the figures can be grouped into blocks that reflect differences between *P. savastanoi* and other *P. syringae* pathovars, with the exception of the type strains of pathovars *phaseolicola* and *glycinea*. Consequently, the proposal subdivides *P. savastanoi* into pathovar *savastanoi*, pathovar *phaseolicola*, and pathovar *glycinea*. These last two names had also been used until now to designate pathovars of *P. syringae*

Recent studies on DNA similarity by hybridization methods indicate that *P. savastanoi*, *P. ficuserectae*, *P. meliae*, and *P. amygdali* should be considered as synonyms, in which case the latter is the correct name of the species (Gardan et al., 1999).

46. **Pseudomonas straminae** Iizuka and Komagata 1963b, 139[AL] emend. Uchino, Kosako, Uchimura and Komagata 2000, 1518.
stra.mi' na.e. L. adj. *straminae* made of straw.

Slender rods, 0.3 × 3.0 µm. Motile with single polar flagellum. Colonies are yellow. Fluorescent pigment is produced. Oxidase reaction positive. Gelatin is liquefied. Nitrates are not reduced to nitrites. Denitrification is negative. H_2S is produced. Starch is not hydrolyzed. Acid produced from glucose. Glucose, gluconate, citrate, succinate, and ethanol are assimilated. Phenol, benzoate, salicylate, *m*-hydroxybenzoate, *p*-hydroxybenzoate, protocatechuate, gentisate, anthranilate, *p*-aminobenzoate, 2-ketogluconate, and 5-ketogluconate are not assimilated. Optimum growth temperature, 25–30°C. No growth at 37°C. Assignment to the genus *Pseudomonas* has been confirmed by 16S rDNA sequence analysis (Anzai et al., 1997). The organism has been isolated from Japanese rice paddies.

The mol% G + C of the DNA is: unknown.

Type strain: IAM 1598.

GenBank accession number (16S rRNA): D84023.

47. **Pseudomonas stutzeri** (Lehmann and Neumann 1896) Sijderius 1946, 115[AL] (*Bacterium stutzeri* Lehmann and Neumann 1896, 237.)
stut' ze.ri. stutzeri Stutzer patronymic, of Stutzer.

Characteristics differentiating the species from other species of *Pseudomonas* are given in Tables BXII.γ.116 and BXII.γ.117. Differentiation from a number of denitrifying pseudomonads can be found in Table BXII.γ.114 and in the chapter on the genus *Burkholderia* appearing in Volume 2 Part C in this *Manual*. Recently isolated colonies are adherent, dark brown, and have a characteristic wrinkled appearance, which usually is lost after repeated transfers in laboratory media. The colonies may eventually become smooth, butyrous, and pale in color. The gelatinase reaction is negative. Among the characteristics useful for its identification are the vigorous denitrification, the appearance of the colonies, and the use of starch as a carbon and energy source. Variations in some of the typical characteristics are observed in some populations, depending of the enrichment conditions. Some strains grow at 43°C. Optimum temperature, ~35°C.

The species is markedly heterogeneous in nutritional properties and in DNA base composition. Further descriptive information: van Niel and Allen (1952), Sijderius (1946), and Palleroni et al. (1970). Found in soil and water, from which it can be isolated after enrichment in media with nitrate under anaerobic conditions at 30°C using various carbon sources. L(+)-Tartrate gives excellent results in the enrichments (van Niel and Allen, 1952) although, paradoxically, strains obtained in this manner may not grow with tartrate in pure culture. Many strains have been isolated from clinical specimens. Recently, the results of studies on the genomic structure and organization, as well as on the genotypic and phenotypic diversity of *P. stutzeri*, have been published (Rosselló et al., 1991, Rosselló–Mora et al.,1994b; Rainey et al., 1994b; Ginard et al., 1997). Seven DNA–DNA similarity groups (genomovars) have been defined in this species (Rosselló-Mora et al., 1994b). This subdivision correlated with clusters obtained by comparison of 16S rDNA gene sequences. One of the genomovars was raised to the category of species, for which the name *P. balearica* was created (see below). The name *P. stanieri* (Mandel 1966) has been proposed for strains with a mol% G + C of ~62. However, this species is not clearly differentiated from *P. stutzeri* based on phenotypic characteristics (Palleroni et al., 1970).

The mol% G + C of the DNA is: from 60.6–66.3 (Bd).

Type strain: AB 201, ATCC 17588, CCUG 11256, DSM 5190.

GenBank accession number (16S rRNA): U26262.

48. **Pseudomonas synxantha** (Ehrenberg 1840) Holland 1920, 220[AL] (*Vibrio synxanthus* Ehrenberg 1840, 202.)
syn.xan' tha. Gr. pref. *syn* along with, together; Gr. adj. *xanthus* yellow; M.L. adj. *synxanthus* with yellow.

The description of this species is given by Haynes and Burkholder (1957) in the seventh edition of the *Manual*.

Gelatinase positive. Growth characteristics in various solid and liquid media are described by Haynes and Burkholder (1957). A distinctive characteristic is the production of an intense, diffusible, yellow to orange pigment in cream or in the cream layer in milk.

rRNA–DNA hybridization studies indicate that this is a species of the genus *Pseudomonas* (De Vos et al., 1989), which was later confirmed by 16S rDNA sequencing analysis (Anzai et al., 1997). Isolated from bitter milk.

The mol% G + C of the DNA is: 61. (T_m).

Type strain: ATCC 9890, LMG 2190.

49. **Pseudomonas syringae** Van Hall 1902141[AL] (*Phytomonas syringae* (van Hall 1902) Bergey, Harrison, Breed, Hammer and Huntoon 1930, 257; *Pseudomonas barkeri* (Berridge 1924) Clara 1934, 11; *Pseudomonas citrarefaciens* (Lee 1917) Stapp 1928, 190; *Pseudomonas citriputealis* (Smith 1913) Stapp 1928, 190; *"Pseudomonas hibisci"* (Nakada and Takimoto 1923) Stapp 1928; *Pseudomonas prunicola* Wormald 1930, 742; *Pseudomonas punctulans* (Bryan 1933) Săvulescu 1947, 12; *Pseudomonas rimaefaciens* Koning 1938, 11; *Pseudomonas spongiosa* (Leifson 1962b); *Pseudomonas tonelliana* (Ferraris 1926) Burkholder 1948b, 132; *Pseudomonas trifoliorum* (Jones, Williamson, Wolf and McCulloch 1923) Stapp 1928; *Pseudomonas utiformica* Clara 1932, 111; *Pseudomonas vignae* Gardner and Kendrick 1923, 275; *Pseudomonas viridifaciens* Tisdale and Williamson 1923, 150.)
sy.rin' gae. M.L. fem. n. *Syringa* generic name of lilac; M.L. fem. gen. n. *syringae* of the lilac.

Characteristics of the species and of some of its pathovars are described in Tables BXII.γ.118 and BXII.γ.120. The

[a]For symbols see standard definitions. Data from Sands et al. (1970) and from Gardan et al. (1992).

[b]Method of Hildebrand (1971); numbers represent pH values at which pitting occurs.

pattern of acid production from sugars will be found in Haynes and Burkholder (1957) and in the original papers describing the nomenspecies here included as pathovars.

Cytochrome *c* is not detectable. Fluorescent pigment is produced. The gelatinase reaction is positive. Rare strains may require organic growth factors. Growth of most strains is slow in mineral media with a single carbon source and is relatively slow in complex media. Nutritional spectrum is less extensive and more heterogeneous than that of the saprophytic fluorescent pseudomonads. Optimum temperature, 25–30°C. The original strain was isolated from lilac (*Syringa vulgaris*, family Oleaceae) but strains conforming to the original description are pathogenic for many unrelated plants.

The mol% G + C of the DNA is: 60.5.

Type strain: ATCC 19310, DSM 6693, LMG 1247, NCPPB 281, PDDCC 3023.

Additional Remarks: The following is a list of pathovars of *P. syringae* and of the respective pathotypes proposed by Dye et al. (1980). The names of the most important host plants and of their botanical families are also included. The list includes pathovar *mori*, although this name has priority over *syringae*. As recommended by Young et al. (1978), *P. syringae* is widely known and it should be conserved over *"P. mori"*. Many of the pathovars in the list may not be distinguishable from *P. syringae* except for their host range. Few phenotypic characters are taxonomically useful.

Studies on the internal subdivision of *P. syringae* into pathovars using various molecular techniques, in particular DNA–DNA hybridization, have suggested that some of the pathovars should be elevated to independent species status. At present, however, attempts in this direction have materialized only in a few instances. The difficulty is in finding sets of phenotypic properties that could help in the ready identification of such species without the need of nucleic acid similarity experiments. A recent study centered mainly on this approach and in ribotyping (Gardan et al., 1999) extended early investigations that defined clusters of genomically related strains within *P. syringae* (Pecknold and Grogan, 1973).

The studies of Gardan and collaborators (1999) defined nine genomospecies. The conclusions included the proposal for synonymy of the names *P. savastanoi*, *P. ficuserectae*, *P. meliae*, and *P. amygdali*, with *P. amygdali* as the earliest name in this group. In addition, genomospecies 3 and 7 may be named in the future *"P. tomato"* and *"P. tagetis"*, respectively, once phenotypic data for differentiation become available. Finally, genomospecies 5 and 9, for which such data are available, are given the species names *P. tremae* and *P. cannabina*, respectively.

The genomospecies 5 (*P. tremae*) is represented by a single strain (Gardan et al., 1999). According to the description given by Gardan and collaborators, *P. tremae* is a nonfluorescent organism, but evaluation of its relationships with other species or pathovars or with nonfluorescent species is not clear at this stage. The description includes a nutritional analysis where the strain appears to be unable to use L-alanine, fructose, glycerol, or gluconate, and it is stated that it did not assimilate the 91 other carbon sources of the Biotype-100 strips (BioMérieux). Since there is only one strain available at this moment, it is not possible to ascertain the intraspecies diversity of the species. Experi-

ments on the DNA relatedness of *P. tremae* and *P. cannabina* to other taxa have been limited mainly to *P. syringae* pathovars but have not included most other species of the genus. Descriptions of *P. tremae* and *P. cannabina*, as given in the paper by Gardan et al. (1999), are transcribed below in the section Other Species.

As a general comment, the taxonomic situation of the members of the conglomerate known under the name *P. syringae* still remains largely unsettled, but it is reasonable to expect that future studies will contribute to reach a satisfactory internal subdivision of the species and a more precise circumscription of pathovars segregated as individual species on the basis of genomic and phenotypic properties.

a. **Pseudomonas syringae** *pathovar* **syringae** van Hall 1902.

Hosts: lilac (*Syringa vulgaris*, family Oleaceae) and several unrelated plants.

Deposited strain: ATCC 19310, NCPPB 281, PDDCC 3023 (neopathotype strain).

b. **Pseudomonas syringae** *pathovar* **aceris** (Ark 1939) Young et al. 1978.

Hosts: *Acer macrophyllum*, *Acer* spp. (family Aceraceae).

The mol% G + C of the DNA is: 61.1.

Deposited strain: ATCC 10853, NCPPB 958, PDDCC 2802 (Sneath and Skerman, 1966) (neopathotype strain).

c. **Pseudomonas syringae** *pathovar* **antirrhini** (Takimoto 1920) Young et al. 1978.

Host: *Antirrhinum majus* (family Scrophulariaceae).

The mol% G + C of the DNA is: 60.4.

Deposited strain: NCPPB 1817, PDDCC 4303 (neopathotype strain).

d. **Pseudomonas syringae** *pathovar* **apii** (Jagger 1921) Young et al. 1978.

Host: celery (*Apium graveolens*, family Umbelliferae).

The mol% G + C of the DNA is: 60.8.

Deposited strain: ATCC 9654, NCPPB 1626, PDDCC 2814 (neopathotype strain).

e. **Pseudomonas syringae** *pathovar* **aptata** (Brown and Jamieson 1913) Young et al. 1978.

Hosts: sugar beet (*Beta vulgaris*, family Chenopodiaceae), *Nasturtium* sp. (family Cruciferae); lettuce (*Lactuca sativa*, family Compositae).

Deposited strain: NCPPB 871, PDDCC 459 (neopathotype strain).

f. **Pseudomonas syringae** *pathovar* **atrofaciens** (McCulloch 1920) Young et al. 1978.

Hosts: wheat (*Triticum* sp.) and other plants of the family Gramineae.

Deposited strain: NCPPB 2612, PDDCC 4394 (neopathotype strain).

g. **Pseudomonas syringae** *pathovar* **atropurpurea** (Reddy and Godkin 1923) Young et al. 1978.

Hosts: *Bromus inermis* and many other *Bromus* spp., *Agropyron repens* and many other plants of the family Gramineae.

Deposited strain: NCPPB 2397, PDDCC 4457 (neopathotype strain).

h. **Pseudomonas syringae** *pathovar* **berberidis** (Thornberry and Anderson 1931a) Young et al. 1978.

Hosts: barberry (*Berberis thunbergii*, *B. inermis*, family Berberidaceae).

The mol% G + C of the DNA is: 59.7–60.1.

Deposited strain: NCPPB 2724, PDDCC 4116 (neopathotype strain).

i. **Pseudomonas syringae** *pathovar* **cannabina** (Šutić and Dowson 1959) Young et al. 1978.

Hosts: *Cannabis sativa* (family Moraceae); *Phaseolus vulgaris*, *Vicia sativa* (family Leguminosae).

The mol% G + C of the DNA is: 59.3–60.3.

Deposited strain: PDDCC 2823 (NCPPB 1437) (neopathotype strain).

j. **Pseudomonas syringae** *pathovar* **ciccaronei** (Ercolani and Caldarola 1972) Young et al. 1978.

Host: carob (*Ceratonia siliqua*, family Leguminosae).

Deposited strain: NCPPB 2355, PDDCC 5710 (pathotype strain).

k. **Pseudomonas syringae** *pathovar* **coronafaciens** (Elliott 1920) Young et al. 1978.

Hosts: *Avena sativa*, *Bromus inermis*, *Agropyron repens* and various other wild and cultivated plants of the family Gramineae. Description as *"P. coronafaciens"* is transcribed by Haynes and Burkholder (1957) in the seventh edition of *Bergey's Manual of Determinative Bacteriology*.

The mol% G + C of the DNA is: 59.3.

Deposited strain: NCPPB 600, PDDCC 3113 (neopathotype strain).

l. **Pseudomonas syringae** *pathovar* **delphinii** (Smith 1904) Young et al. 1978.

Host: *Delphinium* sp. (family Ranunculaceae).

Deposited strain: NCPPB 1879, PDDCC 529 (neopathotype strain).

m. **Pseudomonas syringae** *pathovar* **dysoxyli** (Hutchinson 1949) Young et al. 1978.

Host: *Dysoxylum spectabile* (family Meliaceae).

Deposited strain: : ATCC 19863, NCPPB 225, PDDCC 545 (neopathotype strain).

n. **Pseudomonas syringae** *pathovar* **eriobotryae** (Takimoto 1931) Young et al. 1978.

Host: loquat (*Eriobotrya japonica*, family Rosaceae).

The mol% G + C of the DNA is: 58.3.

Deposited strain: NCPPB 2331, PDDCC 4455 (neopathotype strain).

o. **Pseudomonas syringae** *pathovar* **garcae** (Amaral, Teixeira and Pinheiro 1956) Young et al. 1978.

Host: coffee (*Coffea arabica*, family Rubiaceae) and many other unrelated plants.

Deposited strain: ATCC 19864, NCPPB 588, PDDCC 4323 (pathotype strain).

p. **Pseudomonas syringae** *pathovar* **helianthi** (Kawamura 1934) Young et al. 1978.

Host: sunflower (*Helianthus debilis*, family Compositae).

Deposited strain: NCPPB 2640, PDDCC 4531 (neopathotype strain).

q. **Pseudomonas syringae** *pathovar* **japonica** (Mukoo 1955) Dye et al. 1980 (*Pseudomonas striafaciens* pathovar *japonica* Mukoo 1955.)

Hosts: rye (*Secale cereale*), barley (*Hordeum sativum*), wheat (*Triticum vulgare*), rice (*Oryza sativa*) and many other Gramineae of the genera *Setaria*, *Panicum*, *Bromus*, *Lolium*, *Andropogon*, *Alopecurus*, etc., as well as plants of other botanical families (Solanaceae, Chenopodiaceae, Oxalidaceae, etc.).

Deposited strain: NCPPB 3093, PDDCC 6305 (neopathotype strain).

r. **Pseudomonas syringae** *pathovar* **lachrymans** (Smith and Bryan 1915) Young et al. 1978.

Host: cucumber (*Cucumis sativus*, family Cucurbitaceae).

Deposited strain: ATCC 7386, NCPPB 537, PDDCC 3988 (neopathotype strain).

s. **Pseudomonas syringae** *pathovar* **lapsa** (Ark 1940) Young et al. 1978.

Hosts: corn (*Zea mays*), sugarcane (*Saccharum officinarum*) (family Gramineae).

The mol% G + C of the DNA is: 59.4.

Deposited strain: NCPPB 2096, PDDCC 3947 (neopathotype strain).

t. **Pseudomonas syringae** *pathovar* **maculicola** (McCulloch 1911) Young et al. 1978.

Hosts: cabbage, cauliflower (*Brassica oleracea*, family Cruciferae).

The mol% G + C of the DNA is: 61.3.

Deposited strain: NCPPB 2039, PDDCC 3935 (neopathotype strain).

u. **Pseudomonas syringae** *pathovar* **mellea** (Johnson 1923) Young et al. 1978.

Host: tobacco (*Nicotiana tabacum*, family Solanaceae).

Deposited strain: NCPPB 2356, PDDCC 5711 (neopathotype strain).

v. **Pseudomonas syringae** *pathovar* **mori** (Boyer and Lambert 1893) Young et al. 1978.

Host: mulberry (*Morus* spp., family Moraceae).

Deposited strain: ATCC 19873, NCPPB 1034, PDDCC 4331 (neopathotype strain).

w. **Pseudomonas syringae** *pathovar* **morsprunorum** (Wormald 1931) Young et al. 1978.

Host: *Prunus* spp. (family Rosaceae).

Deposited strain: ATCC 19322, NCPPB 2995, PDDCC 5795 (Sneath and Skerman, 1966) (neopathotype strain).

x. **Pseudomonas syringae** *pathovar* **panici** (Elliott 1923) Young et al. 1978.

Host: proso or broom-corn millet (*Panicum miliaceum*, family Gramineae).

The mol% G + C of the DNA is: 60.7.

Deposited strain: ATCC 19875, NCPPB 1498, PDDCC 3955 (neopathotype strain).

y. **Pseudomonas syringae** *pathovar* **papulans** (Rose 1917) Dhanvantari 1977.

Host: apple (*Pyrus malus*, family Rosaceae).

Deposited strain: NCPPB 2848, PDDCC 4048 (neopathotype strain).

z. **Pseudomonas syringae** *pathovar* **passiflorae** (Reid 1938) Young et al. 1978.

Host: *Passiflora edulis* (family Passifloraceae).

The mol% G + C of the DNA is: 59.4–60.3.

Deposited strain: NCPPB 1387, PDDCC 129 (neopathotype strain).

aa. **Pseudomonas syringae** *pathovar* **persicae** (Prunier et al. 1970) Young et al. 1978.

Host: peach (*Prunus persicae*, family Rosaceae).

Deposited strain: NCPPB 2761, PDDCC 5846 (neopathotype strain).

ab. **Pseudomonas syringae** *pathovar* **pisi** (Sackett 1916) Young et al. 1978.

Host: pea (*Pisum sativum*, family Leguminosae).

Deposited strain: NCPPB 2585, PDDCC 2452 (neopathotype strain).

ac. **Pseudomonas syringae** *pathovar* **primulae** (Ark and Gardner 1936) Young et al. 1978.

Host: *Primula polyantha* (family Primulaceae).

The mol% G + C of the DNA is: 60.4.

Deposited strain: ATCC 19306, NCPPB 133, PDDCC 3956 (neopathotype strain).

ad. **Pseudomonas syringae** *pathovar* **ribicola** (Bohn and Maloit 1946) Young et al. 1978.

Host: golden currant (*Ribes aureum*, family Saxifragaceae).

The mol% G + C of the DNA is: 60.6.

Deposited strain: ATCC 13456, NCPPB 963, PDDCC 3882 (neopathotype strain).

ae. **Pseudomonas syringae** *pathovar* **sesami** (Malkoff 1906) Young et al. 1978.

Host: sesame (*Sesamum indicum*, family Pedaliaceae).

The mol% G + C of the DNA is: 59.4.

Deposited strain: ATCC 19879, NCPPB 1016, PDDCC 763 (neopathotype strain).

af. **Pseudomonas syringae** *pathovar* **striafaciens** (Elliott 1927) Young et al. 1978.

Hosts: oats (*Avena sativa*), barley (*Hordeum sativum*) (family Gramineae).

The mol% G + C of the DNA is: 59.1.

Deposited strain: ATCC 10730, NCPPB 1898, PDDCC 3961 (pathotype strain); NCPPB 2394, PDDCC 4483 (pathogenic reference strain).

ag. **Pseudomonas syringae** *pathovar* **tabaci** (Wolf and Foster 1917) Young et al. 1978.

Host: tobacco (*Nicotiana tabacum*, family Solanaceae).

Deposited strain: NCPPB 1427, PDDCC 2835 (neopathotype strain).

ah. **Pseudomonas syringae** *pathovar* **theae** (Hori 1915) Young et al. 1978.

Host: tea plant (*Thea sinensis*, family Theaceae).

Deposited strain: NCPPB 2598, PDDCC 3923 (neopathotype strain).

ai. **Pseudomonas syringae** *pathovar* **tomato** (Okabe 1933) Young et al. 1978.

Host: tomato (*Lycopersicum esculentum*, family Solanaceae).

Deposited strain: NCPPB 1106, PDDCC 2844 (neopathotype strain).

aj. **Pseudomonas syringae** *pathovar* **ulmi** (Šutić and Tešić 1958) Young et al. 1978.

Host: elm (*Ulmus* sp., family Ulmaceae).

The mol% G + C of the DNA is: 58.7.

Deposited strain: ATCC 19883, NCPPB 632, PDDCC 3962 (neopathotype strain).

ak. **Pseudomonas syringae** *pathovar* **viburni** (Thornberry and Anderson 1931b) Young et al. 1978.

Host: elm (*Ulmus* sp., family Ulmaceae).

The mol% G + C of the DNA is: 60.1.

Deposited strain: ATCC 13458, NCPPB 1921, PDDCC 3963 (neopathotype strain).

50. **Pseudomonas taetrolens** Haynes 1957, 108[AL]

taet' ro.lens. L. adj. *taeter* offensive; L. part. adj. *olens* having an odor; M.L. part. adj. *taetrolens* foul smelling.

The description of this species is given by Haynes and Burkholder (1957) in the seventh edition of the *Manual*.

The cells are short rods with rounded ends, motile by means of one to five polar flagella. Gelatin and starch are not hydrolyzed. Nitrate is not reduced to nitrite. Acid production from a number of substrates is described by Haynes and Burkholder (1957). A decision to allocate the species in the genus *Pseudomonas* has been made based on rRNA–DNA hybridization studies (De Vos et al., 1989). Isolated from foods that have a musty odor.

The mol% G + C of the DNA is: 59.8 (T_m).

Type strain: ATCC 4683, IAM 1653, LMG 2336.

GenBank accession number (16S rRNA): D84027.

51. **Pseudomonas tolaasii** Paine 1919, 210[AL]

to.laa' si.i. Tolaas patronymic; M.L. gen. n. *tolaasii* of Tolaas.

Description is given by Haynes and Burkholder (1957) in the seventh edition of the *Manual*.

Rapid identification tests have been described (Wong and Preece, 1979). Results of a detailed phenotypic study of a collection of strains of this species have been published (Fahy, 1981). Some of the reported characteristics are summarized in Table BXII.γ.115. A gene cluster encoding proteins required for the synthesis of the toxin tolaasin has been identified and characterized (Rainey et al., 1993). Detailed composition of fatty acids is known (Stead, 1992). rRNA–DNA hybridization studies indicate allocation of this species to the genus *Pseudomonas* (De Vos et al., 1985). Fluorescent pigment is produced. Gelatin is hydrolyzed (Haynes and Burkholder, 1957). Pathogenic for cultivated mushrooms. Isolated from brown-spot of cultivated mushrooms.

The mol% G + C of the DNA is: 60.8–61.3 (T_m).

Type strain: ATCC 33618, LMG 2342, NCPPB 1873.

GenBank accession number (16S rRNA): D84028, Z76670.

52. **Pseudomonas veronii** Elomari, Coroler, Hoste, Gillis, Izard and Leclerc 1996, 1142.[VP]

ve.ro'ni.i. M.L. masc. gen. n. *veronii* of Véron, in honor of Professor M.M. Véron, a distinguished French microbiologist.

The following description is taken from the original paper.

Rods, motile by means of single polar flagella. PHB is not accumulated by the cells. The cultures produce a fluorescent pigment on King B medium. The colonies on nutrient agar are smooth, circular, and nonpigmented. They are nonhemolytic on blood agar. The oxidase, catalase, and arginine dihydrolase reactions are positive. Most strains liquefy gelatin. All the strains grow on α-aminobutyrate, D-xylose, L-arabinose, D-mannose, D-galactose, sucrose, butyrate, isobutyrate, erythritol, sorbitol, inositol, D-alanine, L-tryptophan, and trigonelline as the sole source of carbon and energy. No strain is able to use isovalerate, sebacate, azelate, L-mandelate, benzoate, L-kynurenine, histamine, or acetamide. The original paper (Elomari et al., 1996) includes extensive information on a variety of enzymatic activities. Additional properties are summarized in Tables BXII.γ.112 and BXII.γ.113 and in a previous communication by the same group of workers (Elomari et al., 1995).

All strains have been isolated from natural mineral waters.

The mol% G + C of the DNA is: 61–62.

Type strain: CFML 92-134, CIP 104663, DSM 11331.

GenBank accession number (16S rRNA): AF064460.

53. **Pseudomonas viridiflava** (Burkholder 1930) Dowson 1939, 177[AL] (*Phytomonas viridiflava* Burkholder 1930, 63.)

vi.ri.di.fla' va. L. *viridis* green; L. *flavus* yellow; M.L. adj. *viridiflavus* greenish yellow.

Characteristics that are useful for comparison with related taxa are given in Table BXII.γ.118. Further information is given by Haynes and Burkholder (1957), Clara (1934), and Billing (1970b). The following characteristics are mentioned in this last paper. The bacterial mass usually has a yellow tinge in media with 5% sucrose and olive to golden brown in media with yeast extract and glycerol. A blue-green insoluble pigment is produced by some strains. Aside from the characteristics described in the tables, the potato rot and esculin reactions are positive. Fluorescent pigment is produced, and gelatin is liquefied (Haynes and Burkholder, 1957).

From her extensive nutritional screening of strains of the species, Billing (1970b) has concluded that few substrates have diagnostic value. The only ones distinguishing *P. viridiflava* from most other oxidase-negative plant pathogens are the inability to use sucrose and the capacity for use of D(−)-tartrate. This substrate is used by *P. viridiflava*, *P. syringae* pathovar *tomato*, and rarely by other species and pathovars. In addition to these characteristics, Billing (1970b) mentions that the reaction in beans was similar to that produced by *P. syringae* and both were different from the water-soaked lesions produced by *"P. phaseolicola"*.

Pathogenic on bean (*Phaseolus vulgaris*).

The mol% G + C of the DNA is: 59.9 (NCPPB 1810).

Type strain: ATCC 13223, DSM 6694, LMG 2352, NCPPB 635, PDDCC 2848.

GenBank accession number (16S rRNA): Z76671.

Other Species

Some putative *Pseudomonas* species have an uncertain phylogenetic position. The following descriptions are those that are not included in the first edition of the *Manual* (Palleroni, 1984) or in previous editions of *Bergey's Manual of Determinative Bacteriology*.

1. **Pseudomonas abietaniphila** Mohn, Wilson, Bicho and Moore 1999b, 935[VP] (Effective publication: Mohn, Wilson, Bicho and Moore 1999a, 76.)

a.bie.ta.ni′phi.la. M.L neut. n. *abietanum* abietane; Gr. adj. *philos* loving, friendly to; M.L. fem. adj. *abietaniphila* abietane-loving.

The following description is taken from the paper by Mohn et al. (1999a).

Rods. When grown on dehydroabietic acid, the cells are 0.7 × 1.2–2.5 μm. Motile. No information is given on the flagellar number and insertion. Colonies are clear, translucent, smooth, circular, and convex. Catalase positive and oxidase negative. Abietic, dehydroabietic, linoleic and pyruvic acids, as well as L-arabinose, D-galactose, D-glucose, D-xylose, and glycerol are used for growth; 12- plus 14-chlorodehydroabietic and palmitic acids are used poorly. Pimaric, isopimaric, and acetic acids are not used. Main cellular fatty acids are $C_{16:1\ \omega7c}$, $C_{16:0}$, and $C_{18:0}$; minor ones include $C_{10:0\ 3OH}$, $C_{12:0\ 2OH}$, and $C_{12:0\ 3OH}$. Isolated from bleached Kraft pulp mill effluent treatment system near Kamlops, British Columbia, Canada.

The mol% G + C of the DNA is: unknown.

Type strain: Strain BKME-9, ATCC 700689.

2. **Pseudomonas antimicrobica** Attafuah and Bradbury 1990, 320[VP] (Effective publication: Attafuah and Bradbury 1989, 571.)

an.ti.mi.cro′bi.ca. Gr. pref. *anti* against; Gr. adj. *micrus* small; Gr. n. *bios* life; *antimicrobica* against microbes (referring to a wide antimicrobial activity).

Description taken from the original paper (Attafuah and Bradbury, 1989).

Rods, 0.5 × 0.8–1.5 μm, occurring singly, in groups, and occasionally in pairs. Motile by means of one or two polar flagella. Two types of colonies were observed on nutrient agar. Those of one variant (NCIB 9897) were circular, raised, creamy-white, and opaque, rugose and butyrous when raised, with microundulate margins; the other type (NCIB 9898) was moist, smooth, glistening, and slightly viscid, with entire margins and occasionally an orange tinge. A yellowish-orange, water-soluble, nonfluorescent pigment was produced in King A and B media, tyrosine medium and others. No pigment was produced on potato dextrose agar. Gelatinase activity, levan formation, accumulation of PHB, starch hydrolysis, pectolytic activity, and rotting of plant tissue were all negative. Growth occurs with NaCl up to 4%, but it decreases to a trace with 6%.

Acid was produced from arabinose, dulcitol, fructose, galactose, glucose, glycerol, lactose, mannitol, *meso*-inositol, sorbitol, and xylose, but not from maltose, raffinose, salicin, or sucrose. Carbon sources for growth were *N*-acetylglucosamine, D-alanine, L-arabinose, caprate, citrate, gluconate, glucose, glutamate, *p*-hydroxybenzoate, *meso*-inositol, α-ketoglutarate, malonate, mannitol, D-mannose, phenylacetate, L-proline, propionate, and raffinose. No growth on adipate, D-iso-ascorbate, malate, *meso*-tartrate, starch, or ethanol. No organic growth factors were required. A wide spectrum of antibiotic activity was present. Good growth occurred between 15 and 37°C; optimum around 30°C. No growth at 41°C. Additional information may be found in the original paper (Attafuah and Bradbury, 1989) and some comments on the relationship of this species to those of other groups of aerobic pseudomonads. Isolated from the mealybug *Planococcoides njalensis*.

The mol% G + C of the DNA is: unknown.

Type strain: DSM 8361, NCIB 9898.

3. **Pseudomonas cannabina** (ex Šutić and Dowson 1959) Gardan, Shafik, Belouin, Broch, Grimont and Grimont 1999, 477[VP]

can.na′bi.na. L. fem. adj. *cannabina* pertaining to *Cannabis*, the generic name of the host plant, *Cannabis sativa* L.

Rods, 1.1–3.0 × 3.0–4.0 μm, motile by means of one to four polar flagella. Colonies are gray color and are slightly convex. Production of fluorescent pigment in King B medium. The results of LOPAT (levan production, oxidase test, potato rotting, arginine dihydrolase, and tomato hypersensitivity) are +, −, −, −, and +. Nitrate is not reduced. Negative for hydrolysis of starch, esculin, and gelatin. The strains assimilate D-glucose, glycerol, D-saccharate, mucate, citrate, D-gluconate, L-histidine, L-aspartate, L-glutamate, L-proline, L-alanine, and L-serine, but not the other 83 carbon sources of the Biotype-100 strips (BioMérieux). Pathogenic on *Cannabis sativa* L.

The mol% G + C of the DNA is: 60.2 (T_m).

Type strain: CFBP 2341; ICMP 2823; NCPPB 1437.

4. **Pseudomonas flectens** Johnson 1956, 144[AL]

flec′tens. L. v. *flectere* to bend; *flectens* that bends.

The following description is summarized from that in the original paper.

Rods, 0.5–0.75 × 1.4–2.0 μm, with rounded ends. Motile by means of one to two polar flagella. Colonies on meat infusion agar, after 5 d at 27.5°C, circular, 1–1.5 mm in diameter, convex, amorphous, smooth, glistening, with an entire edge, grayish white. No fluorescent pigment is formed. Gelatin liquefaction does not occur. Acid is produced from glucose, mannose, and sucrose, but not from maltose, lactose, starch, glycerol, mannitol, sorbitol, or esculin. Starch hydrolysis is very slight. H_2S is not produced and nitrate is not reduced. The organism is the agent of the pod twist disease of French beans (*Phaseolus vulgaris* L.), where it produces large, diffuse water-soaked lesions on twisted young pods.

The mol% G + C of the DNA is: 31.8 (type strain).

Type strain: ATCC 12775.

Additional Remarks: Strain NCPPB 539, presumed to be the type strain, is not phylogenetically related to the genus *Pseudomonas*, as shown by rRNA–DNA hybridization experiments (De Vos et al., 1989). However, the authenticity of this strain may be questioned because of its unexpectedly low mol% G + C.

5. **Pseudomonas halophila** Fendrich 1989, 205[VP] (Effective publication: Fendrich 1988, 42.)

ha.lo′phi.la. Gr. n. *hals, halos* salt; Gr. v. *philein* to love; M.L. adj. *halophila* salt-loving.

The description is taken from the original paper (Fendrich, 1988).

Rod-shaped cells, 0.8–1.0 × 1.5–5.0 μm, single or in pairs. Motile by means of a polar flagellum. Colonies are circular with entire margins and smooth surfaces, slimy, raised, and reddish-brown colored. Chemoorganotrophic growth on arabinose, cellobiose, fructose, galactose, glucose, lactose, maltose, mannitol, sorbitol, sucrose, trehalose, and xylose with no acid production, and on acetate, caproate, citrate, lactate, pelargonate, propionate, pyruvate,

succinate, alanine, glutamine, esculin, ethanol, and glycerol as carbon and energy sources. Catalase and cytochrome oxidase positive. Gelatinase and urease positive. Hydrolysis of starch or cellulose, production of indole or sulfide, arginine dihydrolase reaction, and lysine and ornithine decarboxylase activities are all negative. Strictly aerobic. Growth occurs between 0.02 and 3.3 ml/l NaCl, with optimum at 0.8 mol/l. The pH range is 4.5–9.6; optimum at 7. Temperature range, 4–37°C; optimum at 28°C. Susceptible to ampicillin, chloramphenicol, erythromycin, nalidixic acid, and penicillin G. Isolated from the north arm of Great Salt Lake, Utah, USA.

The mol% G + C of the DNA is: 57.

Type strain: DSM 3050.

6. **Pseudomonas multiresinivorans** Mohn, Wilson, Bicho and Moore 1999b, 935[VP] (Effective publication: Mohn, Wilson, Bicho and Moore 1999a, 77.)
mul.ti.re.si.ni.vo′rans. L. adj. *multi* many; L. fem. n. *resina* resin; L. part. adj. *vorans* devouring; M.L. fem. adj. *multiresinivorans* devouring many resins.

Rods. When grown on isopimaric acid, cells are 1 × 1.5–2 μm, motile. No information is given about insertion and number of flagella. The cells form clumps. Colonies are clear, translucent, smooth, asymmetrical, and flat. Catalase and oxidase reactions are positive. Can live anaerobically in the presence of nitrate. Pimaric, isopimaric, palmitic, linoleic, benzoic, and acetic acids, as well as L-arabinose, D-glucose, citronellol, ethanol, glycerol, and n-hexadecane are used for growth. Poor utilization of abietic, dehydroabietic, and pyruvic acids, 12- plus 14-chlorodehydroabietic acids, D-galactose, or D-xylose. Main cellular fatty acids are $C_{18:1}$, $C_{16:0}$, and $C_{16:1\ \omega 7c}$; minor ones include $C_{10:0\ 3OH}$, $C_{12:0\ 2OH}$, and $C_{12:0\ 3OH}$. Isolated from a laboratory sequencing batch reactor in Vancouver, British Columbia, Canada.

The mol% G + C of the DNA is: unknown.

Type strain: Strain IpA-1, ATCC 700690.

7. **Pseudomonas tremae** Gardan, Shafik, Belouin, Broch, Grimont and Grimont 1999, 477[VP]
tre′ma.e. M.L. gen. fem. n. *tremae* of *Trema*; generic name of the host plant, *Trema orientalis* BL.

Rods, motile by means of one to four polar flagella. No fluorescent pigment is produced on King B medium. Of the LOPT tests (levan formation from sucrose, oxidase reaction, potato rotting ability, arginine dihydrolase reaction, and tobacco hypersensitive test), the first four are negative. Nitrate is not reduced. Negative for hydrolysis of starch, esculin, gelatin, and Tween 80. The strain assimilates D-saccharate, D- and L-malate, citrate, succinate, fumarate, L-aspartate, and L-glutamate, but not any of the 91 other carbon sources of the Biotype-100 strips (BioMérieux). Pathogenic for *Trema orientalis*.

The mol% G + C of the DNA is: 60.5 (T_m).

Type strain: CFBP3229; ICMP 9151; NCPPB 3465.

8. **Pseudomonas vancouverensis** Mohn, Wilson, Bicho and Moore 1999b, 935[VP] (Effective publication: Mohn, Wilson, Bicho and Moore 1999a, 76.)
van.cou.ver.en′sis. M.L. adj. *vancouverensis* pertaining to the city of Vancouver, Canada.

Rods. When grown on dehydroabietic acid, the cells are 0.9 × 0.9–3.0 μm. Motile. No information is given about number and insertion of flagella. The cells form clumps. Colonies pale yellow, translucent, smooth, circular, and convex. Catalase and oxidase reactions are positive. Abietic, acetic, benzoic, dehydroabietic, linoleic, palmitic, and pyruvic acids, as well as β-citronellol, D-glucose, and glycerol, are used for growth. Acetic, isopimaric, and pimaric acids, and L-arabinose, D-galactose, and D-xylose are not used. Main cellular fatty acids are $C_{16:1\ \omega 7c}$, $C_{16:0}$, $C_{17:0\ cyc}$, and $C_{18:1}$; minor ones include $C_{10:0\ 3OH}$, $C_{12:0\ 2OH}$, and $C_{12:0\ 3OH}$. Isolated from forest soil in Vancouver, British Columbia, Canada.

The mol% G + C of the DNA is: unknown.

Type strain: Strain DhA-51, ATCC 700688.

Genus II. **Azomonas** *Winogradsky 1938, 391[AL]*

Christina Kennedy and Paul Rudnick

A.zo.mo′nas. Gr. adj. *a* not; Gr. n. *zoê* life; Gr. n. *azoê* not sustaining life, nitrogen Gr. n. *monas* a unit, monad; M.L. fem. n. *Azomonas* nitrogen monad.

Cells are 2.0 μm or more in diameter, of variable length and shape, although usually 2.5–3.5 μm in length and generally ellipsoidal- to rod-shaped. They cannot easily be distinguished from cells of *Azotobacter*. Cells may occur singly, in pairs, or in clumps. Motile by peritrichous, lophotrichous, or polar flagella. Gram negative, but sometimes Gram variable, depending on culture age. **Cysts are not formed in aging cultures. All species fix atmospheric nitrogen under aerobic conditions.** Alternative nitrogenases containing vanadium (nitrogenase-2) or iron (nitrogenase-3) only may be synthesized in Mo-deficient media. Cultures can grow both aerobically and microaerobically. Chemoorganotrophic. Sugars, alcohols, and organic acids are used as carbon sources. Ammonium salts and sometimes nitrate (*A. insignis* only) are used as nitrogen sources; amino acids are not used. **Water-soluble and fluorescent pigments are produced by nearly all strains.** Species are catalase-positive. The optimum pH for nitrogen fixation is close to neutrality, but certain strains can also fix nitrogen at a pH of 4.6–4.8. Species are isolated from water or soil.

The mol% G + C of the DNA is: 52–58.6.

Type species: **Azomonas agilis** (Beijerinck 1901) Winogradsky 1938, 400 (*Azotobacter agilis* Beijerinck 1901, 577.)

Further descriptive information

Please note that the large body of data collected by Thompson and Skerman (1979) forms the current basis for the description of the genus *Azomonas* and its species. Most of the information below is provided from a summary of the work of those authors. Exceptions and new data are noted.

The cell shape of *Azomonas* species is similar to that for *Azotobacter* species (Fig. BXII.γ.126) but may vary in aging cultures of *A. agilis*. In *A. insignis*, the cell shape is retained but the size

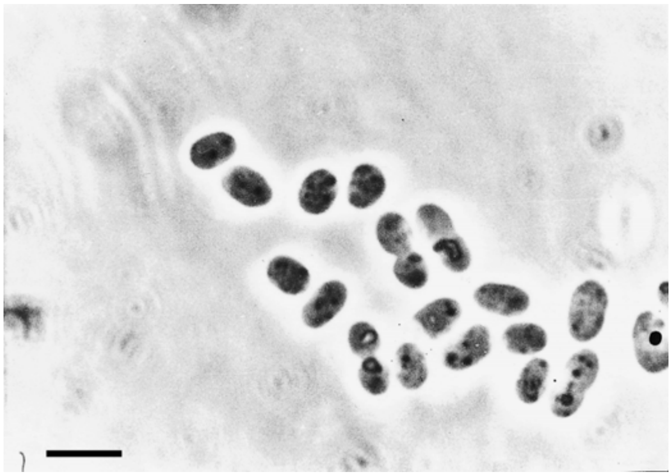

FIGURE BXII.γ.126. Cells of *Azomonas agilis* (phase-contrast microscopy). Bar = 10 μm.

can change. *A. macrocytogenes* produces very large cells and sometimes spindle-shaped or filamentous forms, especially when ethanol is used as the carbon source (Fig. BXII.γ.127). On peptone-yeast extract medium, *A. macrocytogenes* may show distortion of cells, with irregular, filamentous forms predominating. *A. insignis* does not show any distortion, but the cells appear thinner than when grown in glucose medium. *A. agilis* is less affected and does not show distortion.

No cysts are formed by any species; however, in *A. macrocytogenes* cells emerging from saclike capsular structures may occur and be mistakenly identified as germinating cysts (Jensen, 1955a; Tchan, 1968). Page and Collinson (1987) described five *A. macrocytogenes* isolates from Alberta soils, none of which formed cysts after prolonged growth on glucose or with butanol—an encystment inducer for *Azotobacter* species. Moreover, no 5-*n*-alkyl resorcinols—characteristic components of *Azotobacter vinelandii* cysts—could be identified in lipid extracts of the Alberta *A. mac-*

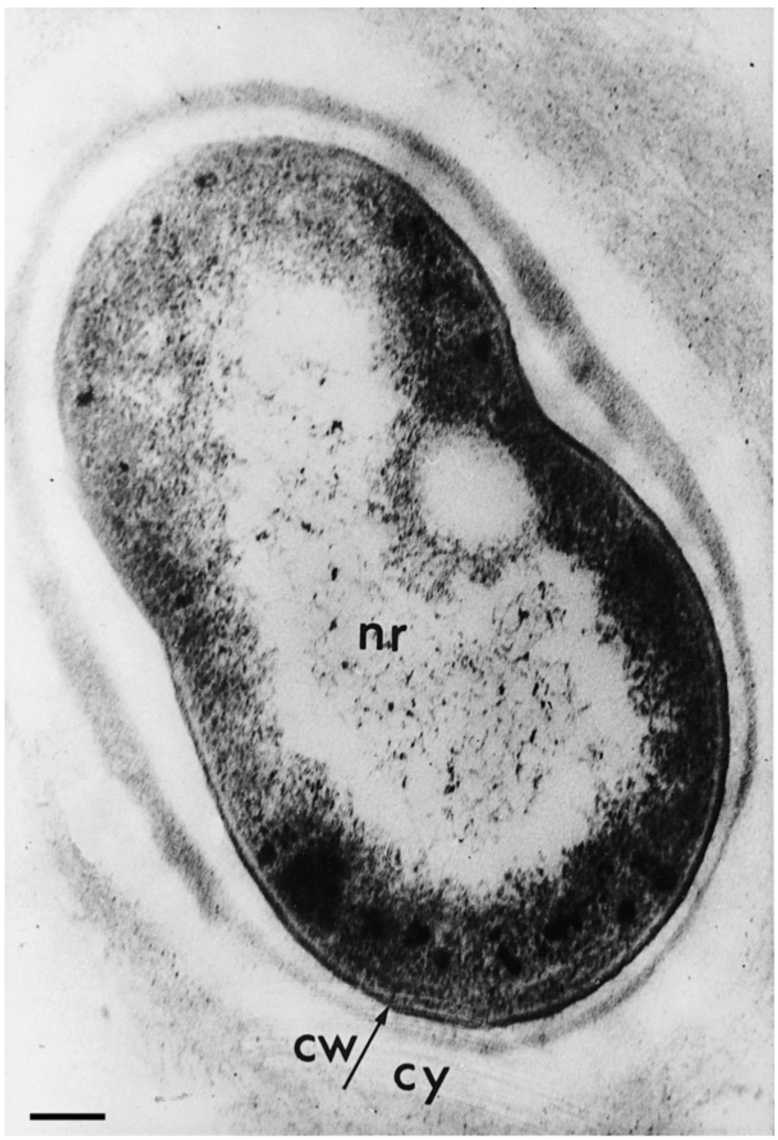

FIGURE BXII.γ.127. Electron micrograph of *Azomonas macrocytogenes*. The nuclear region (*nr*) and cell wall (*cw*) are readily visible. The structure *cy* probably consists of polysaccharide, but can be mistaken for the cyst coat of *Azotobacter*. Bar = 0.2 μm

rocytogenes strains. *A. agilis* and *A. insignis* stain uniformly Gram negative. *A. macrocytogenes* tends to be Gram variable.

All members of the genus are motile, with the flagellar arrangement varying with the species (Table BXII.γ.121).

All species are obligate aerobes, but nitrogen fixation can be enhanced by a decreased oxygen tension (0.04 atm) in some strains. On nitrogen-free agar medium with a sugar as the carbon source, *A. agilis* and *A. insignis* grow at a relatively rapid rate, forming colonies 2–6 mm in diameter after incubation for a few to several days at 30°C. The colonies are opaque, glistening, smooth and convex, and variants rarely appear. Colonies of *A. insignis* are usually smaller than those of *A. agilis. A. macrocytogenes* forms colonies ranging from 1–6 mm in diameter after 1 week of incubation; initially, they may be coarsely wrinkled but later they become smooth. On sucrose agar *A. macrocytogenes* produces voluminous and moist colonies due to the formation of colony-retained homopolysaccharides. No species of *Azomonas* produces diffusible homopolysaccharides, i.e., there is no formation of a diffuse halo around the colonies.

Azomonas macrocytogenes and *A. agilis* produce a yellow-green visible, blue-white fluorescent pigment when grown in iron-deficient medium. This siderophore, isolated from *A. macrocytogenes* ATCC 12334 and named azoverdin, is an isopyoverdin-like chromopeptide (Michalke et al., 1996). Azoverdin is produced in Fe-limited cultures grown at 28°C but not at 34°C (Collinson et al., 1990). This strain synthesizes two outer membrane proteins of 74 kDa and 70 kDa in response to Fe starvation. These proteins may act as azoverdin binding and/or transport sites (Collinson and Page, 1989). *A. macrocytogenes* also produces 3,4-dihydroxybenzoic acid, which can solubilize iron from minerals and may represent the red-violet diffusible pigment reported to be produced by all species of *Azomonas* (Tchan and New, 1984; Collinson et al., 1987). *A. insignis* differs from other azomonads by its production of a brown-black pigment in the presence of benzoate. *A. insignis* is also the only species that fails to form a fluorescent pigment.

Nitrogen fixation can occur by alternative nitrogenase enzymes in species of *Azomonas* (see the genus *Azotobacter*). The evidence for such alternative nitrogenases is physiological and genetic. Growth and nitrogen fixation can occur in molybdate-starved cultures of *A. macrocytogenes*, although at lower rates than in molybdenum-sufficient medium. DNA hybridization studies show that *A. agilis* (ATCC strain 7494) carries genes for all three nitrogenase enzymes encoded by *nif*, *vnf*, and *anf* genes (Fallik et al., 1991). A PCR amplification product specific for the Fe-nitrogenase *anfG* gene but not for the V-nitrogenase *vnfG* gene was detected using *A. macrocytogenes* (ATCC strain 12334) DNA (see *Azotobacter*, Fig. BXII.γ.138). This finding suggests that this species might have one alternative nitrogenase—the Fe enzyme—in addition to the Mo nitrogenase (Loveless and Bishop, 1999). If so, this would be the only member of the *Azotobacter*–*Azomonas* group with this combination of two nitrogenases. Other nitrogen sources for *Azomonas* species are ammonium salts. Only *A. insignis* can generally utilize nitrate. All species are negative for urease activity and can presumably not utilize urea as a nitrogen source—in contrast to *Azotobacter* species. No species can utilize glutamate as an N source.

The optimum temperature for growth is approximately 30°C, although some strains of *A. agilis* prefer 37°C. The minimum temperature for growth is generally close to 14°C; however, some strains, particularly of *A. insignis*, are able to grow at 9–10°C.

Compounds used as sole carbon and energy sources by all species of the genus are shown in Table BXII.γ.122 and are similar to those utilized by all species of *Azotobacter*. Only *A. macrocytogenes* can use D-galactose, melizitose, mannitol, and sorbitol. Maltose is used by *A. macrocytogenes* and most strains of *A. agilis.* Caproate, malonate, and mucate are used by *A. agilis* and *A. insignis* but not by *A. macrocytogenes. A. agilis* utilizes benzoate, catechol, 4-hydroxybenzoate, naphthalene, protocatechuate, and 4-toluate; the other species were not tested (Chen et al., 1993). A soil isolate identified as *A. macrocytogenes* degraded and used polyacrylamide as both a nitrogen and a carbon source (Nakamiya and Kinoshita, 1995). None of 17 amino acids tested can serve as a carbon source for *Azomonas* species, possibly due to a lack of ability to transport most amino acids—as in species of *Azotobacter.*

Catalase is present in all species. A positive oxidase reaction is given by the majority of *A. agilis* and *A. insignis* but rarely by *A. macrocytogenes.* Peroxidase is produced by the other species but not by *A. macrocytogenes.*

[b]See Procedures for Testing Special Characters.

[c]See also Table BXII.γ.121 for additional compounds.

The genome of *Azomonas macrocytogenes* (ATCC 12334) is much smaller than *Azotobacter* species genomes (2.4 versus 3.9–5.3 Mb) (see *Azotobacter* chapter, Table BXII.γ.125). There are no reports of indigenous plasmids within or transfer of plasmids from other bacteria into *Azomonas* species.

No bacteriophages from *Azomonas* species have been reported. Hegazi and Jensen (1973) reported that bacteriophages isolated with *A. chroococcum* and *A. vinelandii* as hosts were unable to infect or form plaques on *A. agilis*, *A. insignis*, and *A. macrocytogenes*.

Tchan and New (1984) indicated that antisera produced against *A. agilis* and *A. insignis* do not cross-agglutinate with members of *Azotobacter*. Norris and Kingham (1968), however, reported that antisera against *A. agilis* do cross-react with *A. vinelandii*. This discrepancy may be due to strain differences or to variability in immune response between animals. Within the genus *Azomonas*, antiserum against *A. insignis* cross-agglutinates with *A. agilis* (Tchan and New, 1984). Immunodiffusion produces numerous cross-precipitation lines. Rocket-line immunoelectrophoresis indicated that *Azomonas* and *Azotobacter* can be differentiated by the unshared precipitation peaks using an appropriate antiserum (Tchan et al., 1983), although at least one thermoresistant antigen is shared by *Azomonas* and *Azotobacter* (Tchan et al., 1980).

All species of *Azomonas* are sensitive to streptomycin (0.2 μg/ml), as are *Azotobacter* species. Sensitivities to chlortetracycline, oxytetracycline, polymyxin, sulfanilamide, penicillin, and neomycin vary depending on the strain. Only *A. insignis* is entirely sensitive to penicillin (Thompson and Skerman, 1979). As for *Azotobacter* species, those of *Azomonas* are somewhat resistant to chloramphenicol.

Azomonas species are resistant to phenol, benzoate, and mercuric chloride to varying degrees. Most strains tolerate sodium fluoride up to 0.01 M. Cadmium tolerance and the ability to remove this metal from the culture medium was reported for *A. agilis* PYO (You and Park, 1998). The resistance of *A. agilis* to iodoacetate can be used for selective isolation of this species (Thompson and Skerman, 1979).

A. agilis and *A. insignis* are aquatic bacteria. *A. macrocytogenes* is found in soil, although no information is available as to whether it also has an aquatic habitat (for further details, see Becking, 1992). Thus, it appears that the genus is ecologically heterogeneous. Only *A. macrocytogenes* is resistant to desiccation: five of seven strains survived desiccation for at least 1 month (Thompson and Skerman, 1979). All species tolerate a salt concentration of up to 1%, suggesting that the aquatic members are

capable of living in contaminated water where concentrations of organic matter and mineral salts can be relatively high.

Enrichment and Isolation Procedures

The enrichment and isolation techniques depend on the ability of *Azomonas* to grow by fixing nitrogen under aerobic conditions, using organic substrate as energy source. Nonselective enrichment methods are similar to those described in the chapter on *Azotobacter*.

Selective enrichment methods (Thompson and Skerman, 1979) Media containing either 1% sodium benzoate (Derx, 1951; Jensen, 1955a) or 1 mM iodoacetate are selective for *A. agilis*. The growth of *A. macrocytogenes* is favored by incorporating 1% benzoate into nitrogen-free sucrose medium (pH of 6.0) and incubating the cultures at a decreased incubation temperature (10–12°C). No selective enrichment method is available for *A. insignis*.

Isolation methods These are similar to those described previously for *Azotobacter* species. The enrichment cultures are inspected daily. When macroscopic growth becomes apparent, the culture is examined by phase-contrast microscopy to detect the presence of *Azomonas* cells (ovoid cells 2.5 × 5.0 μm, or sometimes filamentous forms). Growth will usually occur within 2–5 days. Positive cultures are streaked onto nitrogen-free agar medium with glucose as the carbon source. For selective isolation, nitrogen-free agar media with appropriate selective substances should also be used. Sometimes nitrogen-free iron-deficient agar can be used to encourage pigment production by some species.

Maintenance Procedures

For routine maintenance, *Azomonas* strains should be subcultured at monthly or bimonthly intervals on Winogradsky's agar medium with glucose. Other maintenance methods are similar to those described in the chapter on *Azotobacter*.

Procedures for Testing Special Characters

Methods for determining presence of genes for alternative nitrogenases, for testing ability of strains to grow diazotrophically under Mo-deprivation conditions, cell morphology, and pigment production are the same as those described in the chapter on the genus *Azotobacter*.

Differentiation of the genus *Azomonas* from other genera

The single most distinguishing feature between *Azomonas* and *Azotobacter* is the failure of the former to form cysts in aging cultures or after induction with butanol. For other features that distinguish *Azomonas* from other diazotrophs and from pseudomonads, to which they are most related, see the chapter on *Azotobacter*.

Taxonomic Comments

Analysis of 16s rRNA reveals the close but separate relationship of *Azomonas macrocytogenes* ATCC 12334 to the four *Azotobacter* species characterized (MacDonald and Melton, unpublished results) (see *Azotobacter* chapter, Figs. BXII.γ.139 and BXII.γ.140). Sequences are not available for strains of *A. agilis* and *A. insignis*. Nevertheless, the justification of a single genus with three species remains sound, based on DNA base composition, hybridization analysis, and rRNA cistron similarities (De Smedt et al., 1980). General physiological characteristics, polyamine patterning, distribution of alginate biosynthetic genes, and aromatic biosynthetic pathway enzyme distribution support the common lineage of *Azotobacter* and *Azomonas* species with group I pseudomonads (Byng et al., 1986; Fialho et al., 1990; Goris et al., 1998). While the genus is more heterogeneous than *Azotobacter*, further molecular characterization of *Azomonas* species and strains would be required to justify separation of the group into more than one genus.

Differentiation of the species of the genus *Azomonas*

The differential characteristics of the three species of *Azomonas* are presented in Table BXII.γ.121.

List of species of the genus Azomonas

1. **Azomonas agilis** (Beijerinck 1901) Winogradsky 1938, 400[AL] (*Azotobacter agilis* Beijerinck 1901, 577.)
a′gi.lis. L. adj. *agilis* quick, agile.

The characteristics are as described for the genus and as listed in Tables BXII.γ.121 and BXII.γ.122. The morphology is as shown in Fig. BXII.γ.126. The cells are typically 2–4 × 1.6–3.0 μm. Cells are motile by means of numerous peritrichous flagella—a distinguishing characteristic of this species. The flagella have a wavelength of 2.0–3.0 μm and an amplitude of 0.40–0.59 μm.

Colonies are opaque, low convex, butyrous, and usually mucoid, glistening, and smooth.

Physiological and nutritional characteristics are presented in Tables BXII.γ.121 and BXII.γ.122. Starch is not hydrolyzed. Ammonium salts can be used as a sole source of nitrogen for growth. Neither nitrate nor glutamate can be used as a nitrogen source.

The type strain was isolated by Kluyver and van den Bout (1936).

The mol% G + C of the DNA is: 52–53.2 (T_m).

Type strain: ATCC 7494, DSM 375, WR 83.

2. **Azomonas insignis** (Derx 1951) Jensen 1955b, 156[AL] (*Azotobacter insignis* Derx 1951, 344.)
in.sig′nis. L. adj. *insignis* distinguished by a mark.

The characteristics are as described for the genus and as listed in Tables BXII.γ.121 and BXII.γ.122. Motile by lophotrichous flagella, whose full wavelength may exceed 4 μm). The numerous flagella tend to bind together to form thick, whip-like structures.

Colonies are translucent, low convex, butyrous, and smooth. They are usually small, probably due to low production of extracellular polysaccharides.

Physiological and nutritional characteristics are presented in Tables BXII.γ.121 and BXII.γ.122. Starch is not hydrolyzed. Ammonium or nitrate, but not glutamate, can be utilized as a sole nitrogen source for growth. The ability to use nitrate as a nitrogen source and the inability to use sucrose as a carbon source are characteristics distinctive for this species.

The mol% G + C of the DNA is: 55.1–58.3 (T_m).

Type strain: UQM 1966.

3. **Azomonas macrocytogenes** (ex Baillie, Hodgkiss and Norris 1962, 118) New and Tchan 1982, 381[VP] (*Azotobacter macrocytogenes* Jensen 1955a, 280; *Azotobacter macrocytogenes* (Jensen 1955a) Thompson and Skerman 1981, 215; *Azotobacter agilis* subsp. *jakutiae* Krasil' nikov 1949, 508.)
mac.ro.cy.to' ge.nes. Gr. adj. *macrus* large; Gr. n. *kytos* cell; Gr. v. *gennaio* produce; M.L. part. adj. *macrocytogenes* large cell producing.

The characteristics are as described for the genus and as listed in Tables BXII.γ.121 and BXII.γ.122. The morphology is shown in Fig. BXII.γ.127. Cells are typical of species of *Azomonas* except that motility occurs by polar rather than peritrichous flagella. Usually one or, less frequently, two flagella per cell are observed. The flagellar wavelength is 1.3–1.7 μm and the amplitude is 0.25–0.52 μm. The cells are often surrounded by large capsules.

Colonies on sucrose media are mucoid and large (15 mm in diameter in 7 d) due to the production of colony-retained homopolysaccharides. Starch is not hydrolyzed. Ammonium, but not nitrate or glutamate, can serve as a sole nitrogen source for growth.

The gene *anfG*—but not *vnfG*—is present in strain ATCC 123334, suggesting that this species contains the alternative nitrogenase-3 in addition to nitrogenase-1. The possession of *anfG* is possibly a unique characteristic of this species. The genome size of *A. macrocytogenes* ATCC strain 12334 is 2.4 Mb—smaller than the genomes of other *Azomonas* and *Azotobacter* species (see Table BXII.γ.123 in the chapter on *Azotobacter*). The significance of this small size with respect to the diversity of this organism is not known.

The mol% G + C of the DNA is: 58.2–58.6 (T_m).

Type strain: Jensen O, ATCC 12335, DSM 721, NCIB 8700, WR-111.

Additional Remarks: Other strains include strain M (ATCC 12336), a mutant isolated by Jensen, and strain WR-140, cotype of "*A. agilis* subsp. *jakutiae*" Krasil' nikov 1949.

Genus III. **Azotobacter** *Beijerinck 1901, 567[AL]*

Christina Kennedy, Paul Rudnick, Melanie L. MacDonald and Thoyd Melton

A.zo.to.bac' ter. Fr. n. *azote* nitrogen; M.L. masc. n. *bacter* the equivalent of Gr. neut. n. *bactrum* a rod or staff; M.L. masc. n. *Azotobacter* a nitrogen rod.

Cells range from straight rods with rounded ends to more ellipsoidal or coccoid, depending on the culture medium and age. **Cells are up to 2 μm or more in diameter and 4 μm in length**. *A. paspali* cells are usually longer, 5–10 μm in length, and can be filamentous, up to 60 μm long. Cells are usually single but may occur in pairs, irregular clumps (especially with *A. paspali*), or, more rarely, in chains of varying length. **Encystment** occurs during late stationary phase at low frequency or at high frequency after culturing on butanol. **Motile with peritrichous flagella or nonmotile**. **Aerobic, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor**. **Nitrogen is fixed** under microaerobic conditions (2% oxygen), under full aerobiosis, or after adaptation in hyperbaric oxygen. N_2 fixation uses Mo-, V-, or Fe-containing nitrogenase enzymes, depending on the environmental metal supply. **Water-soluble and water-insoluble pigments are produced by some strains of all species**. Growth is heterotrophic; sugars, alcohols, and salts of organic acids are used as carbon sources. Ammonium salts, nitrate, and urea are used as sources of fixed nitrogen. Very few amino acids are used, probably due to a general deficiency in amino acid transport. The minimum pH for growth in the presence of fixed nitrogen sources ranges from 4.8 to 6.0 with maximum pH 8.5. The optimum pH for diazotrophic growth is 7.0–7.5. **Most isolates are from soil, but a few are from water**. One species (*A. paspali*) has been isolated only from roots of the tropical grass *Paspalum notatum*.

The mol% G + C of the DNA is: 63.2–67.5.

Type species: **Azotobacter chroococcum** Beijerinck 1901, 567.

Further descriptive information

Preliminary note The immense amount of data accumulated by Thompson and Skerman (1979) remains the foundation for the basic morphological and physiological characterization of both *Azotobacter* and *Azomonas*. The data resulted from an analysis of some 90 strains representing the several species of *Azotobacter* and *Azomonas*—including established strains found in international culture collections and their own isolates—for 230 different morphological and physiological attributes. The data were summarized by Tchan and New (1984) in the previous edition of the *Manual*. More current knowledge of *Azotobacter* species is very uneven, particularly with respect to genetic, physiological, and biochemical studies, with *A. vinelandii* being the most studied followed by *A. chroococcum*. Relatively little information has been reported for the other five species, especially for *A. nigricans* and *A. armeniacus*, in each of which only four isolates were previously studied (Thompson and Skerman, 1979). The present authors have drawn on those contributions and on updates from the literature since 1984 to provide a current overview of the characteristics of the genus *Azotobacter*.

Cell morphology In nitrogen-free Winogradsky medium[1] with glucose as the carbon source, the young cells of different species are remarkably similar in appearance (Figs. BXII.γ.128, BXII.γ.129, and BXII.γ.130): rods with rounded ends, 1.6–2.7 × 3.0–7.0 μm. In older cultures, the cells of some species may tend to be ellipsoidal to coccoid. In other species, chains and filamentous forms become more common, and dark-colored granules are observed. *A. paspali* produces long filamentous forms even in young cultures (Fig. BXII.γ.131), and this characteristic—together with the inability of this species to use several carbon sources—differentiates it from the others. In peptone–yeast ex-

1. Winogradsky's nitrogen-free mineral medium is prepared from a 200× stock solution which has the following composition (g/l): KH_2PO_4, 50.0; $MgSO_4 \cdot 7H_2O$, 25.0; NaCl, 25.0; $FeSO_4 \cdot 7H_2O$, 1.0; $Na_2MoO_4 \cdot 2H_2O$, 1.0; and $MnSO_4 \cdot 4H_2O$, 1.0; the pH is adjusted to 7.2 with NaOH. The medium is prepared by using 5.0 ml of the stock solution and 0.1 g/l of $CaCO_3$ and then sterilized at 120°C for 20 min. To make nitrogen-free organic medium, a suitable quantity of organic substrate is added to the mineral medium. (Certain sugars, including glucose, must be sterilized separately before addition to the sterilized mineral medium.) For a solid medium, 15.0 g/l of agar is added.

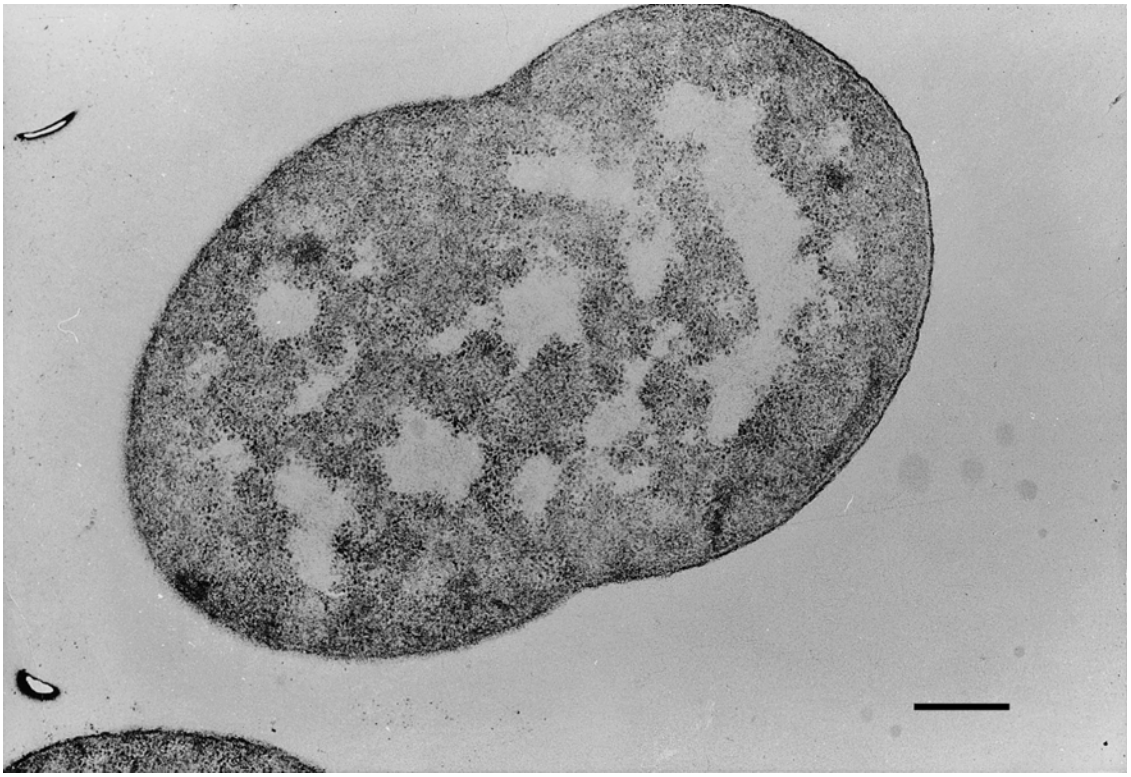

FIGURE BXII.γ.128. Electron micrograph of a vegetative cell of *Azotobacter chroococcum*. Bar = 0.2 μm.

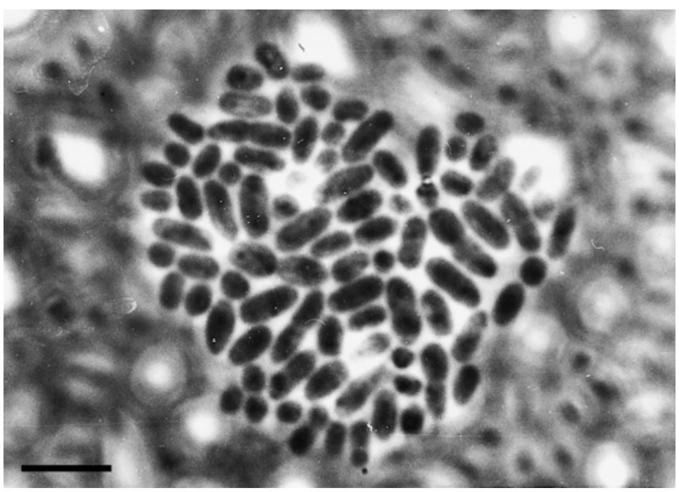

FIGURE BXII.γ.129. Vegetative cells of *Azotobacter chroococcum* (phase-contrast microscopy). Bar = 10 μm.

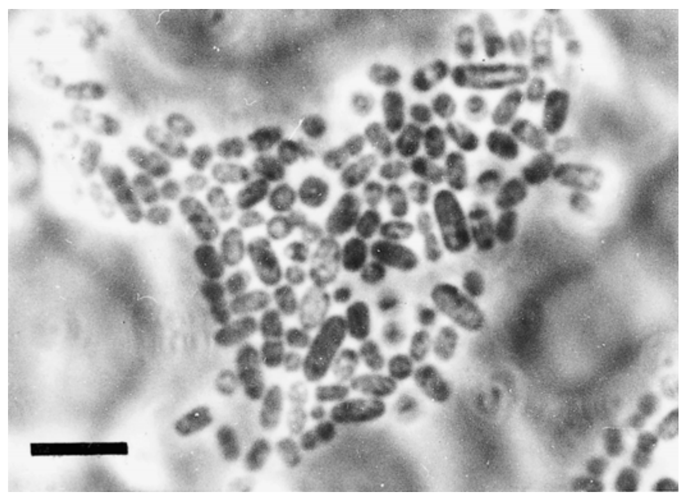

FIGURE BXII.γ.130. Vegetative cells of *Azotobacter nigricans* (phase-contrast microscopy). Bar = 10 μm.

tract agar[2], all members of the genus produce distorted cells (Tchan and New, 1984). The widely-used, nongummy strain AvOP of *A. vinelandii* (see below) cannot grow at all on Luria–Bertani medium (C. Kennedy, unpublished results), a medium with peptone and yeast extract (Sambrook et al., 1989). Cells grown under nitrogen-fixing conditions are smaller than ammonia-grown cells. *A. paspali* cells aggregate in late-log or stationary phase, especially with an increasing C:N ratio (Abbass and Okon, 1993a). The large size of *A. vinelandii* cells correlates with their high DNA content (see later), and their volume was estimated to be 16 times greater than that of *Escherichia coli* cells (Efuet et al., 1996) (Fig. BXII.γ.132).

Cell wall composition *Azotobacter* species form a proteinaceous S-layer as the outermost cell surface component. The layer is structurally similar to that of *Aeromonas salmonicida* and two other *Pseudomonas* species (Bingle et al., 1987). Unlike the S-layer in these organisms, however, the S-layer of *A. vinelandii* can be extracted from whole cells or outer membrane fractions with

2. Peptone-yeast extract agar (g/l): Bacto peptone (Difco), 1.0; yeast extract (Difco), 0.5; NaCl, 0.5; Bacto agar (Difco), 15. The pH is adjusted to 7.2 with NaOH prior to autoclaving, giving a final pH of 7.0.

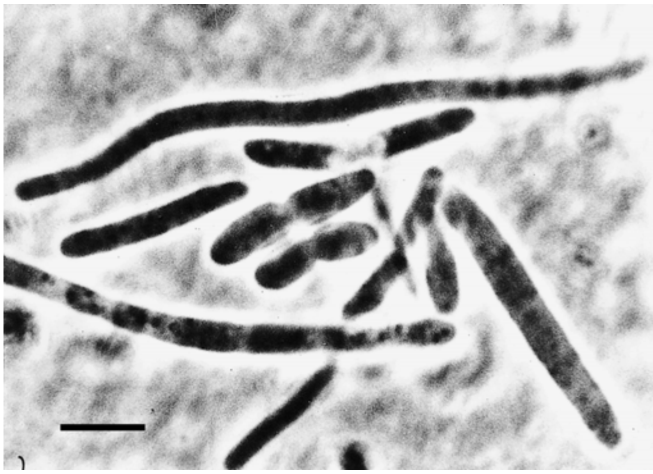

FIGURE BXII.γ.131. Vegetative cells of *A. paspali* (phase-contrast microscopy). Bar = 10 µm.

water. The S-layer of *A. vinelandii* is composed of a ~60 kDa protein, which assembles into tetramers every 12–13 nm. N_2-fixing cells form an elaborate inner membrane network (Oppenheim and Marcus, 1970). Such networks are formed concomitantly with the synthesis of nitrogenase and an increase in the rate of respiration, suggesting an involvement in protecting nitrogenase from oxygen damage. Ammonia-grown cells of *A. vinelandii* develop large deposits of poly-β-hydroxybutyrate (PHB), and the cytoplasm appears less dense. PHB deposits are not seen with cells grown with nitrate or N_2. PHB biosynthesis seems not to be influenced by the fixed nitrogen or carbon supply in *A. chroococcum* (Martinez-Toledo et al., 1995). In *A. beijerinckii*, PHB synthesis is variable and dependent on media and specific culture conditions (Bormann et al., 1998).

The fatty acid composition of vegetative cells differs from that of cysts. In vegetative cells analyzed during mid-exponential phase, 75% of the total fatty acids are C_{16} derivatives, 4% are C_{14}, and 21% are C_{18} (Su et al., 1979). Seventy percent of the total lipids are replaced with 5-*n*-alkylresorcinols and 6-*n*-alkylpyrones during encystment in *A. vinelandii* (Su and Sadoff, 1981; Reusch and Sadoff, 1983a) and in *A. chroococcum* (Kozubek et al., 1996). These molecules—thought previously to be strictly components of plant membranes—are unique to the cysts and probably contribute to desiccation resistance in both *A. vinelandii* (Reusch and Sadoff, 1983b) and in several strains of *A. chroococcum* (Kozubek et al., 1996).

Motility *A. beijerinckii* and *A. nigricans* are nonmotile. Other species are motile by peritrichous flagella, which are often present in large numbers (Fig. BXII.γ.133). *A. vinelandii* OP is a fast-moving bacterium, with a measured average velocity of 74 µm/sec (Haneline et al., 1991). Chemotaxis occurs and requires oxygen; the speed of the cells increases as a function of attractant concentration. Attraction to fructose, glucose, xylitol, and mannitol occurs, especially after pregrowth in these compounds, indicating that chemotaxis is often inducible. Chemotaxis to other compounds, including hexoses, hexitols, pentitols, pentoses, disaccharides, and amino sugars, occurs.

Cultural characteristics When grown at 30°C with sugar—usually sucrose—as the carbon source at 1–2% (w/v) on either Winogradsky's nitrogen-free agar medium or on Burk's medium[3], colonies appear within 48 h at 30°C and reach a diameter of 2–6 mm in a week, depending on the numbers (crowding) per plate. Burk's medium is now more commonly used than Winogradsky's medium for growth of laboratory strains of *A.*

3. Burk's medium has the following composition (g/l): K_2HPO_4, 0.64; KH_2PO_4, 0.20; $MgSO_4 \cdot 7H_2O$, 0.2; NaCl, 0.2; $CaSO_4 \cdot 2H_2O$, 0.05. Sucrose or other carbon sources should be added separately after autoclaving from sterile 20% solutions to give a final concentration of 20 g/l. Na_2MoO_4 and $FeSO_4$ should be added from sterile stock solutions to give a final concentration of 0.001 g/l and 0.003 g/l Fe. Agar is added to a final concentration of 1.2–1.5% (w/v).

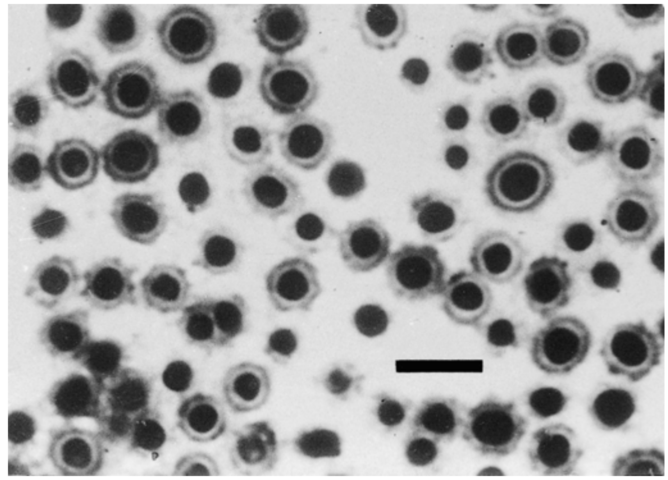

FIGURE BXII.γ.134. Violamine-stained cysts. The central body is surrounded by the cyst coat. Bar = 5 μm.

vinelandii and *A. chroococcum*. Brown's medium[4] with glucose results in higher plate counts of *A. chroococcum* colonies (Thompson, 1989). Colonies of most species are generally smooth, glistening, opaque, low convex, and mucoid; however, variations may occur. For *A. vinelandii*, smaller variant colonies may appear due to decreased production of extracellular polysaccharide. *A. armeniacus* sometimes produces translucent colonies and *A. paspali* forms undulate edged and unevenly convex colonies with a dull or rough surface. On sucrose or raffinose agar, the production of diffusible homopolysaccharides—which results in a diffuse halo around the colony—is species dependent. *A. chroococcum* and some strains of *A. beijerinckii* and *A. nigricans* produce diffusible homopolysaccharides from both sugars, whereas *A. armeniacus* and some other strains of *A. beijerinckii* and *A. nigricans* produce them only from sucrose (Thompson and Skerman, 1979).

Cysts Cysts are formed in fewer than 1% of late stationary cells of *Azotobacter* species grown on glucose or mannitol. Encystment can reach >90% 5 d after the addition of butan-1-ol or β-hydroxybutyrate to growing cultures (Lin and Sadoff, 1968) (Fig. BXII.γ.134). Isopropanol appears to be a better inducer for strains of *A. chroococcum* (Marengo, 1983). During encystment, there is a cessation of most metabolic activities. Cysts are significantly more resistant than vegetative cells to desiccation and damage due to physical and chemical agents (Socolofsky and Wyss, 1962). In ultrastructure, they are composed of a central body containing β-hydroxybutyrate surrounded by capsule-like exine and intine layers, of which alginate is a major component (Fig. BXII.γ.135). Deposition of capsular materials and membrane components in the absence of cell division produces the layers of the exine coat (Hitchins and Sadoff, 1970). Intine vesicles migrate towards the exine where they form a layer internal to the exine. These vesicles have also been visualized during vegetative growth (Vela et al., 1970). This observation provides evidence that cysts are simply resting vegetative cells and are not analogous to bacterial spores, which are more differentiated. The composition of the exine coat in *A. vinelandii* is 32% carbohydrate, 28% protein, and 30% lipid (Lin and Sadoff, 1969).

Alginate synthesis The alginate biosynthetic pathway in *A. vinelandii* has been characterized by Pindar and Bucke (1975). Fructose-6-phosphate is converted to GDP-mannuronic acid, which is polymerized and secreted. The polymer is modified by an O-acetylase and an extracellular C-5 epimerase to form alginate (Rehm et al., 1996). Alginate biosynthesis is apparently essential for encystment in *A. vinelandii* because biosynthetic mutants do not form cysts (Campos et al., 1996). Alginate production is remarkably similar to that in the pathogen *Pseudomonas aeruginosa* (reviewed by May and Chakrabarty, 1994), and genes from each organism can rescue mutations in the other (Moreno et al., 1998). There is industrial interest in the exopolysaccharides synthesized by *A. vinelandii* and *A. chroococcum*, and these polysaccharides can be produced in high concentrations depending on cultural conditions (De la Vega et al., 1991; Pena et al., 2000). The best medium for production of alginate by *A. vinelandii* is that described by Sabry et al. (1996).[5] In *A. vinelandii*, alginate is made to a concentration of 4.5 g/l when cells are incubated at 300 rpm on a shaker under 5% O_2. Alginate production increases with agitation speeds upwards to 700 rpm; however, increasing the speed leads to a decrease in the polymer size from 680,000 Da at 300 rpm to 352,000 Da at 700 rpm. Reduction in size of the polymer is correlated with alginase activity, detected in the more vigorously aerated cultures. The alginate produced by *A. vinelandii* differs from other bacterial sources in that guluronic acid residues can be introduced after polymerization by conversion of a mannuronic residue, and there are apparently eight enzymes which code for this particular C-5 epimerase activity (Ertesvag et al., 1994, 1995; Rehm et al., 1996; Svanem et al., 1999). The resultant alginate formed by the activity of these enzymes gives it industrially favorable gel-forming properties.

---

4. Brown's medium has the following composition (g/l): glucose or mannitol, 5.0; K_2HPO_4, 0.8; $MgSO_4 \cdot 7H_2O$, 0.2; $FeSO_4 \cdot 7H_2O$, 0.04; Na_2MoO_4, 0.005; $CaCl_2$ (anhydrous), 0.15; agar, 15. The phosphate is prepared as a separate 8% (w/v) solution and added to the agar after sterilization by autoclaving (standard conditions) and cooling to 42°C just before pouring plates.

5. Medium for alginate production (per liter): $MgSO_4 \cdot 7H_2O$, 0.3 g; NaCl, 0.4 g; $CaCl_2 \cdot 2H_2O$, 42 mg; KH_2PO_4, 4 mg; K_2HPO_4, 16 mg; $FeSO_4 \cdot 7H_2O$, 2.5 mg; H_3BO_3, 2.9 mg; $ZnSO_4 \cdot 7H_2O$, 2 mg; $Na_2MoO_4 \cdot 2H_2O$, 2 mg; $CuSO_4 \cdot 5H_2O$, 0.3 mg; and $MnCl_2 \cdot 4H_2O$, 0.2 mg.

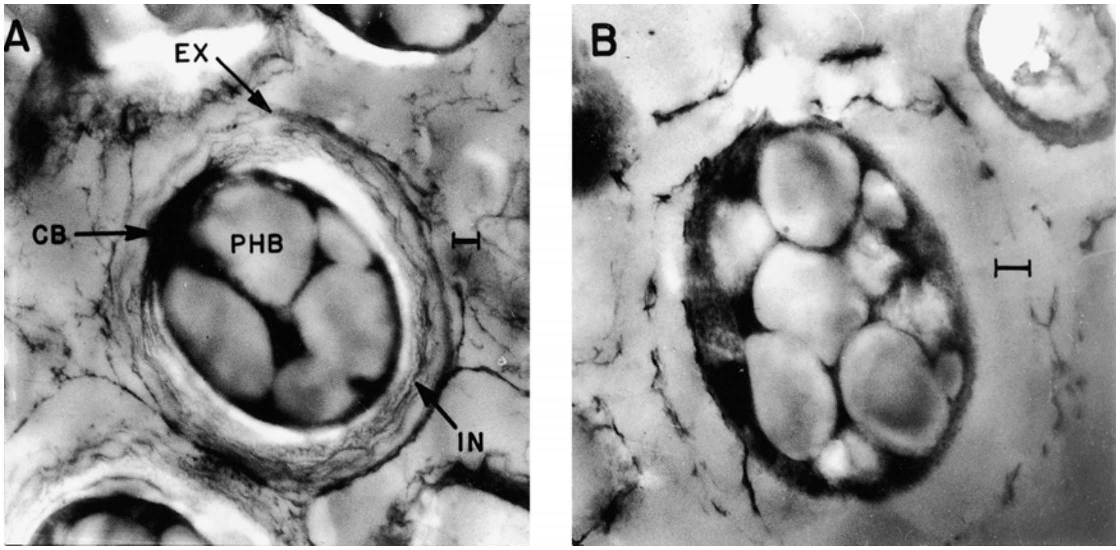

FIGURE BXII.γ.135. Electron micrographs of the cysts formed by strains ATCC 9046 (*A*) and ATR8 (*algR*$^-$) (*B*). Abbreviations: EX, exine; IN, intine; CB, central body; PHB, poly-hydroxybutyrate. The particular exopolysaccharides produced by *A. chroococcum* vary among strains. Cote and Krull (1988) reported the existence of two distinct exopolysaccharides from strain NRRL B-14341 (ATTC 7491), one of which has been identified as an alginate. *A. chroococcum* ATCC 4412 apparently produces only one type of exopolysaccharide, which is alginate-like. Production of this molecule varies with carbon source and air-flow rate, and the best yields occur at 8% sucrose (De la Vega et al., 1991). Since alginate production varies among strains, it may not be possible to differentiate between species based on the production of alginate. *A. beijerinckii* B-1615 produces two different exopolysaccharides in a 9:1 ratio (Likhosherstov et al., 1991). The major polysaccharide consists of D-galactose, L-rhamnose, and pyruvic acid in a 2:1:1 ratio. The minor polysaccharide contains mannuronic and guluronic acid in a 2:3:1 ratio and is an alginate.

Genes encoding products involved in alginate synthesis are found in all members of *Azotobacter* and *Azomonas* and throughout most of *Pseudomonas* group I. (Fialho et al., 1990). The alginate biosynthetic genes of *A. vinelandii* are clustered as operons (Martinez-Salazar et al., 1996; Nuñez et al., 1999), and a similar arrangement is predicted for *A. chroococcum* (Peciña et al., 1999). Although not all of the *alg* genes have been identified in any member of *Azotobacter* or *Azomonas*, their arrangement is probably similar to that in *P. aeruginosa*, in which three large clusters at distinct locations on the chromosome comprise all functions of alginate biosynthesis and regulation (for review, see Gacesa, 1998). It should be noted that not all *A. vinelandii* strains produce alginate. The commonly used nonmucoid laboratory strain, UW136 (a rifampicin resistant derivative of AvOP/UW), may have arisen from insertion of small IS element in *algU* (Martinez-Salazar et al., 1996).

Siderophores As noted earlier, some *Azotobacter* species produce the yellow-green fluorescent peptide siderophore, azobactin, in response to iron limitation. *A. vinelandii* also produces the three nonfluorescent catecholate siderophores, azotochelin, protochelin, and aminochelin, under similar growth conditions (Cornish and Page, 1998). Iron uptake by each of the siderophores is biphasic and energy-dependent. Fe^{+3} uptake mediated by each of the siderophores is sensitive to metal salts: the addition of 40 mM Na^+, K^+, Li^+, or Mg^{+2} inhibits 60% of total uptake. $NH_4{}^+$ also inhibits uptake but to a lesser extent (Knosp et al., 1984). The production of both types of siderophores is repressed by iron compounds in the medium. However, repression of azotobactin synthesis is sensitive to lower concentrations of Fe than is production of the catecholate siderophores. The promoter of the gene encoding the first enzyme in catecholate siderophore synthesis has been characterized (Tindale et al., 2000), and within this promoter is a Fur-box as well as sequences that match the Sox-boxes of *E. coli.* The appearance of these regulatory features, as well as an increase in expression in response to superoxide, suggests that azotochelin may provide protection against oxidative stress under nitrogen-fixing conditions. *A. chroococcum* produces Fe-binding hydroxamates in response to Fe limitation as well as an 85 kDa outer member protein (Fekete et al., 1989). *A. paspali* produces 3,4-dihydroxybenzoic acid (protocatechuate) in both Fe-limited and Fe-sufficient media; this compound solubilizes Fe from minerals (Collinson et al., 1987).

A. salinestris produces a catechol melanin pigment described as an "iron trap" and may function to protect cells from oxidative damage mediated by H_2O_2 and the Fenton reaction (Page and Shivprasad, 1995). The siderophore-like acquisition of iron mediated by this pigment is proposed to occur in a two-step process. In the first step, iron is concentrated in the periplasm by an energy-dependent process and is promoted by a hydroxamate compound produced in conjunction with the pigment. In the second step, the iron is brought into the cytoplasm; this process is sensitive to inhibitors of Na^+-dependent activities of the organism.

Nutrition The ability of species of *Azotobacter* to utilize various carbon and nitrogen sources is important for experimental and applied work, particularly considering how carbon sources can influence the efficiency of nitrogen fixation and how various nitrogen sources can be used in the analysis of Nif^- and other mutants.

Utilization of carbon sources by *Azotobacter* species is shown in Tables BXII.γ.123 and BXII.γ.124. Some carbon sources are utilized by all species, whereas others differentiate the species. Several other less commonly used compounds can be utilized by some species (Thompson and Skerman, 1979). Few reports that further differentiate the species with respect to carbon source utilization have appeared since the work of Thompson and Skerman (1979) and the last edition of the *Manual*. De La Vega et al. (1991) reported that sucrose is degraded by an extracellular invertase in *A. chroococcum* ATCC 4412, whereas it is degraded by an intracellular invertase in *A. vinelandii* UW (ATCC 13705). Chen et al. (1993) found that *A. chroococcum* (ATCC 9043) and *A. vinelandii* UW utilize not only the aromatic compounds benzoate and 4-OH-benzoate but also catechol, naphthalene, protocatechuate, and 4-toluate, which confirmed and extended the findings of Thompson and Skerman (1979). *A. chroococcum* expressed only *ortho* cleavage dioxygenases during growth on naphthalene and 4-toluate, and only *meta* cleavages of other aromatics. *A. vinelandii* expressed both *ortho* and *meta* cleavage enzymes (Chen et al., 1993). Interestingly, growth rates and nitrogenase activities were nearly as high or higher on certain aromatic compounds—benzoate and naphthalene, in particular—for both *A. chroococcum* and *A. vinelandii*. Among isolates enriched from British soils near Leicester for growth on monochloroacetate, one strain—RC26—had many cultural and physiological characteristics that placed it in the genus *Azotobacter* (Diez et al., 1995). This strain was able to dehalogenate a number of different compounds used as pesticides at rates similar to those determined for species of *Pseudomonas*. While this strain has not been characterized with respect to 16S rDNA sequence, it may represent a soil-inhabiting species of *Azotobacter* with capability for bioremediation of agrochemicals.

Nitrogen fixation Nitrogen fixation under aerobic conditions is a principle characteristic of the genus. The major and minor clusters of genes encoding the enzyme synthesized under Mo-sufficient conditions in *A. vinelandii*, sequenced and extensively characterized, are shown in Fig. BXII.γ.136. *A. chroococcum* MCD-1 (derived from ATCC 4412) has a similar major cluster, but has been less well characterized in terms of mutational analysis. Some specific functions of the *nif* gene products are mentioned below; a more extensive review of them can be found in Rangaraj et al. (2000). The *nifHDK* genes encode the basic structural proteins of the nitrogenase enzyme. The other gene products encoded by this *nif* cluster are required for (1) synthesis of the Fe-Mo-cofactor, an essential component of the enzyme for substrate (N_2) binding and reduction (*nifV*, *nifEN*, *nifH*); (2) formation of Fe-S clusters required at other sites in the enzyme which are involved in electron transfer to the cofactor (*nifU*, *nifS*); and (3) participation in other aspects of enzyme maturation (*nifM*, *nifW*). In addition to this is another cluster, located elsewhere in the *A. vinelandii* genome, which includes *nifL* and *nifA* in an operon encoding the regulatory proteins NifL and NifA, and other proteins involved in nitrogenase cofactor synthesis and Mo processing (products of the *nifB fdxN nifO nifQ* operon). NifL prevents expression of the other *nif* genes if high levels of ammonium or oxygen are present, conditions that would either make nitrogenase unnecessary for growth or become inactive, respectively. The NifL protein, which carries a flavin cofactor, inhibits the activity of NifA, which is a transcriptional activator of the other *nif* genes and operons under these conditions (Dixon, 1998). The presence of a *nifL* gene is characteristic of diazotrophs in the *Gammaproteobacteria*, which includes another important diazotroph of this taxon, *Klebsiella pneumoniae*, as well as *Azotobacter vinelandii*—the two species most studied. The *nifL* gene has not been identified in the *Alphaproteobacteria*, *Betaproteobacteria*, or *Deltaproteobacteria* groups of diazotrophs, with the possible exception of *Azoarcus* species in the class *Betaproteobacteria* (B. Reinhold-Hurek, personal communication). Muta-

[b]Results of Thompson and Skerman (1979) on solid media. Machado and Döbereiner (1969) found no growth of *A. paspali* above pH 8.0 in their liquid medium.

[c]See Procedures for Testing Special Characters.

[d]Although there are no reports of PCR or hybridization results to confirm the presence of these genes, they can be inferred to be present on the basis of tests for diazotrophic growth and/or nitrogenase activity.

[e]See Table BXII.γ.123 for additional compounds; also see Thompson and Skerman (1979).

tions in *nifL* can result in constitutive expression of *nif* genes leading to unregulated nitrogenase enzyme overexpression and excretion of ammonium in *A. vinelandii* (Bali et al., 1992). Unlike in most other diazotrophs in the *Proteobacteria*, ammonium inhibition of nitrogen fixation in *A. vinelandii* occurs at only one target, namely, inactivation of NifA by NifL. Posttranslational control of nitrogenase activity by ammonium might occur in *A. chroococcum* (Munoz-Centeno et al., 1996).

In addition to using the classic Mo-containing enzyme for nitrogen fixation, all *Azotobacter* species examined have the po-

tential to synthesize one or more alternative nitrogenases that do not contain Mo. Evidence for such alternative nitrogenases first came from studies with *A. vinelandii* mutants UW10 and UW9—derivatives of AvOP (UW) (ATCC 13705) carrying mutations in the *nifH* and *nifD* genes which encode protein subunits of nitrogenase. Bishop et al. (1980) found that these mutants gave rise to Nif^+ colonies at low frequency and that these strains were resistant to tungstate, an antagonizer of Mo transport. In addition, both UW10 and UW91 were able to grow and fix nitrogen if Mo was eliminated from the growth medium, and it was proposed that *A. vinelandii* could synthesize a Mo-independent form of nitrogenase. Subsequently, by genetics, biochemistry, and gene sequencing, *A. vinelandii* was found to encode three different nitrogenase enzymes with different structural subunits: (1) the traditional Mo nitrogenase (nitrogenase-1, the structural subunits of the enzyme encoded by the *nifHDK* genes), (2) a V-containing enzyme (nitrogenase-2, encoded by the *vnfH vnfDGK* genes), and (3) a Fe-containing nitrogenase (nitrogenase-3, encoded by the *anfHDGK* gene cluster) (see Fig. BXII.γ.136 for *nif*, *vnf*, and *anf* gene cluster arrangements). These alternate nitrogenase systems have been reviewed by Bishop and Joerger (1990) and Rangaraj et al. (2000). Parallel studies with *A. chroococcum* strain MCD1 have indicated the presence of the Nif and Vnf enzymes only. They are encoded by *nif* and *vnf* genes, which have sequences and arrangements similar to those in *A. vinelandii* (see references in legend to Fig. BXII.γ.136). In *A. vinelandii*, all three enzymes require the activity of five other *nif* gene products found within the major and minor clusters of *nif* genes, including *nifB*, *nifM*, *nifS*, *nifU*, and *nifV* (Joerger and Bishop, 1988; Kennedy and Dean, 1992). Some of these *nifB* and *nifV* genes are required for Fe–V cofactor biosynthesis (Rutti-mann-Johnson et al., 1999) and presumably also for Fe–Fe cofactor formation. The molybdate or vanadate concentration in the growth medium (usually Burk's sucrose medium treated to extract metals; see Procedures for testing Special Characters) with 30 μM Fe determines which nitrogenase is available (Bishop and Joerger, 1990). Thus, Mo (whether or not V is present) at a concentration of about 50 nM represses *vnf* and *anf* gene expression. In cultures grown at 30°C, molybdate deficiency (less than approximately 50 nM) prevents expression of the nitrogenase structural genes, *nifHDK* (Jacobson et al., 1986), and when vanadate is present (approximately 50 nM), the *vnfHDGK* genes but not the *anfHDGK* genes are expressed. Repression by Mo of *vnf* and *anf* gene expression occurs far less severely in cultures grown at lower temperatures (14°C or 21°C) (Walmsley and Kennedy, 1991), probably because Mo is less well transported at lower temperatures. This characteristic may have ecological significance, possibly correlating with the better efficiency of the V-nitrogenase for reduction of acetylene at lower temperatures (Dilworth et al., 1988).

Three strains of *A. chroococcum* [MCD1 (ATCC 4412), ATCC 480, and ATCC 9043] have been analyzed for alternative nitrogenase genes by Southern hybridization. All were found to have *nif* and *vnf* genes, but not *anf* genes (Fallik et al., 1991). Con-

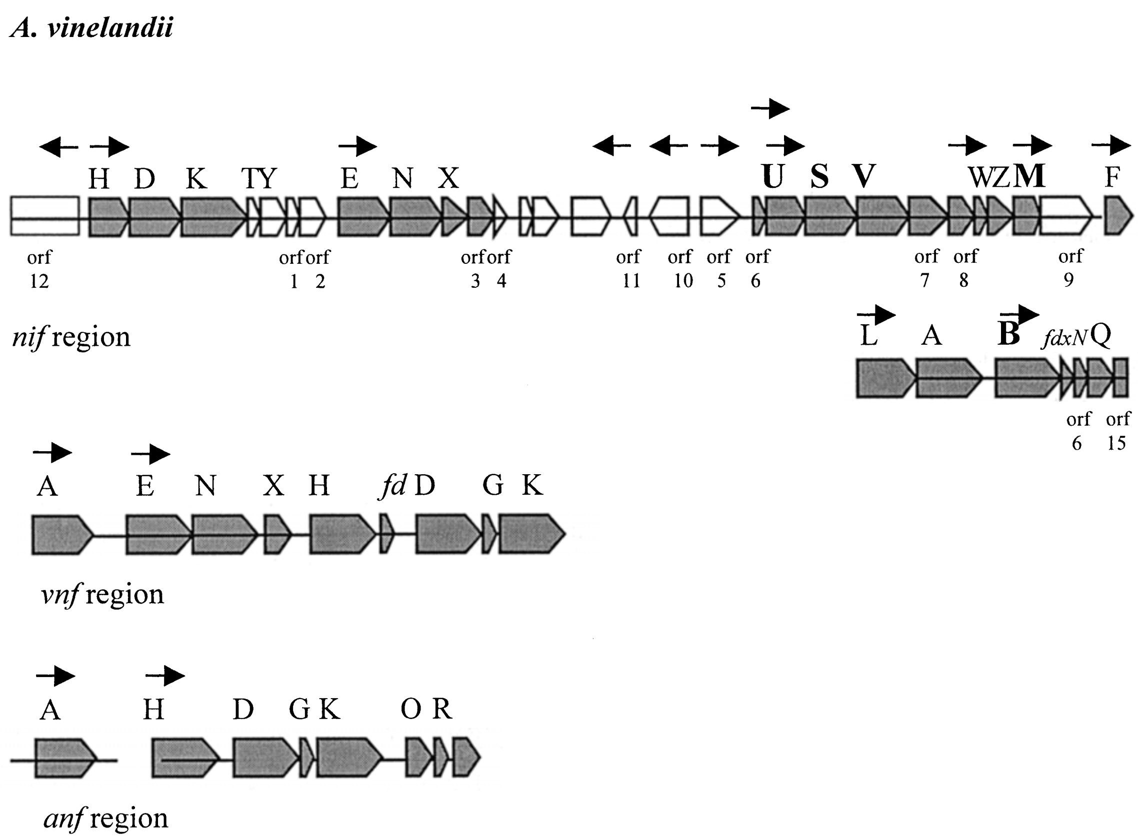

FIGURE BXII.γ.136. Physical map of the *A. vinelandii* nitrogen-fixation genes. *nif* genes encode products involved in the synthesis of the primary Mo-containing enzyme (Jacobson et al., 1989; Joerger and Bishop, 1988; Joerger et al., 1990) while the *vnf* (Joerger et al., 1990) and *anf* clusters encode alternative nitrogenases (see text) (Joerger et al., 1989; Mylona et al., 1996). Bold letters in larger font indicate genes which are essential for all three nitrogenase systems. *Open arrows* depict genes that are not essential for nitrogen fixation (Jacobson et al., 1989). *Small arrows* indicate locations of promoters and direction of transcription. *A. chroococcum nif* and *vnf* genes are arranged similarly (Evans et al., 1988; Fallik and Robson, 1990).

sequently, this property may characterize the species (Nif^+, Vnf^+, Anf^-). *A. beijerinckii* (ATCC 19360), *A. nigricans* (ATCC 35009), and *A. salinestris* (ATCC 49674) also apparently contain *nif* and *vnf* genes only (Fallik et al., 1991; Loveless and Bishop, 1999). Only *A. vinelandii* and *A. paspali* (strains ATCC 23367 and ATCC 23833) among the *Azotobacter* species (and also *Azomonas agilis*) carry *nif*, *vnf*, and *anf* genes and can synthesize any of the three nitrogenases, depending on environmental conditions of Mo or V supply. Consequently, their phenotype is Nif^+, Vnf^+, Anf^-.

Oxygen control of nitrogenase activity in Azotobacters Nitrogen fixation is a process that is oxygen-sensitive due to the O_2-lability of the nitrogenase component proteins. However, in *Azotobacter* species, N_2 fixation can occur under fully aerobic conditions in all species examined except *A. salinestris*. Even the latter species can adapt to aerobic diazotrophy under conditions of Fe limitation, which increases production of a melanin catechol that may trap Fe and be involved in oxygen tolerance (Page and Shivprasad, 1995). In *A. chroococcum*, a shift of cultures to hyperbaric oxygen conditions (> 20%) is followed by a period of cessation of nitrogenase activity which then returns after further incubation, probably because of conformational protection by the FeSII protein, discussed below and in Robson and Postgate (1980). Aerotolerance in *A. vinelandii* is due mainly to a low O_2 affinity, high K_m cytochrome *d* terminal oxidase encoded by the *cydAB* genes. Mutation in either of these genes results in mutant strains unable to grow aerobically on N_2, which represents a loss of respiratory protection. Under low (2%) O_2, the mutants can fix nitrogen and grow (Kelly et al., 1990). The CydR protein represses transcription of *cydAB* under conditions of low O_2 (Wu et al., 1997a) during which the cytochrome *c* pathway provides respiration (Rey and Maier, 1997). A supply of ATP and reducing equivalents are additional factors that may be important to prevent oxygen damage to nitrogenase (Oelze, 2000). Another factor of significance is the FeSII or Shethna protein (Dervartanian et al., 1969). This protein binds to and protects Mo nitrogenase from oxygen damage—but apparently does not bind to or protect either of the alternative Vnf or Anf nitrogenases—during periods of O_2 stress (Dervartanian et al., 1969; Moshiri et al., 1994). *A. vinelandii* mutant strains lacking the FeSII Shethna protein show reduced viability under carbon deprivation if O_2 is present (Maier and Moshiri, 2000). This protein is also found in *A. chroococcum* where it provides "conformational protection" from O_2 damage to nitrogenase (Robson, 1979). An FeSII DNA probe from *A. vinelandii* hybridized only to *A. chroococcum* genomic DNA among several diazotrophs tested (Moshiri et al., 1994). The FeSII protein may therefore be found only in species of *Azotobacter* and thus may be a distinguishing characteristic. Production of alginates and an alginate capsule may form a barrier to oxygen transfer (Sabra et al., 2000), adding to the battery of mechanisms elaborated by azotobacters for protecting nitrogenase from damage by oxygen in an obligate aerobe.

Other nitrogen sources Most *Azotobacter* species can utilize nitrate as a nitrogen source in an assimilatory fashion by reduction to nitrite and then ammonium. Genes for nitrate and nitrite reductases, *nasB* and *nasA*, have been isolated from *A. vinelandii* OP. The *nasAB* operon, regulated from a σ^{54}, NtrC-dependent promoter, is repressed by ammonium and requires nitrate for full expression (Ramos et al., 1993). Soluble nitrate reductases have been purified from *A. vinelandii* and *A. chroococcum* (Guerrero et al., 1973; Gangeswaran et al., 1993). Nitrate transport and reduction have been studied in *A. chroococcum*. Although the genes have not been characterized in this organism, the physiology of nitrate assimilation is similar to that in *A. vinelandii*. Ammonium prevents full synthesis/activity of the enzyme, and nitrate is required for full activity.

All *Azotobacter* species are urease positive in physiological tests—a feature that distinguishes *Azotobacter* from *Azomonas* species (Thompson and Skerman, 1979). This feature is consistent with the fact that urea is a good nitrogen source in both *A. vinelandii* and *A. chroococcum*. It is also a useful trait, because urea added to media at 5–10 mM does not prevent nitrogenase synthesis, in contrast to the effects of ammonium. Consequently, urea allows studies of expression of these genes in liquid cultures (e.g., Walmsley and Kennedy, 1991).

Other aspects of metabolism H_2 uptake systems are similar in both *A. vinelandii* and *A. chroococcum*, having been best characterized physiologically in the latter species. H_2 recycling occurs in N_2-fixing cultures: H_2, a byproduct of the reduction of N_2 to ${NH_4}^+$, is re-oxidized to H^+ by a Ni-dependent hydrogenase encoded by the 16-gene *hup* cluster in *A. chroococcum* (Du and Tibelius, 1994; Du et al., 1994) and by a similar 16-gene *hox/hyp* cluster in *A. vinelandii* (Menon et al., 1992; Garg et al., 1994). Hydrogenase activity is apparently beneficial in *A. chroococcum*, as shown by the ability of the Hup^+ strain MCD-1 to outcompete a Hup^- mutant for survival under controlled carbon-limited chemostat conditions (Yates and Campbell, 1989). In *A. vinelandii*, both Hox^+ and Hox^- strains yielded very similar amounts of protein in chemostat cultures (Linkerhagner and Oelze, 1995). In addition, both had similar respiratory activities, and, in the wild-type, only a small fraction of total respiratory activity was due to H_2-dependent O_2 consumption. This finding led the authors to conclude that hydrogenase does not benefit *A. vinelandii* during carbon-limited growth under N_2-fixing conditions.

In regard to ferredoxins, it is remarkable that *A. vinelandii* can synthesize at least 12 different ferredoxin-like proteins (Jung et al., 1999), some of which—Fe-SI, FixX, FdxN, FixFd—have been implicated in electron transfer to nitrogenase. However, no mutation in a single ferredoxin-encoding gene prevents electron transfer to nitrogenase; thus, there is an apparent redundancy of function in this respect. The VnfFd ferredoxin is required for activity of the V-containing nitrogenase (Fig. BXII.γ.136) (Raina et al., 1993). Another ferredoxin is the Fe-SII Shethna protein, described above, which protects nitrogenase from inactivation by O_2. Known ferredoxins in *A. chroococcum* include those encoded by a gene adjacent to *vnfH*, and FdI and FdII, corresponding to ferredoxins characterized in *A. vinelandii* (George et al., 1984; Robson et al., 1986; Thomson, 1991).

Genetic Characteristics *A. vinelandii* can be readily studied genetically because the widely-used, non-gummy strain AvOP (ATCC 13705), derived from AvO (ATCC 12518), is easy to handle. AvOP was also named strain UW in studies at the University of Wisconsin (Bishop and Brill, 1977) and CA in studies at North Carolina State University (P. Bishop laboratory). This strain harbors no indigenous plasmids, is a high-frequency recipient during conjugation, and can be transformed with either linear or plasmid DNA. It becomes competent for DNA uptake after growth on Fe- and Mo-free medium (Page, 1985). Another widely-used derivative of UW is UW136, wild-type for nitrogen fixation but carrying a mutation for rifampicin resistance (Bishop and Brill, 1977). The features of UW and UW136 allow easy genetic studies and manipulation by introduction of wide-host-range plasmids

and isolation of mutant strains, either by transposition or gene replacement techniques (see later). In addition, nitrogenase and other important enzymes have been isolated and analyzed from strain AvOP (UW) because this strain is relatively easy to grow on either a small or large scale for preparation of extracts for protein purification. The strain has more recently become a focus of study for alginate biosynthesis. To date, sequences are available for more than 200 of its genes.

Azotobacter chroococcum has also been well-studied genetically with respect to a number of traits, and although there are no reports of successful transformation in strains of this species, the cells can receive plasmids by conjugation with *Escherichia coli* donors. Strain MCD1, a non-gummy derivative of ATCC 4412 (NCIB 8033) cured of three of five indigenous plasmids, has been used for most genetic studies (Robson et al., 1984). The sequences of approximately 50 genes in *A. chroococcum* have been reported to date.

The genome sizes of several *Azotobacter* species have been determined by pulsed-field gel electrophoresis of large chromosomal DNA fragments generated by rare-cutting restriction endonucleases. The sizes range from 3.10 Mb for *A. chroococcum* NCIB 9043 to 4.57 Mb for *A. vinelandii* UW (MacDonald and Melton, manuscript submitted) (Table BXII.γ.125). In another study, Manna and Das (1994) found the M4 strain of *A. chroococcum* to have a genome size of 5.3 Mb. This size disparity supports previous findings of genomic variation within *A. chroococcum* (Becking, 1992). The presence of a single circular chromosome in *A. vinelandii* is indicated from genetic analysis (Blanco et al., 1990). The size of the *A. paspali* genome is about the same as that of *A. vinelandii*, ~4.5 Mb, even though it might be expected that the *A. paspali* genome would be smaller because the organism uses fewer compounds as carbon sources and has a more restricted rhizosphere habitat.

The origin of replication of *A. vinelandii*, including a 200 bp segment capable of replicating plasmid pBR322 in *E. coli* polA, has been identified and sequenced. A larger fragment of 1652 bp, which includes the 200 bp ori sequence, contains 14 putative DnaA protein binding sites, ten putative binding sites for the IHF protein, and 19 GATC boxes (potential sites for Dam protein methylation), all of which are involved in initiation of DNA replication in *E. coli* and other organisms (Singh et al., 2000). Genes involved in general recombination in *A. vinelandii* include *recA* and *recF* (Venkatesh and Das, 1992; Badran et al., 1999). The former is more closely related to the *recA* gene of *P. aeruginosa* than to that of *E. coli*, which supports other phylogenetic data discussed below.

Multiple chromosomes are common in the two species examined, *A. vinelandii* and *A. chroococcum*. In *A. vinelandii*, the chromosome number is variable and can reach about 80 copies per cell in late-exponential phase cells; in old stationary-phase cultures the amount of DNA is drastically reduced, possibly in preparation for cyst formation (Maldonado et al., 1994). In exponential cultures of *A. chroococcum* MCD-1, cells contained 20–25 genome equivalents (Robson et al., 1984).

No indigenous plasmids in *A. vinelandii* AvOP (UW) wild-type and derived mutant strains have been detected in the author's laboratory or by several other investigators who study this organism. One strain of *A. paspali* did not harbor any plasmids (Do Nascimento and Tavares, 1987). Robson et al. (1984) reported finding between two and six plasmids in each of eight strains of *A. chroococcum* examined; these plasmids ranged in size from 10.5 kb to 300 kb. The *A. chroococcum* strains included NCIB 8003 (ATCC 4412); strain MCC-1, a Nalr Smr and non-gummy derivative of NCIB 8003; and six new isolates from soils in Sussex, UK. One plasmid in NCIB 8003 appeared to be of the IncP class. Plasmids were cured by growing strains for several generations using the agents ethidium bromide, acriflavin, or mitomycin. The cured strains showed no altered phenotypes that are usually associated with plasmids, except for possibly one trait, the production of agar-diffusible exopolysaccharides. Evidence for a plasmid encoding a gene or genes for degradation of 2,4-dichlorophenoxyacetic acid (2,4-D) in strain MSB1 of *A. chroococcum* was reported (Balajee and Mahadevan, 1989). The presence of single or multiple plasmids might be a distinguishing feature of *A. chroococcum*. Reports of plasmids in other species of *Azotobacter* are not available.

Wide-host-range plasmids of the IncQ and IncP classes can be transferred from *E. coli* by conjugation to *A. chroococcum* strain MCD1 and its derivatives (Kennedy and Robson, 1983; Ramos and Robson, 1987) and by either conjugation or transformation to *A. vinelandii* strain AvOP and mutant derivatives (Kennedy and Robson, 1983; Doran et al., 1987; Kennedy and Toukdarian, 1987; Glick et al., 1989). This genetic manipulation allows for the isolation of numerous genes from IncP cosmid libraries by mutant complementation, and analysis of gene function by specific genes cloned into either IncP or IncQ plasmids. Introducing wide-host-range plasmids of the IncQ compatibility group can result in reduced growth rates in *A. vinelandii* (Glick et al., 1986).

The state of competence for transformation of strains of *A. vinelandii* is associated with siderophore production and can be induced by growth on Fe-deficient or Fe- and Mo-deficient media (Page, 1985; Page and Grant, 1987). Competent cells can be transformed with either plasmid or linear DNA (Doran et al., 1987). Interestingly, the transformation frequency was enhanced 10- to 50-fold when pKT210 (IncQ) carried an insert fragment of *A. vinelandii nif* DNA, suggesting that *A. vinelandii* possesses a homology-facilitated transformation system. Mutated genes can be introduced directly on plasmids unable to replicate or on linear chromosomal DNA prepared from mutant strains; recombination with the chromosome at sites flanking the mutation leads to replacement of the wild-type genes (e.g., as described by Jacobson et al., 1989, and in many other reports).

The rRNA genes of several aerotolerant diazotrophs were an-

TABLE BXII.γ.125. Comparison of genome size and rRNA (*rrn*) copy number among isolates of the family *Azotobacter* and *Azomonas*

Strain	Genome size[a] (Mb)	Copies of *rrn* genes
Azotobacter chroococcum (ATCC 7493)	3.9 ± 0.02	8
Azotobacter chroococcum (ATCC 9043)	3.1 ± 0.32	7
Azotobacter chroococcum[b] M4	5.3	NR[c]
Azotobacter paspali (ATCC 23822)	4.3 ± 0.24	6
Azotobacter paspali AP1	4.5 ± 0.05	6
Azotobacter paspali (ATCC 11562)	4.6 ± 0.01	6
Azotobacter paspali (ATCC 12095)	4.6 ± 0.01	6
Azotobacter vinelandii UW (ATCC 1218)	4.6 ± 0.35[d]	6
Azomonas macrocytogenes	2.4 ± 0.01	7

[a]Genome size determined by summing restriction fragments generated by rare-cutting enzyme digestion. Values are derived from at least three data sets of two separate enzyme digestions (MacDonald and Melton, manuscript submitted).

[b]Determined by Manna and Das (1994).

[c]NR, not reported.

[d]Manna and Das (1993) reported a genome size of 4.5 Mb for this strain.

alyzed in hybridization experiments by De Smedt et al. (1980) to determine their phylogenetic relationship. The results indicated the validity of the grouping of all the *Azotobacter* species identified in this description and the species described below (with the exception of *A. salinestris*, which was not available at the time of their analysis). In a further and more recent analysis, the *Azotobacter* species *A. vinelandii* (ATCC 13705 derivative, CA), *A. chroococcum* (ATCC 9043), and *A. salinestris* (ATCC 49674) all carry an arrangement in the rRNA operon that consists of the 16S rRNA gene (*rrs*), a spacer region containing the tandem tRNA gene sequences for tRNAIle and tRNAAla, the 23S rRNA gene (*rrl*), a second spacer region, and the 5S rRNA gene (MacDonald and Melton, manuscript submitted). *A. paspali* (ATCC 23833) also possesses the 16S–23S–5S gene arrangement; however, the tRNAs within the 16S–23S spacer region were not identified. All the *Azotobacter* species examined here contain six, seven, or eight duplicated copies of the rRNA gene cluster (Table BXII.γ.125).

Not surprisingly, the codon usage of *A. vinelandii* is similar to that of *A. chroococcum* (Rudnick and Kennedy, unpublished analysis). The mol% G + C content of the DNA of the former species was earlier estimated from T_m experiments to be 64.9–66.5 and the latter to be 65.8–67.5% (De Ley, 1968). For genes that encode proteins, the sequences of individual genes available for each species numbering about 200 and 50, respectively, indicated a mol% G + C content of 62.5 for *A. vinelandii* and 66.7% for *A. chroococcum*. Interestingly, the *anf* genes of *A. vinelandii* have a mol% G + C value (58.3) lower than that of the *nif* and *vnf* genes (64.4% each). The *anf* cluster of *A. paspali* is also lower in mol% G + C (54.3%) than that of the genome (63.2–64.6%, from T_m experiments). In addition, the clusters of genes encoding uptake hydrogenases, *hox/hyp* in *A. vinelandii* and *hup* in *A. chroococcum*, had a higher mol% G + C value than the total DNA in these species—70.7 and 70.2, respectively. This may reflect the acquisition of these genes—both *anf* and *hup/hox*—by lateral transfer from other organisms during the course of evolution of the genus *Azotobacter*.

Isolation of mutants Transposon mutagenesis is easily achieved in *A. vinelandii* and *A. chroococcum* using Tn5 carried on suicide vectors unable to replicate in these host organisms (for examples, see Kennedy et al., 1986; Joerger et al., 1989; Contreras et al., 1991; Luque et al., 1993; Tibelius et al., 1993; Wu et al., 1997a). In addition, Tn10 was successfully used to isolate mutants of *A. vinelandii*, including methionine auxotrophs (Contreras and Casadesus, 1987). When Tn5 was introduced into *A. beijerinckii* (NCIB 11292), the cells of most of the isolates had abnormal morphologies and rapidly lost viability when subcultured. In contrast, Tn76 was successfully used to make mutants in this strain (Owen and Ward, 1985). Contreras et al. (1991) developed a method to "freeze" Tn5 mutations in *A. vinelandii* by replacing the original transposon with a defective Tn5, resulting in highly stable mutants.

Isolation of auxotrophic mutants of *A. vinelandii*, attempted in many laboratories during the 1970s and 1980s, was largely unsuccessful. It was believed that high DNA content (originally reported by Sadoff et al., 1979), and hence high chromosome copy numbers, leads to difficulty in segregation of mutant phenotypes. However, the successful isolation of many other types of mutations over the past 15 years by transposon mutagenesis or antibiotic resistant cassette insertion in cloned genes, followed by transfer into strains and subsequent gene replacement, has shown that isolation of mutant strains of *Azotobacter* is not inherently difficult. The variable DNA content of this organism, described above, does indicate that there are growth phases and conditions when the chromosome number is low, thereby allowing for "normal" segregation of introduced, selectable mutations in nonessential genes.

Although isolation of auxotrophs remains difficult, success has been achieved in the construction of Ade$^-$, Met$^-$, and Leu$^-$ mutants (Mishra and Wyss, 1968; Contreras and Casadesus, 1987; Manna and Das, 1997). *A. vinelandii* is unable to transport many amino acids (Toukdarian et al., 1990; D. Dean, personal communication). Although Mishra et al. (1991) reported that threonine was transported at a rate similar to that found for *E. coli* and methionine at a rate more than twice that in *E. coli*, five others tested were transported at a fraction of the rate in *E. coli*. In *A. beijerinckii*, RP4::Tn76 was successfully used to isolate Nif$^-$ mutants and auxotrophs requiring adenine or leucine (Owen and Ward, 1985). D. Dean and coworkers (personal communication) found that tryptophan auxotrophs could be isolated in *A. vinelandii* only if the strain harbored a wide-host-range plasmid carrying the tryptophan transport genes from *Escherichia coli*. Also consistent with the idea that amino acids are not easily transported into species of *Azotobacter* and *Azomonas* are the data of Thompson and Skerman (1979), who found that none of the 17 amino acids tested could serve as carbon sources in any of the species of these genera. Thus, limited capability of amino acid transport is probably a general characteristic of *Azotobacter* and *Azomonas*.

Mutations have now been introduced into many genes of *A. vinelandii* and *A. chroococcum*, resulting in gene replacement and the construction of mutant strains. A Nif$^-$ mutant of *A. paspali* was constructed by the conjugation and recombination of a kan^r cassette with the *nifHDK* operon, leading to gene replacement (Fallik et al., 1993). Some mutations are "lethal" in *A. vinelandii*, due to the essential nature of the genes under study. These genes include *glnA*, which encodes glutamine synthetase—the sole pathway for assimilation of ammonium (Kennedy and Toukdarian, 1987; Toukdarian et al., 1990); the *isc* and *fdxD* genes, which encode enzymes and a ferredoxin for Fe–S cluster formation (Zheng et al., 1998; Jung et al., 1999); and the *glnK* and *glnD* genes, which encode proteins that sense and signal the status of the nitrogen supply to glutamine synthetase to activate or inactivate the enzyme (Meletzus et al., 1998; Colnaghi et al., 2001). The ability of *A. vinelandii* to harbor high copy numbers of the chromosome is an advantage in that this feature allows identification of essential genes. Both wild-type and mutated copies marked by antibiotic resistance gene insertion can be maintained and identified by hybridization or PCR analysis; when selective pressure is removed by growth in medium without antibiotics, the chromosomes carrying the mutated essential genes are rapidly lost along with antibiotic resistance.

Bacteriophages Bacteriophages isolated from soil using *A. vinelandii* and *A. chroococcum* as indicator strains are capable of lysing cultures of *A. chroococcum*, *A. vinelandii*, and, to a lesser degree, *A. beijerinckii*; however, they do not affect *Azomonas* (Hegazi and Jensen, 1973). Four serologically distinguishable phages have been identified that can apparently lysogenize *A. vinelandii* strain O (ATCC 12518), resulting in a pseudolysogenic state in which the bacteria are converted to an unencapsulated form (Thompson et al., 1980). Bishop et al. (1977) described a general technique for isolating phage able to infect *A. vinelandii* from

soil samples.[6] No information on phages is available for *A. nigricans*, *A. armeniacus*, and *A. paspali*.

Antigenic structure The most recent and informative study is that of Tchan et al. (1983), which, by a method of immunoelectrophoresis, related cross-reacting antigenic determinants between and within the species of *Azotobacter* and of *Azomonas*. In these studies, species of *A. vinelandii* and *A. paspali* were found to be immunologically more homogeneous than strains of *A. chroococcum*—probably because of the wider geographical distribution of isolates of the latter. In addition, *A. vinelandii* and *A. paspali* were more similar to each other than to other *Azotobacter* species, but all were related. *Azomonas* species were related at about the same level to each other as to *Azotobacter* species.

Antibiotic sensitivity Table BXII.γ.124 summarizes the data from Thompson and Skerman (1979), from other researchers, and from one of the authors' laboratory. Of special note is that all isolates of *Azotobacter* are very sensitive to streptomycin and kanamycin/neomycin: the minimal inhibitory concentration (MIC) for streptomycin is <0.2 μg/ml, and for kanamycin/neomycin it is <1.0 μg/ml. This was also observed by Page and Shivprasad (1991a) for a more recently distinguished *Azotobacter* species, *A. salinestris*. These concentrations are important for constructing mutants that carry cassettes encoding genes for resistance to these antibiotics. Most strains are also relatively insensitive to chloramphenicol (MIC being 50 μg/ml or more), useful in counterselection of *E. coli* donor strains in conjugation experiments.

Ecology and plant growth stimulation *Azotobacter* species are generally found in soils of slightly acid to alkaline pH (reviewed in Becking, 1992). While the numbers are generally fairly low ($<10^4$ cells per g of soil), they are found throughout the world, typically in 30–80% of soils sampled, but rarely in polar regions. Because of their relatively high requirement for phosphorus, they are more commonly found in fertile soils than in sand. The numbers are generally not higher in rhizospheres than in open locations (Jensen, 1965). There are several reports of isolation of *Azotobacter* species from plant leaves and other surfaces. Most isolates are of *A. chroococcum*, which has also been isolated from freshwater canals and watercourses. *A. vinelandii* has been isolated far less frequently and may be more abundant in tropical regions; it has occasionally been isolated from freshwater (Thompson and Skerman, 1979). *A. beijerinckii* is found more often in acid soils than the other *Azotobacter* species, which reflects its laboratory tolerance to lower pH. *A. salinestris*, a Na-dependent species, has been isolated from slightly saline soils in western Canada, in Egypt, and in Australia (Page and Shivprasad, 1991a; Wang et al., 1993). The other species are rarely isolated, and may be restricted regionally. Little information is available for *A. nigricans* and *A. armeniacus*, and the distribution of these two species in their habitats remains unknown. Only *A. paspali* is known to have a constant association with the root system of a plant, *Paspalum notatum* cv Batatais (Döbereiner, 1966), where availability of organic substances and a more suitable pH is conditioned by the plant in its rhizosphere. The restriction of *A. paspali* to the rhizosphere of *Paspalum* may be related to its reduced ability to utilize many organic substances that can be utilized by other species of *Azotobacter* that are more widely distributed in soils. In addition, *A. paspali* is the only species antagonistic to Gram-positive bacteria, a property that may be advantageous for life in the rhizosphere (Thompson and Skerman, 1979).

The ability of *Azotobacter* species, mainly *A. chroococcum*, to enhance the growth of various crop plants was widely studied in Egypt and Russia in 1950–1970. Although beneficial effects were often observed, on the order of 10–20% better growth, the practice of inoculation of crops has been largely abandoned due to inconsistency of results. The benefits sometimes observed are likely due to the production of plant growth-stimulating substances by azotobacters, rather than to transfer of bacterially fixed nitrogen to the plants. *A. paspali* synthesizes and excretes indole acetic acid, three gibberellins, and two cytokinins (Barea and Brown, 1974). Stimulation of growth of inoculated plants (both tomato and *Paspalum notatum*) was observed by these authors, even though no acetylene reduction activity could be measured. *A. paspali* also enhanced growth of several crop seedlings, particularly in the root surface area (Abbass and Okon, 1993b) (Fig. BXII.γ.137). Although *A. paspali* initially colonized the roots in both sets of experiments, cell survival was low over time (Barea and Brown, 1974; Abbass and Okon, 1993b). Two strains of *A. chroococcum* that were able to stimulate growth of wheat seedlings produced indoleacetic acid and gibberellins (Pati et al., 1995). In another report, growth of *A. chroococcum* was enhanced in the presence of maize root exudates, which also stimulated the production of auxins, gibberellins, and cytokinins by this organism (Martinez-Toledo et al., 1988). These results should prompt a reexamination of whether numbers of *Azotobacter* might be higher in rhizospheres than in nonrhizosphere soils.

Enrichment and Isolation Procedures

The enrichment techniques are based on the ability of *Azotobacter* to grow by fixing nitrogen aerobically or microaerobically and to use organic substrates as an energy source. Soil, macerated roots or leaves, or other samples are suspended in water; then aliquots of diluted suspension are incubated in liquid or semisoft N-free agar or on the surface of N-free agar plates using Winogradsky's or Burk's medium with 1% glucose or sucrose. All species except *A. salinestris* will grow diazotrophically on agar plates incubated in air, a feature useful for their enrichment and isolation because of the particularly high tolerance to oxygen during diazotrophic growth.

A specific enrichment method for *Azotobacter* species is that of Döbereiner (1995). Plates containing LG growth medium (Burk's medium with 2 ml/l bromothymol blue [0.5% solution in ethanol]) are inoculated with about 100 mg of finely sieved soil suspended in 1 ml of sterile water, or with appropriate dilutions of soil. Colonies of *A. chroococcum* appear after 24 h of incubation at 30°C as moist white colonies that become dark brown after 3–5 d. *A. vinelandii* colonies are similar but do not turn dark brown. *A. paspali* colonies appear only after 48 h; they become yellowish in the center due to assimilation of bromothymol blue and acidification of the medium.

6. Sites selected for enrichment were high in decomposed organic material. Inoculum was prepared by growing a 15-liter culture of *A. vinelandii* to about 5×10^8 cells/ml in Burk's medium. After inoculation, each site was irrigated with 1 liter 2% sucrose every other day. Soil sample extracts for phage assay were prepared by suspending 5.0 g soil in 15 ml phosphate buffer. Soil particles were removed by centrifugation. Extracts were filter-sterilized (45 μm pore size), then 1 ml of the sterile extract was added to 19 ml of a culture of *A. vinelandii* ($\sim2.5 \times 10^7$ cells/ml). After incubation overnight with vigorous shaking, filter-sterilized samples (0.1 ml) of cultures were tested for the presence of phage by a soft agar overlay method. Four ml of molten 0.5% agar were mixed with 0.1 ml freshly grown *A. vinelandii* cells ($\sim10^8$) and with aliquots of extracts and dilutions. The mixture was poured onto a fresh plate of Burk's agar medium and incubated for 24–48 h at 30°C and observed for the presence of phage plaques.

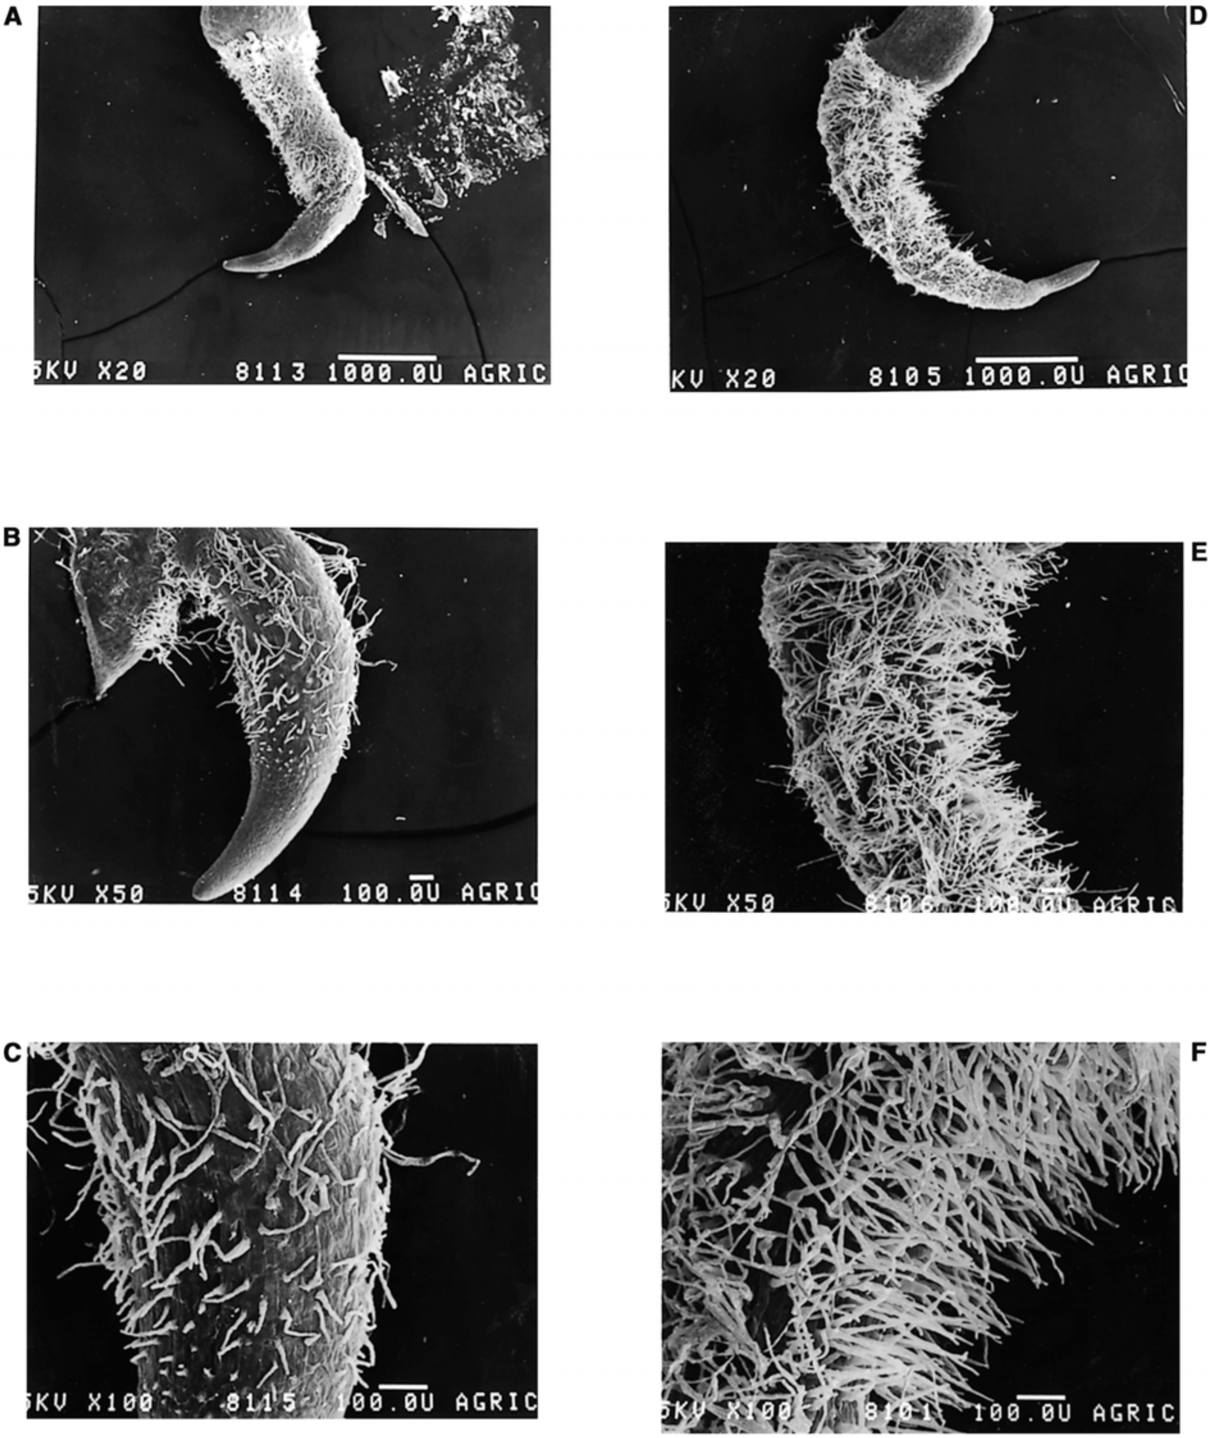

FIGURE BXII.γ.137. Scanning electron microphotographs of the inoculation effects with *A. paspali* (5×10^8 CFU/ml) 48 h after inoculation on the morphology of root hair development of canola seedlings. *Right column*, inoculated seedling; *left column*, uninoculated seedlings.

Thompson and Skerman (1979) described selective enrichment for various *Azotobacter* species based upon the addition to Winogradsky's medium of substances selectively stimulatory or inhibitory to species of *Azotobacter*. *A. vinelandii* can be selectively enriched by using L-rhamnose, ethylene glycol, erythritol, or D-arabitol as the carbon source. Alternatively, 1.0% sodium benzoate or 0.1% phenol can be used to inhibit the growth of other *Azotobacter* species. Incubation at 37°C favors the development of *A. vinelandii*. *A. beijerinckii* can be selectively enriched using L-tartrate, *o*-hydroxybenzoate, D-glucuronate, or D-galacturonate. A pH of 6 or slightly less favors the growth of this species. *A. chroococcum* is the most common species and needs no special enrichment for its isolation. *A. armeniacus* can be enriched with caprylate but *A. vinelandii* will also grow in this medium; however, further isolation can differentiate these two species. *A. paspali* can be isolated from the rhizosphere of *Paspalum notatum*. There

is no selective medium for this species but an incubation temperature of 35–37°C will favor its growth. There is no specific method to isolate *A. nigricans*.

For isolation of *Azotobacter* strains, liquid enrichment cultures are inspected daily. When macroscopic growth becomes apparent, the culture is examined with phase-contrast microscopy to detect the presence of *Azotobacter* cells, which are recognizable by their general morphology. Growth is usually obtained within 2–5 d. Positive cultures are streaked onto nitrogen-free agar medium with glucose or sucrose as the carbon source. For selective isolation, nitrogen-free agar media with appropriate selective substances should also be used. Sometimes nitrogen-free iron-deficient agar media can be used to encourage pigment production by some species. For soils containing sufficiently high numbers of *Azotobacter*, the different species can be isolated directly on agar plates: 0.1–0.5 g dry soil or an appropriate dilution is spread on the surface of nitrogen-free agar medium as described above.

Maintenance Procedures

For routine maintenance, *Azotobacter* should be subcultured at monthly or bimonthly intervals on Winogradsky's or Burk's agar medium with sucrose, except that glucose should be substituted for sucrose in the case of *A. armeniacus* and certain other strains which prefer glucose.

Thompson (1989) preserved many strains by suspending the cells from agar-grown cultures (10^9–10^{10} cells/ml) in 0.5 ml of 10% (v/v) glycerol. The suspensions were placed in glass ampules, rapidly frozen, and stored in liquid nitrogen. On revival, ampules were rapidly warmed by agitation in a water bath at 33°C until thawing occurred. All cultures remained viable for up to 7.5 years, grew with short lag phases, and suffered no apparent phenotypic changes. The following method of preservation has been used in the Kennedy lab: high density cell suspensions of *A. vinelandii* in glycerol (10–50%) have been stored in cryogenic microfuge tubes at −20°C or −80°C, with successful revival after four or more years.

Dimethyl sulfoxide (DMSO) has been used in the laboratory of Dr. Dennis Dean, Virginia Polytechnic Institute and State University, with great success for preservation of *A. vinelandii* wild-type and mutant derivatives of strain AvOP (personal communication). One-ml portions of freshly prepared 7% DMSO in 0.1 M sterile phosphate buffer (pH 7) are transferred to a sterile cryotube and a few loopfuls of fresh cells grown on Burk's medium are suspended in the DMSO solution. The suspension is vortexed to ensure a homogenous suspension without aggregates, then frozen at −80°C. The application of this method to other *Azotobacter* species has not been tested.

A paraffin oil preservation method has been used by Tchan and New (1984). Ten milliliters of a suitable nitrogen-free agar medium is poured into a 28 ml capacity McCartney bottle and allowed to solidify to form a slope approximately 3 cm in length with a base 2 cm in height. The culture is inoculated in the middle of the surface of the slope with a single stroke. When the growth reaches about 1 mm in thickness, the culture is checked for purity. Then 5–7 ml of sterile paraffin (mineral) oil is poured into the bottle to completely cover the slope. (It is important that no agar medium should be in direct contact with air, otherwise the culture can dry out and some cultures may die.) Usually *Azotobacter* survives for many months (even years) by this method. This method is particularly advantageous for frequently used stock cultures.

For preservation by lyophilization, dense culture suspensions in 10% sucrose solution (Bascombe and Jackson, 1965) can be freeze-dried and stored at 5°C. This method may not be suitable for all species.

Procedures for Testing Special Characters

Identification of alternative nitrogenase genes Although the characterization of species with respect to their ability to grow on Mo-deficient medium, with or without the addition of V, is incomplete in terms of the spectrum of isolates examined, the results of Fallik et al. (1991) and Loveless and Bishop (1999) suggest that (1) *A. chroococcum*, *A. beijerinckii*, *A. nigricans*, and *A. salinestris* carry the *nif* and *vnf* genes; (2) *A. vinelandii*, *A. paspali*, and *Azomonas agilis* have genes for all three nitrogenases, *nif*, *vnf*, and *anf*; and (3) *Azomonas macrocytogenes* has the *nif* and *anf* genes only. In addition, Loveless et al. (1999) described seven new isolates from aquatic samples or wood-chip mulch in North Carolina by their ability to grow on Mo-deficient medium. These organisms, by 16S rDNA analysis, are taxonomically within the *Gammaproteobacteria*, and most related to the fluorescent pseudomonads. All had genes encoding the Mo nitrogenase (nitrogenase-1) and the V nitrogenase (nitrogenase-2). Four of the isolates also encoded the Fe-only nitrogenase (nitrogenase-3) These isolates may represent a new taxon of diazotrophs. The procedures for identification of these genes by hybridization and/or PCR analysis are therefore important in characterizing isolates in terms of the ability to synthesize the alternative nitrogenases that contain V (nitrogenase-2) or Fe only (nitrogenase-3), in addition to the classical Mo nitrogenase (nitrogenase-1) found in all other diazotrophs characterized. The methods for determining the presence of alternative nitrogenases are as follows:

1. Method of Loveless et al. (1999): blots of genomic DNA isolated from test strains restricted with enzymes such as *Eco*RI are hybridized to specific gene probes isolated from *A. vinelandii* and radiolabeled. The probes are *nifD* (from pTMR18; Bishop et al., 1985), *vnfD* (from pVDSJ1; Jacobitz and Bishop, 1992), and *anfD* (from pPJD3A2; Premakumar et al., 1992).
2. Method of Fallik et al. (1991): hybridization of Southern blots of restriction enzyme-digested DNA from test strains to radiolabeled gene probes. The probes consist of *A. chroococcum nifDK* (from pER4; Jones et al., 1984), *vnfDGK* (from pSEQ10; Robson et al., 1989), and *A. vinelandii anfDGK* (from pJWD3; Joerger et al., 1989).
3. Method of Loveless and Bishop (1999): PCR analysis for the presence of the genes *vnfG* or *anfG*, which indicate the presence of nitrogenase-2 and nitrogenase-3, respectively. *vnfG* is located between the *vnfD* and *vnfK* genes, and *anfG* between the *anfD* and *anfK* genes (see Fig. BXII.γ.138). The PCR primers flanking the *vnfG* and *anfG* genes—which anneal to conserved sequences within *vnfD* and *vnfK* or within *anfD* and *anfK*—will amplify the *vnfG* or *anfG* genes if they are present. The PCR products of these reactions can be analyzed by determination of their size on agarose gels and subsequent sequence determination. Sequences of specific primers used for identification of *anfG* and *vnfG* in the *Proteobacteria* and the expected product sizes obtained after PCR amplification are shown in Table BXII.γ.126.

Diazotrophic growth in the absence of molybdenum This procedure is carried out to help reveal the presence of alternative nitrogenase-2 (with the addition of V) or of alternative nitro-

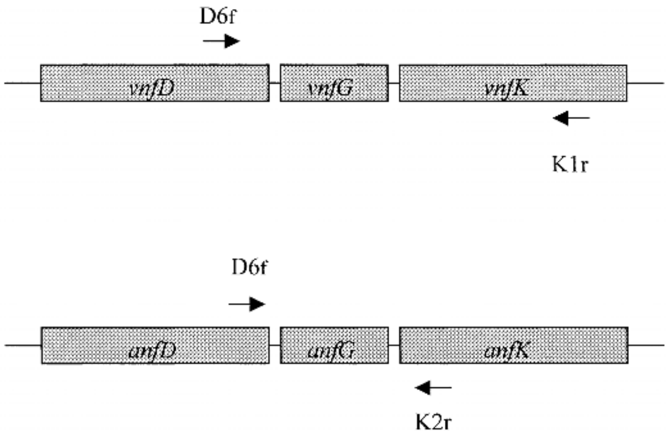

FIGURE BXII.γ.138. PCR primer annealing sites for the amplification of *vnf*G or *anf*G which can be used for the identification of alternative nitrogenases. (Reproduced with permission from T.M. Loveless and P.E. Bishop, Canadian Journal of Microbiology *45:* 312–317, 1999, ©National Research Council of Canada.)

genase-3, traits characteristic of species of *Azotobacter* and *Azomonas*. The preparation of media to test the growth of diazotrophs in the absence of Mo is critical because Mo can contaminate many sources of chemicals used to prepare media and the water supply. Alternative nitrogenase synthesis can be inhibited by as little as 20 nM Mo. Two methods are described here that have been successfully used to extract Mo from laboratory-prepared media. The first, modified from Eady and Robson (1984), uses 8-hydroxyquinoline (a chelator of Mo) and dichloromethane to remove 8-hydroxyquinoline from the medium. Chemicals for Burk's medium are dissolved in double-glass-distilled water, phosphates and other chemicals prepared separately as two different 20× stock solutions (20 fold more concentrated than in the final medium). The 20× solution of chemicals (but not the 20× phosphate buffer) is adjusted to pH 3.5 with 5M HCl. 8-Hydroxyquinoline (0.2 g/l) and dichloromethane (25 ml/l) are added to both 20× stock solutions. The stock solutions are stirred using a Teflon-coated magnetic bar for 2 h. The dichloromethane is allowed to settle and then siphoned off. This extraction procedure is repeated six times. The pH is then adjusted to 7.1 with pellets of NaOH, and the excess 8-hydroxyquinoline removed by repeated extractions with dichloromethane until the medium is colorless. An alternative is to use 1,2-dichloroethane instead of dichloromethane for extraction (Luque et al., 1993).

The second method employs activated charcoal to extract molybdenum from concentrated stock solutions (Schneider et al., 1991). In this method, 50 g of pulverized activated charcoal (Merck) is suspended in 1 liter of doubly distilled water and stirred for 2 d at room temperature. This suspension is degassed by boiling for 10 min then cooled to room temperature, and 50-ml aliquots are placed on a 5 cm round filter paper disc (e.g., Whatman #1). The water is suctioned through the filter, resulting in a 5-mm layer of activated carbon. After washing the filter with 100 ml doubly distilled water, the stock solutions (50 ml) are suctioned through the filter. The method is more efficient if concentrated single-nutrient-component solutions, adjusted to pH 2–4, are filtered through the activated charcoal then mixed together by dilution into doubly distilled water, followed by pH adjustment.

Regardless of the method used to extract Mo from media, it is essential to use either commercially supplied plasticware, which is usually free of contaminating Mo, or glassware that has been soaked for 24 h or more in a solution of 5% Decon (or similar commercial product) and 0.5% EDTA in pure water (as purified through a MonoQ column, Millipore) for 24 h, followed by rinsing in pure water. Additions of Mo or V compounds are made as necessary, usually $Na_2MoO_4 \cdot 2H_2O$ or V_2O_5 at 1 μM.

Cell morphology Cultures grown for 24–48 h on both agar and liquid media should be used for the study of general morphology by phase contrast microscopy. Motility may be observed in wet mounts, but it is advisable to incorporate some air bubbles in the mount to insure an adequate supply of oxygen. Motile cells are usually found near the edge of an air bubble.

Cysts These resting forms are best studied with cultures at least 2 weeks old that have been grown on nitrogen-free medium containing 0.2% butanol. If the culture will not grow on butanol (e.g., *A. paspali*), nitrogen-free medium with 0.2% glucose can be used. The cysts may be stained with violamine[7] (Winogradsky, 1938), acridine orange[8] (Tchan, unpublished data), or with a mixture of neutral red and light green SF yellowish (Vela and Wyss, 1964). Examination by phase-contrast microscopy is sometimes helpful when violamine stain is used.

Pigment production The production of diffusible pigments in the presence or absence of benzoate is not constant on iron-

7. Violamine stain consists of violamine "2 R", 1.0 g; phenol, 5.0 g; and water, 100 ml. An air-dried, fixed smear is treated with violamine stain for 45 sec, washed, and counterstained with dilute crystal violet (0.05% or less) for 1 min. After rinsing with water, the preparation is mounted in water for microscopic examination.

8. Acridine orange stain: Cells are suspended in a 0.01% aqueous solution of acridine orange. One drop is deposited on a slide, covered with 2 drops of mineral oil. Drops are then spread and a cover glass applied. A monolayer of cell suspension can be found in the preparation where the depth of liquid is such that motile cells are immobilized to facilitate microscopic examination. When examined by fluorescence microscopy, the vegetative cells are green and the cysts have a green central body and a red coat.

TABLE BXII.γ.126. PCR primer sequences for identification of *vnfG* and *anfG*, which indicate the presence of genes for nitrogenase-2 or nitrogenase-3[a]

Primer	Anneals to	Sequence[b]	Expected size of PCR product[c]
D6f	*vnfD*	5′-CGGGATCCGAAGACTTYGARAAGGTCAT-3′	1700 bp (*vnfG*)
K1r	*vnfK*	5′-GGGGGTACCACTTCYAWGCAGAACT-3′	
D7f	*anfD*	5′-GCTCTAGACGCSATCTAYTCGCCGA-3′	750 bp (*anfG*)
K2R	*anfK*	5′-CGGAATTCCGATGCAATCCTTGAT-3′	

[a]From Loveless and Bishop (1999).

[b]Single letter code: I, inosine; Y, C or T; R, A or G; S, C or G; W, A or T.

[c]Use of primers D6f and K1r with test strain DNA should amplify a fragment carrying *vnfG*; primers D7f and K2R should amplify a fragment carrying *anfG* (see Fig. BXII.γ.139). For PCR amplification conditions, see Loveless and Bishop (1999).

containing media, and is unreliable for strain differentiation. Diffusible pigments are readily produced on the following iron-deficient media (Thompson and Skerman, 1979). Any one of the three basal agar media[9] is modified by omission of $FeSO_4 \cdot 7H_2O$ and reduction of $Na_2MoO_4 \cdot 2H_2O$ to 1 µg/ml. Glucose is added to give a concentration of 10 g/l. The medium is inoculated by depositing a small drop of a suspension of culture on the surface of the agar. The plates are examined in daylight for diffusible pigment and under ultraviolet light (wavelength 364 nm) for fluorescent pigments. The medium of Stainer and Scholte (1970) can also be used for the production of nondiffusible pigments or, for those strains that will not grow on this medium, the basal medium of Thompson and Skerman can be used when enriched with sodium gluconate (2.0 g/l).

Differentiation of the genus *Azotobacter* from other genera

Phenotypic characteristics can differentiate the genus *Azotobacter* from others. Genera most closely related taxonomically, i.e., found in the *Gammaproteobacteria* class, order *Pseudomonadales*, family *Pseudomonadaceae*, are *Azomonas* and several others for which no nitrogen-fixing species/strain has been identified, except for certain isolates of *Pseudomonas stutzeri*. Like *Azotobacter*, *Azomonas* species can fix nitrogen under aerobic conditions while *P. stutzeri* cannot. *Azotobacter* species can utilize urea as nitrogen source and form cysts in older cultures or after growth in butanol (or propanol) while *Azomonas* species cannot, although general cultural and morphological characteristics are similar. In addition, among genera able to grow aerobically on dinitrogen, which includes not only *Azotobacter* and *Azomonas*, but also *Beijerinckia* and *Derxia*, members of the *Alphaproteobacteria* class, the latter two genera are morphologically and physiologically different from *Azotobacter*. Distinguishing characteristics are summarized in Table BXII.γ.127.

Taxonomic Comments

One new species, *A. salinestris*, has been added to the genus since the last edition of the *Manual*. Several isolates of this species were previously classified as strains of *A. chroococcum*, and then distinguished on the basis of Na-dependent growth under most conditions and decreased aerotolerance during diazotrophic growth (Page and Shivprasad, 1991a).

In this edition of the *Manual*, *Azotobacter* and *Azomonas* are classified in the phylum *Proteobacteria*, class *Gammaproteobacteria*, order *Pseudomonadales*, and family *Pseudomonadaceae*. In the previous edition of the *Manual*, these two genera comprised the family *Azotobacteraceae* (Tchan, 1984). 16S rDNA sequencing of species of the two genera indicated that the family was distinct from, but closely related to, the fluorescent pseudomonads in *Pseudomonas* Superfamily I within the gamma group of *Proteobacteria* (MacDonald and Melton, unpublished studies). By the least squares distance matrix method, *Azotobacter* strains formed an assemblage into one group with a close association to *Azomonas macrocytogenes*, and clusters of pseudomonads in another group; both groups were stemmed to *E. coli* with an evolutionary distance of 0.01 or less (Fig. BXII.γ.139). The maximum parsimony tree exhibited a limited outcropping of organisms (Fig. BXII.γ.140). This can be interpreted as a hierarchy of phylogeny, which begins with the stem organism *E. coli*, progressively branches off the pseudomonads and *Azomonas macrocytogenes*, then clusters the *Azotobacter* species. The parsimony tree had a higher average bootstrap confidence level than the least squares distance tree, 89.5% vs. 75.8%, respectively (MacDonald and Melton, manuscript submitted).

Phylogenetic analysis using other genes or features have placed *A. vinelandii* and *Azomonas macrocytogenes* in the *Pseudomonas* group I lineage with *P. aeruginosa*. These studies included a comparison of four *P. aeruginosa* alginate (*alg*) genes to those from species of the *Pseudomonas* group I, group V, and enteric lineages (Fialho et al., 1990). The comparison indicated the greatest homology with the species of *Pseudomonas* group I, which included *A. vinelandii* but not *P. stutzeri*—which did not have an *algD* gene—or *Azomonas macrocytogenes*—which also did not show homology at this locus. A comparison of aromatic amino acid biosynthetic pathways also indicated the same evolutionary relationship between the group I pseudomonads and the species of *Azotobacteraceae* (Byng et al., 1986); this was consistent with groupings previously defined by rRNA–DNA hybridization studies. As with the rDNA analysis (De Smedt et al., 1980), immunoelectrophoresis—performed with antisera prepared to each of several strains and tested against one another (Tchan et al., 1983)—indicated that the six *Azotobacter* species were more similar to each other than to any *Azomonas* species and that the three *Azomonas* species were as distant from each other as each is from *Azotobacter* (Tchan et al., 1983).

A proposed reclassification of *Azotobacter paspali* to a new genus, *Azorhizophilus* (Thompson and Skerman, 1979), is not justified because this species clearly belongs to the *Azotobacter* genus based on 16S rDNA relatedness (Figs. BXII.γ.139 and BXII.γ.140). Moreover, as in *A. vinelandii*, *A. paspali* carries genes for the synthesis of all three types of nitrogenase. Another genus, *Azomonotrichon*, was suggested for the single species *A. macrocytogenes*, which was originally classified as an *Azomonas* species based on numerical analysis of common features (Thompson and Skerman, 1979). Reclassification as *"Azomonotrichon macrocytogenes"* is not supported by 16S rRNA gene sequence analysis, im-

9. Basal agar media (as cited in Thompson and Skerman, 1979): The medium of Norris and Jensen (1958) consists of (g/l): K_2HPO_4, 1.0; $CaCl_2 \cdot 2H_2O$, 0.1; $MgSO_4 \cdot 7H_2O$, 0.2; $FeSO_4 \cdot 7H_2O$, 0.05; $Na_2MoO_4 \cdot 2H_2O$, 0.005; and Ionagar (Oxoid), 10.0; pH 7.3. An acidic modification of this medium consists of (g/l): K_2HPO_4, 0.3; KH_2PO_4, 0.7; $MgSO_4 \cdot 7H_2O$, 0.2; $FeSO_4 \cdot 7H_2O$, 0.05; $Na_2MoO_4 \cdot 2H_2O$, 0.005; and Ionagar (Oxoid), 10.0; pH 6.2. An enriched modification of the medium consists of Norris and Jensen's medium containing 0.5% yeast extract (Difco).

TABLE BXII.γ.127. Differential characteristics of the genus *Azotobacter* and other aerobic diazotrophic genera[a]

Characteristic	*Azotobacter*	*Azomonas*	*Beijerinckia*	*Derxia*
Dumbbell-shaped cells with polar granules	−	−	+	−
Monotrichous flagellum	−	D	−	+
Cyst formation	+	−	−	−
Autotrophic growth on N_2	−	−	−	+
Mol% G + C of DNA	63.2–67.5	52–58.6	55–61	69–73

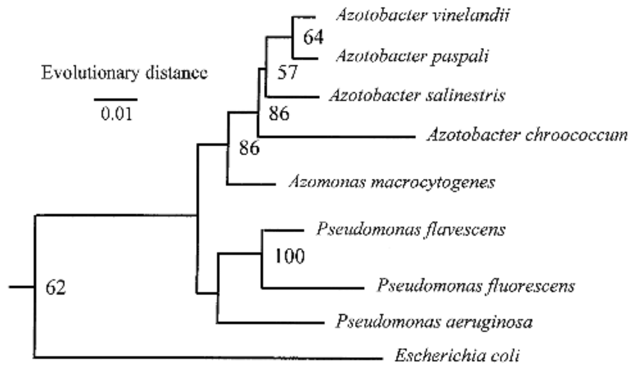

FIGURE BXII.γ.139. Least squares distance matrix tree showing phylogenetic relationships of *Azotobacter* and *Azomonas*. The tree is representative of the best fit of 100 data sets by the least squares distance algorithm and 100 bootstrapped pseudosamples. The evolutionary distance is 0.01. Bootstrap confidence values of 50% or greater are represented at each node of the tree (Courtesy of M.L. MacDonald and T.T. Melton, unpublished studies).

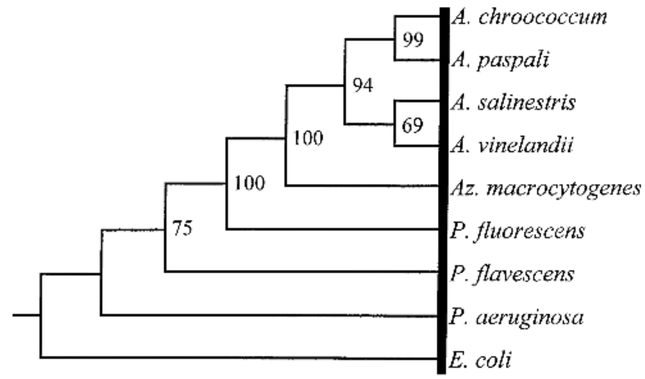

FIGURE BXII.γ.140. Maximum parsimony tree showing phylogenetic relationships of *Azotobacter* and *Azomonas*. The tree is representative of the best fit of 100 data sets by the maximum parsimony algorithm and 100 bootstrapped pseudosamples. Tree branch length is not significant for this algorithm. Bootstrap confidence values of 50% or greater are represented at each node of the tree (Courtesy of M.L. MacDonald and T.T. Melton, unpublished studies).

munological analysis (Tchan et al., 1983), and comparison of protein profiles (Jana et al., 1992). Previous inclusion of the nitrogen-fixing genera *Beijerinckia* and *Derxia* in the family *Azotobacteraceae* is now fully discounted by 16S rRNA gene sequence analysis. In this edition of the *Manual*, *Beijerinckia* is included in the class *Alphaproteobacteria*, and *Derxia* is placed in the class *Betaproteobacteria*, but distant from *Azotobacter* or *Azomonas* species.

Most species of *Azotobacter* and *Azomonas* were not extensively studied after 1979 with the exception of *A. vinelandii** and *A. chroococcum*, as reviewed in this chapter. A detailed history of the species, together with cultural, morphological, and physiological characteristics of approximately 90 isolates, can be found in Thompson and Skerman (1979) and references therein. See also Becking (1992) for further descriptive information.

**Editorial Note:* During 2002 and 2003, a rough draft of the sequence of the genome of *A. vinelandii* became available through the U.S. Department of Energy Joint Genome Institute. Automated annotation of this genome has been carried out at Oak Ridge National Laboratories by Frank Larrimer and associates and at The Institute for Genome Research. A fully annotated finished genome may be available in 2004.

Acknowledgments

We thank Adam Field and Angela Smedke for assistance in compiling DNA sequences for analyzing codon usage and mol% G + C content. We also thank Mali Gunatilaka for help at many stages of preparation of the manuscript. Finally, we would like to dedicate this chapter to Thoyd Melton who passed away before its publication. His contributions to the studies of the genetics and physiology of *Azotobacter vinelandii* were significant. He was a devoted scientist who was ardent about research, teaching, and his fellow colleagues.

Further Reading

Becking, J.H. 1992. The family *Azotobacteraceae*. *In* Balows, Trüper, Dworkin, Harder and Schleifer (Editors), The Prokaryotes, 2nd ed., Vol. 3, Springer-Verlag, New York. 3144–3170.

Differentiation of the species of the genus *Azotobacter*

The differential characteristics of the species of *Azotobacter* are presented in Table BXII.γ.123. Other characteristics of the species are indicated in Table BXII.γ.124.

List of species of the genus Azotobacter

1. **Azotobacter chroococcum** Beijerinck 1901, 567[AL]

chro.o.coc′ cum. Gr. n. *chroa* color; Gr. n. *coccus* a grain; M.L. neut. n. *chroococcum* colored coccus.

The morphology is shown in Figs. BXII.γ.128 and BXII.γ.129. Cells appear as blunt rods to ellipsoid forms, 1.6–2.5 μm in diameter and 3–5 μm in length. Chains of cells are occasionally observed in some strains. Cysts (sometimes referred to as "microcysts") are formed in old cultures or after addition of isopropanol to exponential cultures. Cells have randomly placed granules, described as metachromatic or sudanophilic (Thompson and Skerman, 1979). Motile cells from 1- to 2-d-old cultures have peritrichous flagella with a wavelength of 2.5–3.3 μm and an amplitude of 0.37–0.76 μm. Colonies are opaque and convex, and, for most strains, are mucoid, glistening, and smooth. A brown-black nondiffusible pigment is produced in aging colonies. Many organic compounds can be used as carbon sources. Distinguishing physiological and nutritional characteristics of the species are presented in Tables BXII.γ.123 and BXII.γ.124. N_2, ammonium, nitrate, and urea are used as nitrogen sources. N_2 is fixed under aerobic or microaerobic conditions. Ammonium prevents N_2 fixation by inhibition of expression of *nif* genes and possibly by inactivation of Mo nitrogenase (nitrogenase-1). In three strains tested, one "alternative" nitrogenase is synthesized when Mo supply is very low (nitrogenase-2, carrying the Fe-V cofactor). This correlates with the presence of *vnf* but not *anf* genes in these strains. For other characteristics, less distinguishing, see Thompson and Skerman (1979). The genome size varies between 3.1 and 5.3 Mb. There are 6 or 7 copies of the *rrn* operon.

The mol% G + C of the DNA is: 65.8–67.5 (T_m).
Type strain: R. L. Starkey's strain 43, ATCC 9043, DSM 2286, WR-88.

2. **Azotobacter armeniacus** Thompson and Skerman 1981, 215[AL] (Effective publication: Thompson and Skerman 1979, 272 (*Azotobacter agilis* subsp. *armeniae* Kirakosyan and Melkonyan 1964, 41; *Azotobacter vitreus* subsp. *armeniae* Kirakosyan and Melkonyan 1964, 41.)
ar.me.ni.a' cus. M.L. neut. n. *armeniacus* named after Armenia, U.S.S.R., where the species was isolated.

The morphology is as described for the genus and most other species. Cells are motile with peritrichous flagella having a wavelength of 2.0–2.9 μm and an amplitude of 0.40–0.59 μm. Colonies are opaque, mucoid, and more highly convex than those of other species. Brown-black to red-violet water-soluble pigments are produced. No strain has been tested for the presence of alternative nitrogenases. Distinctive features include inability to utilize nitrate or ammonium for growth, but strains are urease positive. Physiological and nutritional characteristics of the species are presented in Tables BXII.γ.123 and BXII.γ.124.
The mol% G + C of the DNA is: 63.5–65.0 (T_m).
Type strain: N28, DSM 2284, WR-136.

3. **Azotobacter beijerinckii** Lipman 1904, 248[AL]
bei.jer.inck' i.i. M.L. gen. n. *beijerinckii* of Beijerinck; named after M.W. Beijerinck of Delft, the Dutch microbiologist.

The morphology of cells is similar to that of *A. chroococcum* and can vary depending on culture conditions. The cells are nonmotile and lack flagella. Colonies are smooth, but variants may arise due to the quantity of extracellular polysaccharide produced. Growth at 37°C is poor or does not occur. A yellowish or cinnamon-colored pigment is produced in aging cultures. Many isolates are acid tolerant. Physiological and nutritional characteristics of the species are presented in Tables BXII.γ.123 and BXII.γ.124. Ammonium and nitrate are used as nitrogen sources. Type strain ATCC 193600 carries both *nif* and *vnf* genes but not *anf*, indicating that *A. beijerinckii* can synthesize nitrogenase-1 and nitrogenase-2.
The mol% G + C of the DNA is: 66.0–66.2 (T_m).
Type strain: ATCC 19360, DSM 378, NCIB 8948, WR-135.
Two subgroups of *A. beijerinckii* have been delineated. The acid-tolerant subgroup corresponds to "*A. beijerinckii* subsp. *acidotolerans*" Tchan. The other subgroup is distinguished by its sensitivity to 0.05% phenol or 40 μg/ml of diamond fuchsin, its inability to use sorbitol or aconitate, and its failure to produce diffusible homopolysaccharides.

4. **Azotobacter nigricans** Krasil' nikov 1949, 506[AL]
ni' gri.cans. L. adj. *nigricans* black.

The cells (Fig. BXII.γ.130) are round-ended rods, as are typical of other species of *Azotobacter*. The cells are nonmotile and lack flagella. Colonies are smooth, but variants occur due to the quantity of extracellular polysaccharide produced. Most colonies are opaque but can be translucent. Pigments are produced and are usually red-violet. Growth at 37°C is poor or does not occur. Strains have been isolated from soils in Eastern Europe. Physiological and nutritional characteristics are presented in Tables BXII.γ.123 and BXII.γ.124. Ammonium and nitrate are used as nitrogen source in preference to nitrogen. The type strain carries *nif* and *vnf* but not *anf* genes, indicating an ability to synthesize nitrogenase-1 and nitrogenase-2.
The mol% G + C of the DNA is: 64.5 (T_m).
Type strain: ATCC 35009, DSM 2288, UQM 1967.

a. **Azotobacter nigricans** *subsp.* **nigricans** Krasil' nikov 1949, 506[AL]

In aging colonies, a brown-black water-soluble pigment is usually produced.
The mol% G + C of the DNA is: 64.5 (T_m).
Type strain: ATCC 35009, DSM 2288, UQM 1967.

b. **Azotobacter nigricans** *subsp.* **achromogenes** Thompson and Skerman 1981, 215[VP] (Effective publication: Thompson and Skerman 1979, 12.)
a.chro.mo' ge.nes. Gr. pref. *a* not; Gr. n. *chroma* color; Gr. suff. *-genes* born of; N.L. neut. adj. *chromogenes* not producing color.

Aging colonies produces only a yellow nondiffusible pigment within the colony.
The mol% G + C of the DNA is: 64.5 (T_m).
Type strain: A-2 of Jensen (WR-41).

5. **Azotobacter paspali** Döbereiner 1966, 364[AL] (*Azorhizophilus paspali* (Döbereiner 1966) Thompson and Skerman 1981, 215.)
pas.pal' i. M.L. gen. n. *paspali* of Paspalum; named after *Paspalum*, the generic name of a grass.

The general morphology is similar to that of other *Azotobacter* species, but the cells are longer than usual, 5–10 μm in the exponential phase. Long filamentous cells up to 60 μm can occur (Fig. BXII.γ.131). Cells are motile by numerous peritrichous flagella having a wavelength of 2.3–2.8 μm and an amplitude of 0.40–0.59 μm (Fig. BXII.γ.133). Some strains have "curly" flagella with a wavelength of 1.1–1.4 μm and an amplitude of 0.25–0.34 μm. Colonies are opaque with an entire or undulate edge, raised, usually not evenly convex, and butyrous with a dull or rough surface. Physiological and nutritional characteristics are presented in Tables BXII.γ.123 and BXII.γ.124. Ammonium but not glutamate can be used as the sole nitrogen source for growth. Thompson and Skerman (1979) reported the ability of *A. paspali* isolates to utilize nitrate as nitrogen source but failed to detect nitrite production from nitrate or nitrite disappearance in standard tests. This conclusion should be reexamined because nitrate assimilation is not known to occur other than by nitrate reduction to nitrite and nitrite reduction to ammonium. Urea is hydrolyzed. Genes for both alternative nitrogenases (nitrogenase-2 *vnf* and nitrogenase-3 *anf*) were detected in two strains (the type strain ATCC 23833 and also ATCC 23367). Distinctive features include (1) production of a yellow-green fluorescent pigment (as for *A. vinelandii*); (2) utilization of fewer compounds as carbon sources than other *Azotobacter* species. The carbon sources used include maltose, trehalose, melibiose, raffinose, mannitol, and others (Thompson and Skerman, 1979). The organism has never been isolated from environments other than the rhizosphere of the grass *Paspalum notatum* cv. Batatais. Genome size is uniform, 4.3–4.6 Mb in four strains tested, as is number of copies (six) of the *rrn* operon.
The mol% G + C of the DNA is: 63.2–64.6 (T_m).
Type strain: Ax-8, ATCC 23833, DSM 2283, WR-129.

6. **Azotobacter salinestris** Page and Shivprasad 1991b, 374[VP]
sal.in.es′ tris. N.L. adj. *salinus* saline; L. suff. *-estris* belonging to, living in; N.L. adj. *salinestris* living in saline environments.

The morphology is described as coccobacilli (oval with pointed ends); cells are approximately 2 × 3–4 µm in young or exponential cultures Older cells are round with a diameter of 3–5 µm, pleomorphic, and are often found in pairs and chains of six-to-eight cells. Cysts are formed. Cells are motile by means of peritrichous flagella 9–10 µm long, with a wavelength of 2.7–2.9 µm and an amplitude of 0.36–0.55 µm. Cells from old cultures are nonmotile. Physiological characteristics include growth at temperatures between 30° and 36°C. The optimal temperature for N_2 fixation is 35°C. Cells and colonies grow at pH 6.2–8.0. The optimal pH for growth on N_2 is 7.2; on nitrate it is pH 7.3, and on ammonium it is pH 7.5. N_2 fixation occurs best in microaerophilic cultures, but cells can be adapted to aerobic diazotrophy. Most strains, except the type strain, produce a capsule and synthesize poly-β-hydroxybutyrate. The type strain, ATCC 49674, and strain 253 contain *nif* and *vnf* genes and can fix nitrogen in the absence of Mo with V. Growth under most conditions requires the presence of 1 mM Na^+. Strains are urease positive, amylase positive, and catalase positive (with Na^+). No fluorescent compounds are synthesized, even when cultures are Fe limited. Carbon sources include fructose, galactose, glucose, sucrose, mannitol, melibiose, 0.25% sodium benzoate, and starch. Nitrogen sources are N_2, ammonium, and nitrate. A brown-black to tan-brown pigment, allomelanin (a catechol melanin), is produced by most strains when grown at high aeration under N-fixing conditions. Growth is inhibited by K^+ and Rb^+, with Rb^+ having the greatest effect. For other characteristics, see Tables BXII.γ.123 and BXII.γ.124.[10]

The mol% G + C of the DNA is: 65.19–65.98 (T_m).

Type strain: 184, ATCC 49674, DSM 11553.

GenBank accession number (16S rRNA): AF035213.

10. Not all traits tested by Thompson and Skerman (1979) for the other *Azotobacter* species have been tested in *A. salinestris.*

7. **Azotobacter vinelandii** Lipman 1903, 238[AL] (*Azotobacter miscellum* Pshenin 1964, 617.)
vine.lan′ di.i. M.L. gen. n. *vinelandii* of Vineland; named after Vineland, New Jersey, where the species was first isolated.

The morphology is similar to that of *A. chroococcum* and can vary from rods to more coccoid forms. The cells typically are 1.6–2.5 × 3–5 µm. Ammonium-grown cells are more coccoid in stationary phase (Fig. BXII.γ.133). Cysts are formed in old cultures or after addition of butanol to exponential cultures. Motile cells from 1- to 2-d-old cultures have peritrichous flagella with a wavelength of 2.0–3.0 µm and an amplitude of 0.40–0.59 µm. The velocity of motile cells can be 74 µm/sec. A few strains are nonmotile. Colonies are opaque and convex, and, for most strains, are mucoid, glistening, and smooth. Distinguishing physiological and nutritional characteristics of the species are presented in Tables BXII.γ.123 and BXII.γ.124; utilization of rhamnose and phenol as carbon sources is distinctive. A yellow-green fluorescent pigment is produced, especially under conditions of Fe limitation. Other diffusible pigments can also be produced. N_2, ammonium, nitrate, and urea, but not glutamate, are used as nitrogen sources. N_2 is fixed under aerobic or microaerobic conditions. Ammonium prevents N_2 fixation by inhibition of expression of *nif* genes and possibly by inactivation of Mo nitrogenase (nitrogenase-1, carrying the Fe–Mo cofactor). In strain AvOP (ATCC 13705), two "alternative" nitrogenases can be synthesized when Mo supply is very low (nitrogenase-2, carrying the Fe–V cofactor and nitrogenase-3, with a Fe–Fe cofactor, synthesized in the absence of Mo and V). This correlates with the presence of *vnf* and *anf* genes. For other characteristics, less distinguishing, see Thompson and Skerman (1979). The genome size is 4.6 Mb. Six copies of the *rrn* operon are present.

The mol% G + C of the DNA is: 64.9–66.5 (T_m).

Type strain: ATCC 478, DSM 2289, WR-100.

Genus IV. **Cellvibrio** *Blackall, Hayward and Sly 1986, 354*[VP] *(Effective publication: Blackall, Hayward and Sly 1985, 95)*

THE EDITORIAL BOARD

Cell.vib′ ri.o. M.L. n. *cell* abbreviation of M.L. n. *cellulosum* cellulose, which is degraded by the organism; M.L. masc. n. *Vibrio* a generic name; M.L. masc. n. *Cellvibrio* cellulose (degrading) vibrio.

Aerobic Gram-negative **slender curved rods** (0.2–0.5 × 1.0–1.3 µm). Motile with **mixed flagellation**. **Oxidize glucose and hydrolyze cellulose**. **Produce curdlan polysaccharide from glucose**. Catalase and oxidase positive. Do not utilize organic acids. No growth factors required.

The mol% G + C of the DNA is: 46.1–54.1.

Type species: **Cellvibrio mixtus** Blackall, Hayward and Sly 1986, 354 (Effective publication: Blackall, Hayward and Sly 1985, 95.)

FURTHER DESCRIPTIVE INFORMATION

Cells possess mixed flagellation, with up to 11 lateral flagella; the lateral flagella, which are not always present, have a smaller diameter and a shorter wavelength than the single polar flagellum. The enzymes involved in the degradation of polysaccharides and in the metabolism of the degradation products have been studied in *Cellvibrio mixtus, "Cellvibrio vulgaris", "Cellvibrio fulvus"*, and *"Cellvibrio gilvus"*, but the taxonomic position of the latter three strains has not been determined (see Taxonomic Comments).

ENRICHMENT AND ISOLATION PROCEDURES

Enrichment and isolation can be carried out by incubation of rhizosphere soil samples in liquid mineral salts medium containing cellulose or dextran as a carbon source followed by streaking onto agar medium containing the same carbon source (Blackall et al., 1985).

Maintenance Procedures

Strains can be stored on slants of sucrose peptone or peptone yeast extract agar at 7°C (Blackall et al., 1985).

Taxonomic Comments

The genus *Cellvibrio* was first described by Winogradsky (1929), but did not appear on the Approved Lists (Skerman et al., 1980). Blackall et al. (1985) revived the genus based on the description of a number of newly isolated cellulose- and dextran-hydrolyzing strains which they compared to selected *Pseudomonas*, *Aeromonas*, *Vibrio*, *Xanthomonas*, *Cytophaga*, and *Cellulomonas* strains as well as to strains of *"Cellvibrio vulgaris"* and *"Cellvibrio fulvus"*. In a numerical taxonomic analysis of phenotypic characters the new isolates clustered with each other and with *"Cellvibrio vulgaris"* and *"Cellvibrio fulvus"* but separately from all the other organisms. However, the new isolates differed from the *"Cellvibrio vulgaris"* and *"Cellvibrio fulvus"* strains and from the organisms described by Winogradsky in failing to produce pigment on cellulose agar; they also differed from *"Cellvibrio vulgaris"* and *"Cellvibrio fulvus"* in the mol% G + C of the DNA (50.1 ± 4.0 for the new isolates and 44.9 and 44.6 for the latter two strains).

List of species of the genus Cellvibrio

1. **Cellvibrio mixtus** Blackall, Hayward and Sly 1986, 354^{VP} (Effective publication: Blackall, Hayward and Sly 1985, 95.)
mix' tus. M.L. masc. adj. *mixtus* mixed referring to the type of flagellation.

On semi-opaque mineral salts–cellulose medium all strains form circular white colonies with entire edges surrounded by a zone of clearing. Produce acid from L-arabinose, dextrin, galactose, glucose, lactose, maltose, mannose, melibiose, raffinose, sucrose, trehalose, and xylose. Hydrolyze chitin, esculin, pectate (at neutral and alkaline pH only), and starch, but not casein, DNA, gelatin, or Tween 80. Do not produce gas from nitrate, H_2S from cysteine or indole from tryptophan. Voges–Proskauer and methyl red tests negative. Produce α-glucosidase, β-glucosidase, and β-xylosidase.

The mol% G + C of the DNA is: 53–55 (T_m).
Type strain: UQM 2601.

a. **Cellvibrio mixtus** *subsp.* **mixtus** Blackall, Hayward and Sly 1986, 354^{VP} (Effective publication: Blackall, Hayward and Sly 1985, 95.)

Properties are as for the species with the following additions: produce acid from cellobiose and melezitose. Produce β-glucuronidase and β-galactosidase. Do not hydrolyze dextran. Gram-negative; cells soluble in 3% KOH.

The mol% G + C of the DNA is: 52.6 (T_m).
Type strain: UQM 2601.
GenBank accession number (16S rRNA): AF448515.

b. **Cellvibrio mixtus** *subsp.* **dextranolyticus** Blackall, Hayward and Sly 1986, 354^{VP} (Effective publication: Blackall, Hayward and Sly 1985, 95.)
dex.trano.lyticus. dextran dextran, a chemical; Gr. adj. *lyticus* dissolving; M.L. masc. adj. *dextranolyticus* dextran dissolving.

Properties are as for the species with the following additions: hydrolyze dextran and produce acid from fructose. Gram-negative, but cells not soluble in 3% KOH.

The mol% G + C of the DNA is: 55.2 (T_m).
Type strain: UQM 1666.

Genus V. **Mesophilobacter** *Nishimura, Kinpara and Iizuka 1989, 380*^{VP}

The Editorial Board

Me.so.phi.lo.bac' ter. Gr. n. *mesos* middle; Gr. adj. *philus* loving; M.L. *bacter* rod, staff; M.L. masc. n. *Mesophilobacter* mesophilic rod.

Gram-negative nonmotile aerobic pleomorphic rods. (0.5–0.6 × 1.0–2.0 μm). Catalase positive; oxidase negative. Nonsporeforming, non–acid-fast, nonfermentative, nonencapsulated. Resistant to penicillin. **Optimum growth at 33–37°C.**

The mol% G + C of the DNA is: 44.0–46.9.

Type species: **Mesophilobacter marinus** Nishimura, Kinpara and Iizuka 1989, 380.

Further descriptive information

The strains were isolated from seawater (Nishimura et al., 1986b, 1989).

Cells of young cultures may be stout (0.8–1.0 × 1.5–3.0 μm) or may be elongated up to 15 μm in length. Cells in stationary cultures are coccoid with diameters 0.6–0.9 μm (Nishimura et al., 1989).

Enrichment and Isolation Procedures

Strains of this species were isolated from seawater on seawater agar or modified nutrient agar as described by Nishimura et al. (1986b).

Differentiation of the genus *Mesophilobacter* from other genera

Nishimura et al. (1989) provide a table of characteristics that differentiate *Mesophilobacter* from the genera *Moraxella*, *Acinetobacter*, and *Psychrobacter*.

List of species of the genus Mesophilobacter

1. **Mesophilobacter marinus** Nishimura, Kinpara and Iizuka 1989, 380^{VP}
ma.ri' nus. L. adj. *marinus* of the sea, marine.

Description as for the genus with the following additional characteristics. No change in litmus milk. No H_2S produced. Voges-Proskauer test negative. Methyl red test

positive. Reduces nitrate to nitrite. Assimilates acetate, citrate, D-fructose, fumarate, gluconate, D-glucose, malate, maltose, D-ribose, succinate, sucrose, and trehalose. Produces acid from cellobiose, D-fructose, D-glucose, D-mannitol, and D-ribose. Grows in presence of 7% NaCl. Major fatty acids $C_{16:0}$, $C_{16:1}$, and $C_{18:1}$.

The mol% G + C of the DNA is: 44.0–46.9 (HPLC).

Type strain: 14S-4, DSM 9142, IAM 13185, NCIMB 13183.

Genus VI. **Rhizobacter** *Goto and Kuwata 1988, 238*[VP]

MASAO GOTO

Rhi.zo.bac′ ter. Gr. n. *rhiza* a root; M.L. masc. n. *bacter* masc. equivalent of Gr. neut. n. *bacterion* rod, staff; M.L. masc. n. *Rhizobacter* root rod.

Straight to slightly curved, nonsporeforming, encapsulated rods 0.9–1.3 × 2.1–2.5 μm. **Poly-β-hydroxybutyrate granules are formed.** Cells stain Gram negative. **Motile by polar flagella or lateral flagella or both** but motile cells are rare in the populations. **Aerobic** with respiratory metabolism of glucose. Good growth is obtained at 28–30°C; no growth at 35°C. Growth occurs at pH between 5.0 and 9.0. Utilizes D-glucose as a sole source of carbon and energy. **White or yellowish white, plicated, tough, or viscid colonies on agar plates**; if yellow, the pigment differs from xanthomonadines. **Floccular growth consisting of globular units in liquid media; fingerlike projections never occur. Oxidase and catalase positive. The following are positive**: H_2S from cysteine and auxin, reduction of nitrate to nitrite, *o*-nitrophenyl-β-D-galactopyranoside (ONPG) test, and growth inhibition by KCN. Negative for denitrification, methyl red, and production of arginine dihydrolase, nitrogenase, fluorescent pigment, indole, and acetoin formation. Susceptible to 10 μg of vibriostatic agent O/129 phosphate. **Hydrolyzes starch, dextrin, and glycogen.** Cannot utilize benzene derivatives as carbon sources. Does not require NaCl or growth factors. Contains ubiquinone Q8. The type species occurs in soil and is a plant pathogen, causing galls on carrot roots in nature.

The mol% G + C of the DNA is: 67–71.

Type species: **Rhizobacter dauci** *corrig.* Goto and Kuwata 1988, 238 (*Rhizobacter daucus* (sic) Goto and Kuwata 1988, 238.)

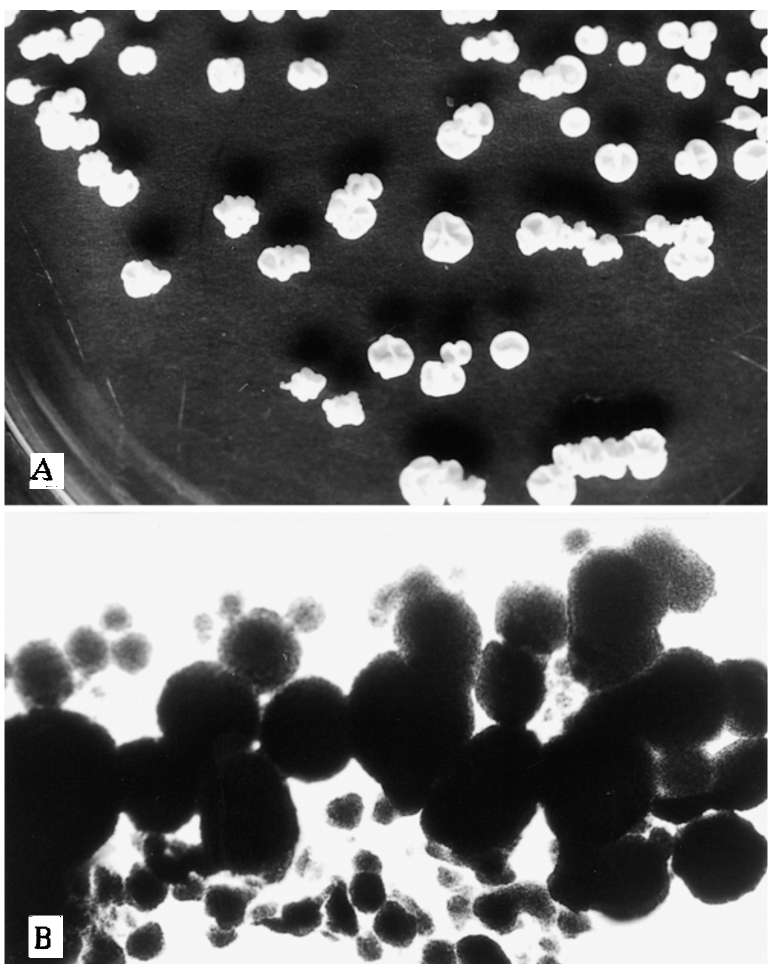

FIGURE BXII.γ.141. Colony morphology of *R. dauci* H6[T]. (*A*) Plicated colonies of wild type on DPPG agar. (*B*) Globular aggregates of bacterial cells in DPPG liquid medium. (× 100)

Further descriptive information

The growth on agar plates depends on the concentrations of ingredients: growth is best on a 10-fold dilution of potato-peptone-glucose (DPPG) agar, a 10-fold dilution of yeast extract-peptone-glucose (DYPG) agar, or Casitone-yeast extract agar[1]. This oligotrophic trait seems to be due to the presence of peptone, which significantly retards the growth of the bacterium.

Although this bacterium is aerobic, it can grow slowly under anaerobic conditions. After several days, the colonies on DPPG agar plates are 1.5–2.0 mm in diameter, white, opaque, tough, and pulvinate or capitate with entire margins. Later the colonies develop highly plicated surfaces and undulating margins (Fig. BXII.γ.141A).

Plication is less distinct or absent when glucose is omitted from the medium. The colonies on DYPG agar plates are yellowish white but otherwise identical to those on DPPG agar plates. The colonies are so tough and adhere so firmly to the agar surfaces that they are difficult to remove with a platinum loop. The agar surface is slightly depressed for about 1–2 mm around a colony.

Growth in liquid media is floccular, and the medium never clouds uniformly. The flocs are composed of globular aggregates of bacterial cells 60–200 μm in diameter (average, 120 μm) (Fig. BXII.γ.141B). The flocs adhere to the test tube wall in the early stages of growth and then develop into a film or pellicle, which eventually fall to the tube bottom.

The results of the oxidation-fermentation test are not clear-cut. Because of the slow growth, as well as the considerable amount of growth and acid production that take place in the tubes sealed with mineral oil, the oxidation-fermentation test may be misread in the early stages of growth. After several days of incubation, however, growth and acid production in the open tubes become conspicuously greater than growth and acid production in the sealed tubes, making determination of oxidative metabolism easier.

This bacterium uses diverse kinds of compounds as a sole source of carbon: L-arabinose, D-arabinose, xylose, fructose, galactose, glucose, lactose, maltose, melibiose, sucrose, raffinose, carboxymethylcellulose, dextrin, glycogen, adonitol, inositol, mannitol, sorbitol, salicin, gluconate, mucate, quinate, and tartrate. The following are used weakly: isoleucine, leucine, methanol, and propanol.

Other physiological and biochemical characteristics include positive reactions for gelatinase, lecithinase, urease, pit formation on pectate gel, hydrolysis of Tween 80 and esculin, production of H_2S, and indoleacetic acid and/or its derivatives, and negative reactions for casein hydrolysis, tyrosinase, deoxyribonuclease, and phenylalanine deaminase. No detectable change occurs in litmus milk cultures.

Slimy colony mutants are often detected during the storage of agar slant cultures at room temperature. These mutants grow faster than the parents and form abundant viscous slime on agar media.

The bacterium causes bacterial carrot gall that is a typical soil-borne disease. In natural infection, galls develop along the entire length of the storage roots from the crown to the root tip. Small galls may also be found on the fibrous roots. Galls vary in size from a few millimeters to approximately 1 cm in diameter (average, several millimeters). Large galls may be formed by the union of several smaller galls. Galls are often distributed along lenticles, in severe cases forming a ring around the root (Fig. BXII.γ.142A). The galls are light brown and have very rough surfaces. Another characteristic of the disease is the development of numerous adventitious fibrous roots.

On artificially inoculated carrot seedlings, hypertrophied areas become apparent on the wounded roots 7–14 d after inoculation, and outgrowths like those on naturally infected plants develop about 1 month after inoculation. The disease is particularly severe on the roots, which are injured by scratching the epidermis with a sterilized sharp needle. The bacterial cells occupy the narrow fissures formed in gall tissues, and deposit heav-

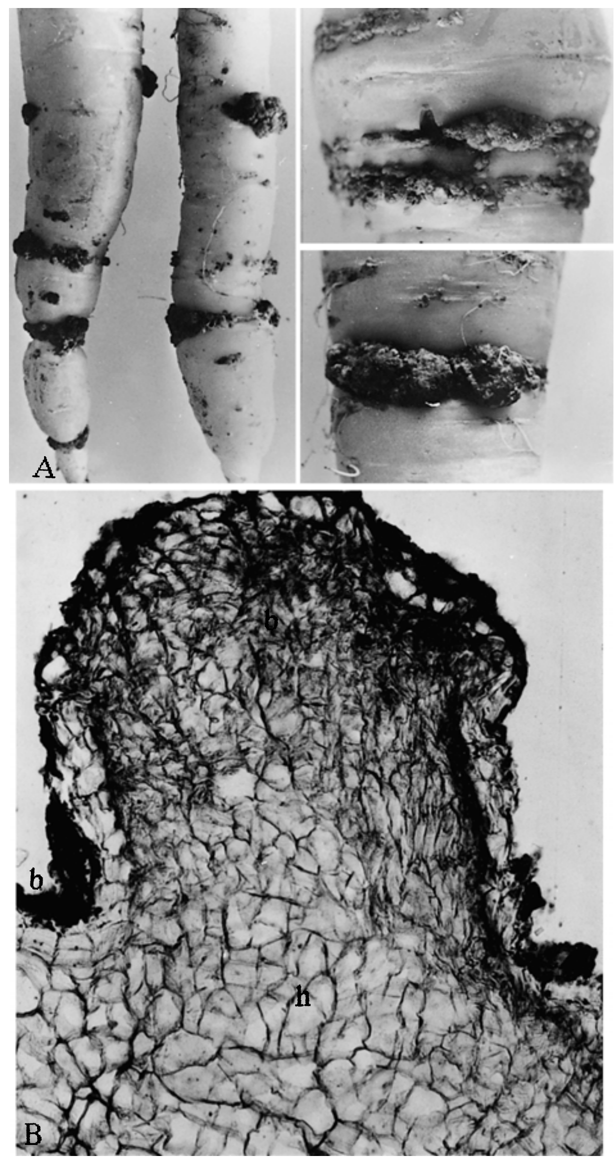

FIGURE BXII.γ.142. Characteristics of carrot bacterial gall. (*A*) Symptoms of galls formed on carrot roots. (*B*) Transverse section of an outgrowth showing hyperplastic tissues (*h*) and bacterial cells found in bacterial fissures and on gall surface (*b*).

1. DPPG agar consists of potato extract (20 g of potato in 1000 ml of water), 1000 ml; peptone, 1 g; glucose, 10 g; and agar, 15 g; pH 6.8. DYPG agar consists of peptone, 1 g; yeast extract, 0.5 g; glucose, 10 g; agar, 15 g; and water, 1000 ml; pH 6.8. Casitone-yeast extract agar consists of Casitone (Difco), 5 g; yeast extract, 2.5 g; agar, 15 g; and water, 1000 ml; pH 6.8.

ily on the surface of galls (Fig. BXII.γ.142B). When tomato seeds are immersed for several minutes in bacterial suspension and planted in sterilized soil, the conspicuous outgrowths develop along the main root, giving a thick club-shaped appearance and causing a remarkable growth inhibition of whole plant parts.

Enrichment and Isolation Procedures

Isolation of *Rhizobacter dauci* is difficult because of its preference for oligotrophic media and its slow growth on agar plates, which can be overgrown by soil bacteria that contaminate the habitat. In practice, a small piece (approximately a 2-mm cube) of outgrowth including the surface is cut out of a fresh gall, washed briefly, macerated in 10 ml of sterilized distilled water, and subjected to 10-fold serial dilution with sterilized distilled water. The suspensions are plated onto a DPPG agar. The plates are incubated aerobically at 28°C. The bacterium is easily recognizable after 1 week or so because of its slow-growing, white, plicated, tough colonies. It may be further purified by single-colony isolation procedures.

Maintenance Procedures

For routine work, the bacterium may be stored either as the suspensions in sterilized distilled water at room temperature or as the stab cultures on DPPG agar medium at 4°C. Lyophilization is preferable for long-term preservation. For reviving the lyophilized cultures, freeze-dried cells are suspended in a few milliliters of sterilized distilled water and plated immediately on DPPG agar, and again after storing the suspension overnight at room temperature. The typical wild-type colonies with plicated surface are often formed on the latter plates.

Differentiation of the genus *Rhizobacter* from other genera

See Table BXII.γ.128.

Taxonomic Comments

This bacterium is characterized by the lateral flagellation and the susceptibility to vibriostatic agent 0/129. These features have been known in the members of the family *Vibrionaceae*, facultative anaerobes (Baumann and Schubert, 1984), but are not common in the aerobes (Goto, 1988). Until the phylogenetic data became available, the bacterium was most appropriately placed in the family *Pseudomonadaceae* based on various other phenotypic characteristics.

Rhizobacter dauci resembles *Rhizomonas suberifaciens* in its preference for oligotrophic media, wrinkled colony formation, and polar or lateral flagellation. However, the former is clearly distinguished from the latter by the higher mol% G + C of the DNA, a different major ubiquinone, the large number of carbon sources utilized, and significantly larger dimensions of the cells (van Bruggen et al. 1990).

Rhizobacter dauci resembles *Zoogloea* spp. in formation of zoogloeae but is differentiated by its plant pathogenicity, shape of the zoogloeae, susceptibility to the vibriostatic agent 0/l29 phosphate, lower tolerance to NaCl, lack of growth at 35°C, positive lecithinase reaction, lack of a litmus milk reaction, and a wider spectrum of carbon sources used (Crabtree and McCoy, 1967; Friedman and Dugan, 1968).

Colonies of *Rhizobacter dauci* resembles those of *Beijerinckia* spp. grown on nitrogen-free glucose mineral agar (Becking, 1984). However, *Beijerinckia* spp. are distinct from *R. dauci* in plant pathogenicity, positive nitrogenase activity, and the significantly lower mol% G + C.

List of species of the genus Rhizobacter

1. **Rhizobacter dauci** *corrig.* Goto and Kuwata 1988, 238[VP] (*Rhizobacter daucus* (sic) Goto and Kuwata 1988, 238.)
dau' ci. M.L. n. *Daucus* generic name of carrot, host plant; M.L. masc. gen. n. *dauci* of the carrot.

The characteristics are as described for the genus and as listed in Table BXII.γ.128. The morphology is as depicted as Fig. BXII.γ.141.

The mol% G + C of the DNA is: 67–71 (T_m).

Type strain: H6, ATCC 43778, ICMP 9400, LMG 9036.

TABLE BXII.γ.128. Differential characteristics of the genus *Rhizobacter* and other genera of the family *Pseudomonadaceae*

Genus VII. **Rugamonas** *Austin and Moss 1987, 179^AL (Effective publication: Austin and Moss 1986, 1907)*

MAURICE O. MOSS AND DAWN A. AUSTIN

Ru.gamo'nas. L. fem. n. *ruga* wrinkle; Gr. fem. n. *monas* unit, monad; M.L. n. *Rugamonas* wrinkled unit.

Rods 0.8–0.9 × 2.4–4.0 μm, in young cultures. **Intracellular granules of prodigiosenes develop in cells more than 7 d old.** Cells in cultures less than 7 d are motile by one or more polar or subpolar flagella. **Colonies on Bennett's agar[1] after 4 d at 20°C are pink to deep red, wrinkled, and rubbery in consistency after 5 d**, with a diameter of approximately 3 mm. Oxidase and catalase positive, strictly aerobic and oxidative metabolism, unable to metabolize carbohydrates fermentatively. Nitrates are reduced to N_2 anaerobically. Growth occurs in the presence of 0.0–0.5% (w/v) NaCl. Arginine decarboxylase negative. Lysine and ornithine decarboxylases are produced by some strains. Esculin, chitin, DNA, RNA, gelatin, lecithin, Tween 20, 40, 60, and 80, tyrosine, and urea are degraded but not allantoin, cellulose, elastin, hypoxanthine, starch, and xanthine. H_2S is not produced on triple sugar iron agar. The gluconate and Koser's citrate tests are positive; Voges–Proskauer, methyl red, and melonate tests are negative. β-Galactosidase (ONPG method) positive. Has been isolated from river water.

The mol% G + C of the DNA is: 66–67.

Type species: **Rugamonas rubra** Austin and Moss 1987, 179 (Effective publication: Austin and Moss 1986, 1908.)

FURTHER DESCRIPTIVE INFORMATION

As cultures age, cells show reduced motility and become increasingly pleomorphic. Cultures grown in Bennett's broth form pink/red flocs after 7 d. Colonies on Bennett's agar at 20°C are white, shiny, and circular after 2–3 d, pink after 4 d, and deep red, wrinkled, and rubbery in consistency after 5 d, with a diameter of approximately 3 mm. The tough rubbery consistency is characteristic of all isolates of *R. rubra* obtained so far, as is the production of red pigments of the prodigiosene family. The type strain was shown to produce 6-methoxy-2-methyl-3-pentylprodigeosene (prodigiosin) but the predominant pigment was the 3-heptyl analogue (Fig. BXII.γ.143).

On rich media such as Bennett's agar, the initially pillar-box red colonies become a deep maroon color and colonies often have a green metallic sheen. These color changes reflect both the reduction in pH and overproduction of the prodigiosenes, which can be seen as dark granular inclusions in wet mounts prepared for motility studies. At this stage viability drops rapidly and no viable organisms can usually be recovered from colonies after 14 d incubation on Bennett's agar.

Temperature range for growth after 168 h is 1.2–30.6°C; optimum, 20°C. No growth at 37°C. The cardinal temperatures are sensitive to the period of incubation and after 48 h the following have been recorded: T_{min}, 5.6°C; T_{opt}, 26.4°C; T_{max}, 30.6°C (Moss, 1983).

R. rubra has only been reported from a lowland, freshwater river site where it occurred in low but persistent numbers during a 5-month period (January to May 1984), especially after rainfall 24–48 h before collection of samples (Austin and Moss, 1986). Although it is not possible to assign this organism to a particular ecological niche, the utilization of a wide range of sugars, amino acids, and organic acids as sole carbon sources suggests that it may have the ability to exploit a range of environments.

ENRICHMENT AND ISOLATION PROCEDURES

Maximum recovery of isolates from river water was achieved by making fivefold serial dilutions up to 1/125 using ¼ strength Ringer's buffer and plating 0.5-ml samples onto large (12-cm) plates of modified Bennett's agar supplemented with neomycin hydrochloride, cycloheximide, and nystatin, all at 50 μg/ml. Plates are incubated at 20°C for up to 14 d, and tough membranous colonies are streaked onto plates of Bennett's agar to ensure purity (Austin and Moss, 1986).

MAINTENANCE PROCEDURES

For medium-term storage, cultures are inoculated into dilute peptone water, incubated to allow turbidity to develop, and then stored at ~4°C. For long-term storage, freeze drying is not successful but storage in liquid nitrogen has given adequate survival. The type strain has been successfully recovered after 15 years' storage in liquid nitrogen using the following double-strength cryoprotectant (composition per liter of distilled water): K_2HPO_4, 12.6 g; sodium citrate, 0.9 g; $MgSO_4 \cdot 7H_2O$, 0.18 g; $(NH_4)_2SO_4$, 1.8 g; KH_2PO_4, 3.6 g; glycerol, 44 ml; sterilized by filtration. A 1-ml sample of a 3-d-old culture of the organism in Bennett's broth is thoroughly mixed with 1 ml of cryoprotectant in a freeze vial (Nunc) and stored in liquid nitrogen.

DIFFERENTIATION OF THE GENUS *RUGAMONAS* FROM OTHER GENERA

One of the most striking features of *Rugamonas* is the production of flocs in liquid culture and tough rubbery colonies on solid media. Table BXII.γ.129 shows some of the characteristics that distinguish three well-characterized Gram-negative, motile, prodigiosin-producing species of *Rugamonas*, *Alteromonas*, and *Serratia*.

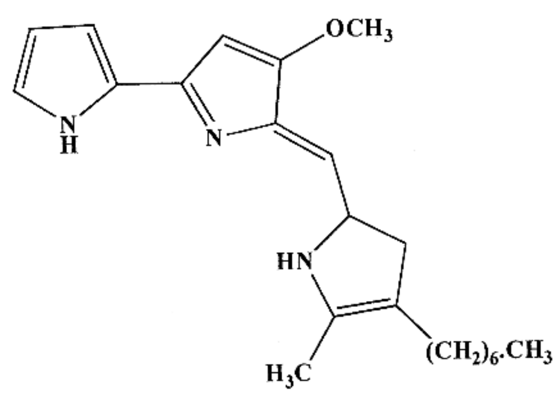

FIGURE BXII.γ.143. The structure of 6-methoxy-2-methyl-3-heptylprodigeosene, which is produced by *Rugamonas* strains.

1. Bennett's broth (Keeble and Cross, 1977) contains (g/l distilled water): yeast extract (Difco), 1.0; beef extract (Lab Lemco), 1.0; Bacto casitone (Difco), 2.0; and glucose, 10.0; pH 7.3. For a solid medium, 10.8 g/l of agar (LabM no. 2 or Oxoid no. 1) are added.

TABLE BXII.γ.129. Characteristics differentiating three Gram-negative, motile, prodigiosin-producing species

Taxonomic Comments

The general characteristics of *Rugamonas* isolates suggest an affinity with the *Pseudomonadaceae* but they cannot be comfortably placed in any existing genera. They are distinguished from *Pseudomonas* and *Alteromonas* by their floc-forming ability in liquid cultures and from *Zoogloea* by the mol% G + C of the DNA.

List of species of the genus Rugamonas

1. **Rugamonas rubra** Austin and Moss 1987, 179[AL] (Effective publication: Austin and Moss 1986, 1908.)
rub′ra. L. fem. adj. *rubra* red.

The characteristics are as given for the genus. In addition, the following enzymes are produced: alkaline phosphatase, acid phosphatase, esterase-lipase, leucine arylamidase, and phosphoamidase. Esterase is produced by some strains. Phenylalanine deaminase is not produced. Sole carbon sources include D-alanine, L-arabinose, DL-arginine, *meso*-inositol, sodium DL-lactate, cellobiose, D-fructose, D-galactose, L-histidine, maltose, D-mannose, D-raffinose, D-ribose, DL-serine, sodium acetate, trisodium citrate, D-sorbitol, sucrose, and trehalose. The following are not used: adonitol, *i*-erythritol, sodium malonate, D-melibiose, D-melizitose, D-rhamnose, DL-valine, and D-xylose. Lactose is used by some strains.

By disk assay, strains are sensitive to chloramphenicol, chlortetracycline, erythromycin, gentamicin, oxytetracycline, streptomycin, and tetracycline (each at 10 μg/disk); furazolidone (50 μg), kanamycin (30 μg), novobiocin (5 μg), sulfafurazole (500 μg), and cotrimoxazole (25 μg). Resistant to ampicillin (2 μg), cloxacillin (5 μg), colistin sulfate (10 μg), neomycin (10 μg), nitrofurantoin (200 μg), and penicillin G (1.5 U).

Isolated from river water.

The mol% G + C of the DNA is: 66.7 ± 0.1 (T_m).

Type strain: Strain MOM 28/2/79, ATCC 43154, CCM 3730, NCIMB 12552.

Genus VIII. Serpens *Hespell 1977, 380*[AL]*

Robert B. Hespell

Ser′pens. L. fem. n. *serpens* snake, serpent.

Rod-shaped cells, 0.3–0.4 μm wide by 8–12 μm long. Occur singly in pairs. Cysts or coccoid bodies not formed, but cells in the stationary phase of growth are longer (16–25 μm) and often possess blebs or spherical protuberances. Gram negative. **Extremely flexible and capable of serpentine-like motility in agar gels. Possess bipolar tufts of 4–10 flagella and also a few lateral flagella.** Poly-β-hydroxybutyrate or other internal granules not formed. Have a strictly respiratory type of metabolism with oxygen as the sole electron acceptor. **Grow aerobically but prefer oxygen concentrations less than that of an air atmosphere. Catalase and oxidase positive.** Chemoorganotrophic. **Lactate is the only effective carbon and energy source**, although very slight growth occurs with acetate or α-ketoglutarate. Carbohydrates, fatty acids, and sugar alcohols are not catabolized. Casein hydrolysate, peptone, yeast extract, and, for most strains, ammonium chloride can serve as nitrogen sources; nitrates and nitrites are not used. Vitamins are stimulatory but not required. Optimum temperature, 28–30°C. On media containing 1.8–2.0% agar, colonies are cream colored, round, 3–6 mm in diameter, and have a filamentous edge. **On media with less than 1.5% agar, only subsurface spreading colonies occur**. Found in the sediments of eutrophic freshwater ponds.

The mol% G + C of the DNA is: 66.

Type species: **Serpens flexibilis** Hespell 1977, 381.

Further descriptive information

The most striking morphological feature is the complex, serpentine-like movement of the cells when observed in slides of agar pieces removed from the edge of a spreading colony (Fig. BXII.γ.144). The organisms move very rapidly and display a furious lashing and bending of the cells; coiling into a knot-like configuration is also common. In liquids, the movement is less violent and the cells move rapidly with reversals along a straight line axis with a gentle flexing of the body, and the distal or trailing tip of the cell vibrates intensely (Fig. BXII.γ.144E–H). No tumbling type of movement is evident. Motility occurs in buffer solutions of polyvinylpyrrolidine having a viscosity greater than 1000 centipoise (Greenberg and Canale-Parola, 1977). In comparison, viscosities of 60 and 1000 centipoise prevent the motility of *Escherichia coli* and *Spirochaeta halophila*, respectively. The structural basis permitting such cell flexibility is unknown, but the organisms possess a thin peptidoglycan layer and a morphologically typical Gram-negative outer membrane.

**Editorial Note:* The chapter on *Serpens* is reprinted from the 1st edition of *Bergey's Manual of Systematic Bacteriology*.

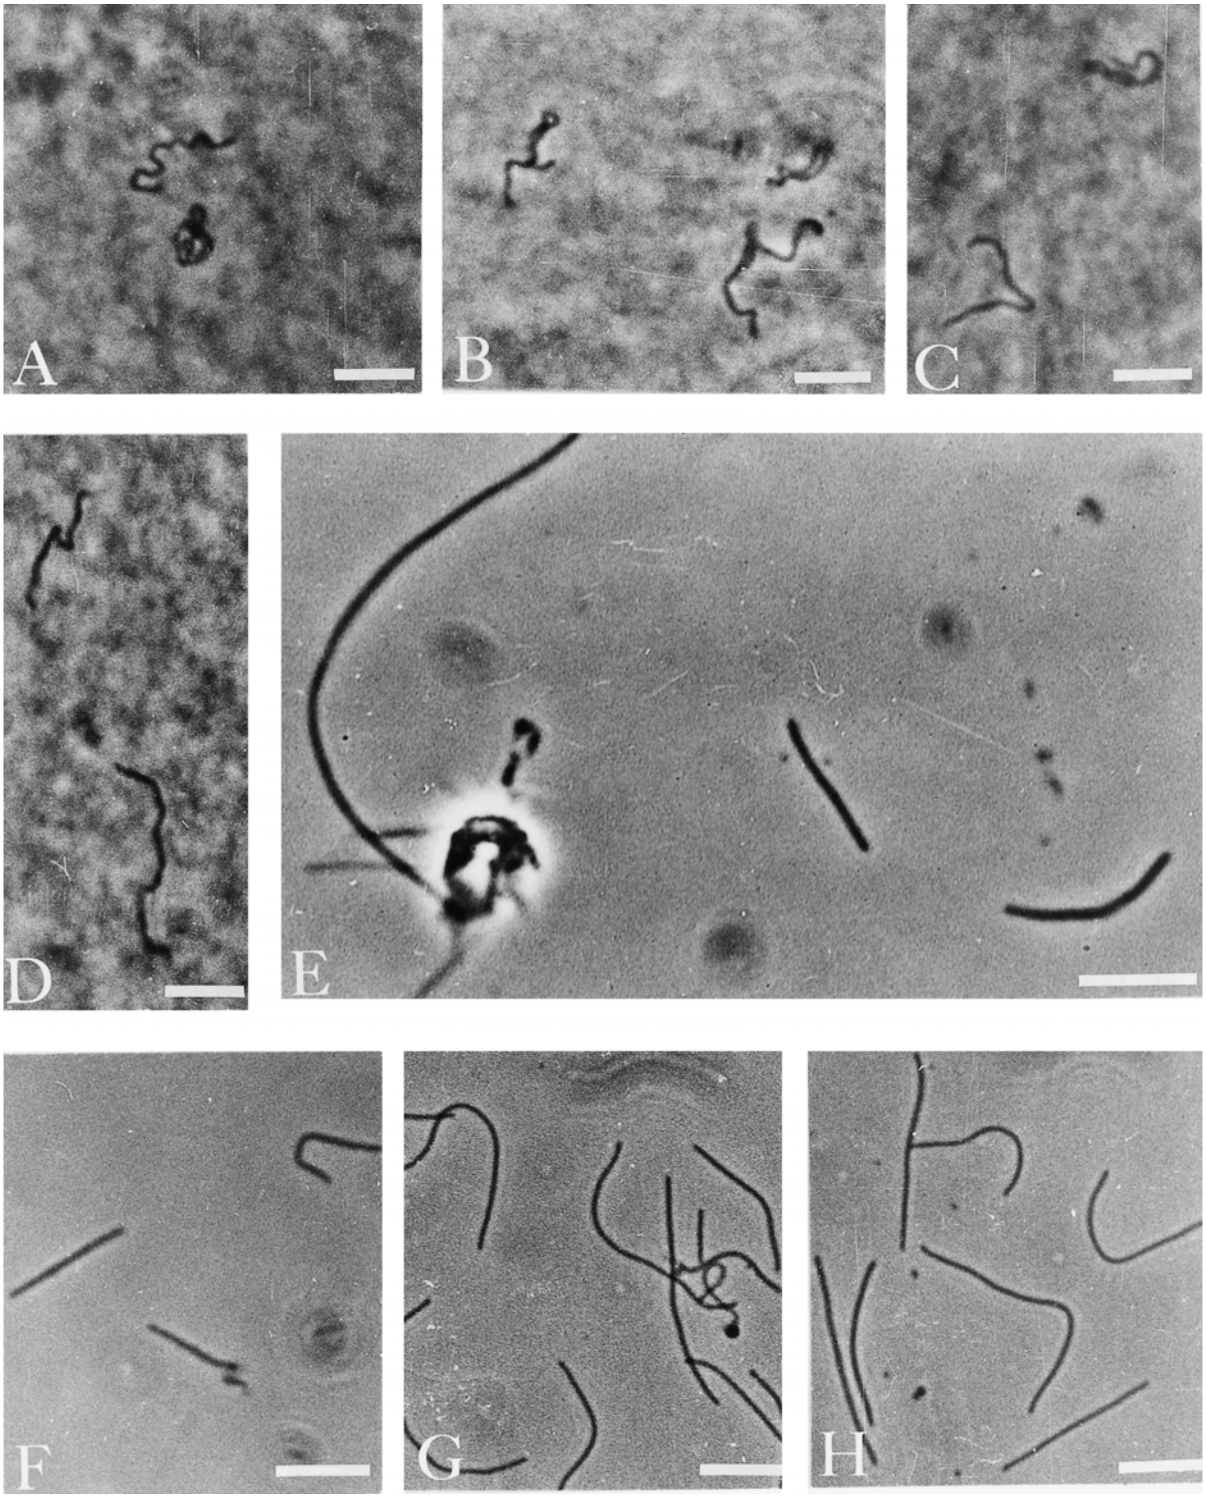

FIGURE BXII.γ.144. Living cells of *Serpens flexibilis* PFR-1. Wet-mount preparations, phase contrast. Cells in agar pieces excised from subsurface, spreading growth (*A–D*) displayed rapid motion with bending, lashing, and serpentine-like movements. Cells rapidly reversed themselves between coiled and uncoiled forms (*A*). In liquid menstrua (*E– H*) logarithmic-phase cells (*F* and *H*) showed straight-line movements with flexing of the cell body. Stationary cells often clumped (*E*) and had protuberances (*G*). Bars = 3.0 μm. (Reproduced with permission from R.B. Hespell, International Journal of Systematic Bacteriology *27*: 371–381, 1977, ©International Union of Microbiological Societies.)

Although growth occurs aerobically, *S. flexibilis* prefers oxygen tensions less than that of an air atmosphere, growing subsurface (1–3 mm deep) in stationary liquid media or in media with agar concentrations of less than 1.5%. The type strain and all other strains examined can use only lactate as an effective oxidizable carbon and energy source. Cell extracts contain only trace levels of the key enzymes of the Embden–Meyerhof–Parnas or hexose monophosphate pathways, but the tricarboxylic acid cycle en-

zymes are in high levels. Vitamins are not required for growth, but yeast extract is often stimulatory. Most strains can use ammonium chloride as a sole nitrogen source, but increased growth rates and cell yields occur with media containing peptone or casein hydrolysate.

Enrichment and Isolation Procedures

S. flexibilis can be readily isolated from the upper few centimeters of the sediments of eutrophic freshwater ponds. Traditional enrichment culture techniques employing lactate as the carbon source are not useful for isolation as the organisms often become

FIGURE BXII.γ.145. Transmission electron micrograph of *S. flexibilis* PFR-1 cells. The insets (*A* and *B*) are higher magnifications of the ends of the same cell stained with phosphotungstic acid. Although the overall cell shape has been preserved, some flagella have detached, and an aggregate of four flagella remains at one end of the cell. Several laterally inserted flagella are present, and their insertion points (*arrows*) are more clearly evident in the insets. Bars = 0.25 μm. (Reproduced with permission from R.B. Hespell, International Journal of Systematic Bacteriology *27*: 371–381, 1977, ©International Union of Microbiological Societies.)

overgrown by other heterotrophic bacteria. However, selective isolation can be accomplished by the use of membrane filters overlayed on a Petri dish of appropriate media, a technique that has also been employed for the isolation of thin spirilla and spirochetes (Canale-Parola et al., 1966). A small inoculum of pond water/mud slurry is deposited in the center of a sterile cellulose filter disk (0.3–0.45 μm pore diameter) that has been placed on the surface of a plate of isolation medium.[1] After incubation for 6–12 h at 30°C, the disk is removed and the plate is incubated for 2–4 d. The organisms grow as a subsurface, whitish veil that diffuses from the center of the plate. By picking from the edge of the veil and streaking onto a second plate, cloned cultures may be obtained. Although aerobic spirilla and spirochetes can also be obtained in this manner, these organisms can usually be distinguished from *S. flexibilis* by light microscopic observations, but definitive confirmation should be done by electron microscopy.

1. Isolation medium (per 90 ml water): yeast extract, 0.2 g; peptone, 0.1 g; hay extract, 10 ml; and agar 1.0 g. The hay extract is prepared by boiling 10 g of hay in 100 ml of water for 15 min and clarifying the mixture by centrifugation. The pH of the isolation medium is adjusted to 7.0 with KOH before sterilization.

Maintenance Procedures

S. flexibilis is grown routinely in LYPP broth[2] and can be maintained by biweekly transfers on slants of LYPP agar. The organism can be preserved indefinitely by lyophilization or by storage in liquid nitrogen.

Taxonomic Comments

The genus presently consists of a single species, *S. flexibilis*.*

2. LYPP broth (per 100 ml water): 60% sodium lactate syrup, 1.0 ml; yeast extract, 0.3 g; peptone, 0.2 g; and K_2HPO_4, 0.35 g. The pH of the medium is adjusted to 7.2 prior to autoclaving. LYPP agar is prepared by adding 1.5 g of agar.

**Editorial Note:* Woese et al. (1982) reported that *S. flexibilis* is closely related to *Pseudomonas pseudoalcaligenes* (SAB = 0.9) and might be considered as a variant pseudomonad that had initially developed a defect in its system for synthesizing septa. Ahmad and Jensen (1987) found that *S. flexibilis* lacked the "overflow" pathway in the biosynthetic pathway for aromatic amino acids and shared this trait with most members of the *Pseudomonas aeruginosa* group.

List of species of the genus Serpens

1. **Serpens flexibilis** Hespell 1977, 381[AL]
flex.i.bi′ lis. L. adj. *flexibilis* flexible, pliant.

The description of the species is the same as that for the genus. The morphological features of the type strain are depicted in Figs. BXII.γ.144 and BXII.γ.145.

The mol% G + C of the DNA is: 66 (Bd).

Type strain: PFR-1, ATCC 29606.

Family II. **Moraxellaceae** Rossau, Van Landschoot, Gillis and De Ley 1991, 317[VP]

Elliot Juni and Kjell Bøvre

Mo.ra.xel.la′ ce.ae. M.L. fem. pl. n. *Moraxella* type genus of the family; *-aceae* ending to denote a family; M.L. fem. pl. n. *Moraxellaceae* the *Moraxella* family.

Organisms are **rod shaped, coccoid**, or coccal or may exhibit a characteristic multicellular micromorphology. Cells usually single but may also occur in pairs or short chains. Endospores are not formed. Gram negative, but there may be a tendency to resist decolorization. The cells are **nonmotile** in liquid media but pilus-associated surface-bound motility ("twitching motility") may be observed. Psychrotrophic or mesophilic. Strains of all recognized species usually have an optimum growth temperature between 14 and 36°C. Some species have capsules. Pili (fimbriae), pilus-associated colony morphology, and **competence for natural transformation** are frequently detected. Colonies are not pigmented. Chemoorganotrophic and aerobic. Several species have complex growth factor requirements while some species grow readily in simple defined media containing a single organic carbon and energy source. Except for acinetobacters, all strains are oxidase positive. **Usually catalase positive. Indole is not produced.** Except for some strains of *Acinetobacter* and *Psychrobacter*, **no acid is produced from carbohydrates**. True waxes may be present. Fatty acid profiles show the presence of mainly unbranched, saturated and mono- or di-unsaturated fatty acids composed of 16 and 18 carbon atoms. Most strains reside indigenously on mucosal membranes of humans and animals. Except for *Moraxella catarrhalis*, *Moraxella nonliquefaciens*, *Moraxella bovis*, and *Moraxella osloensis*, most strains are rarely involved in disease of humans or other animals. Strains of *Acinetobacter* and *Psychrobacter* are found in soil and water or in association with food products and have been isolated from the skin or mucous membranes of humans and other animals. The *Moraxellaceae* belong to the *Gammaproteobacteria* and to rRNA superfamily II.

The mol% G + C of the DNA is: 38–50.

Type genus: **Moraxella** Lwoff 1939, 173 emend. Henriksen and Bøvre 1968, 391.

Further comments With the exception of *M. caviae*, *M. caprae*, *M. phenylpyruvica*, and *M. lincolnii*, strains competent for natural transformation have been found for the other genera of the *Moraxellaceae*, thus making it possible to establish genetic relationships among all members of the family. Genetic studies involving the highly conserved streptomycin-resistance locus (resulting from mutation of S12, a protein component of the small ribosomal subunit) have made it possible to detect intergeneric, as well as interspecies, relationships. Because of the definitive, although frequently weak, genetic interactions involving the streptomycin-resistance marker, it is possible to recognize newly discovered and previously uncharacterized members of the *Moraxellaceae*. Using genus-specific transformation of nutritionally deficient mutants of certain conserved genes, it has been possible to assign strains of all species of a genus to that particular genus in a few of the genera of the *Moraxellaceae*.

Taxonomic Comments

The first description of a rod-shaped bacterium involved in eye infection in humans was made independently by Morax (1896) and by Axenfeld (1897). This so-called Morax–Axenfeld bacillus was Gram negative, nonmotile, occurred frequently as diploid pairs, and required serum or other complex media for growth. In subsequent years, organisms with similar properties were isolated from patients with conjunctivitis. In 1939, Lwoff proposed that these organisms, as well as some others, be placed in a new genus, *Moraxella*. Seeking to find a family that included the genus *Moraxella*, Henriksen (1952) suggested, and it was later formally proposed (Henriksen and Bøvre, 1968), that based on similarities in morphology, Gram stain and oxidase reaction, as well as other properties, the family *Neisseriaceae* was a likely candidate. However, from results of studies involving genetic transformation (Bøvre and Hagen, 1981), DNA–DNA hybridization (Tønjum et al., 1989), DNA–rRNA hybridization (Rossau et al., 1986, 1989), and 16S rDNA sequencing (Enright et al., 1994), it can be concluded that there is presently no basis for including the moraxellae in the family *Neisseriaceae*.

In 1962, Bøvre and Henriksen demonstrated transformation of streptomycin resistance among the oxidase-positive moraxellas. In independent studies by Bøvre (1963) and Catlin (1964), it was shown that interspecies transformation of the high-level streptomycin resistance marker could take place between *Neisseria catarrhalis* and strains of moraxellae. It was proposed that organisms previously called *Neisseria catarrhalis* be renamed as *Moraxella catarrhalis* (Henriksen and Bøvre, 1968). In 1970, Catlin proposed that organisms named *Neisseria catarrhalis* be transferred to the genus *Branhamella*. For pedagogic reasons Bøvre (1979) suggested that the genus *Moraxella* be divided into the subgenus *Moraxella* for the six rod-shaped species (*Moraxella (Moraxella) lacunata*, *M. (M.) bovis*, *M. (M.) nonliquefaciens*, *M. (M.) osloensis*, *M. (M.) phenylpyruvica*, and *M. (M.) atlantae* and the subgenus *Branhamella* for the coccal species (*Moraxella (Branhamella) catarrhalis*, *M. (B.) caviae*, *M. (B.) ovis*, and *M. (B.) cuniculi*: the latter three coccal groups frequently being referred to as the “false neisseriae”). In the light of recent findings, use of the subgeneric terms *Moraxella* and *Branhamella* should be discontinued. Transformation studies (Bøvre and Hagen, 1981) have shown that all the coccal species are members of the genus *Moraxella*. Other groups considered to have been species of the genus *Moraxella* are, in fact, separate genera of the family *Moraxellaceae*.

Early studies of the nutritional and physiological properties of the moraxellae (Baumann et al., 1968a) revealed that one group (*M. osloensis*) was nutritionally unexacting and three groups (*M. lacunata*, *M. nonliquefaciens*, and *M. bovis*) displayed various levels of nutritional requirements.

For many years, bacteria now known to be strains of *Acinetobacter* were associated with the genus *Achromobacter*. In 1923, the Bergey’s Manual Committee proposed a new genus, *Achromobacter*, to include all nonpigmented, Gram-negative, and aerobic saprophytes (see Ingram and Shewan, 1960). In 1954, Brisou and Prévot proposed that nonmotile achromobacters be considered species of the newly defined genus *Acinetobacter*. With the introduction of the oxidase test in diagnostic bacteriology, it was noted that organisms previously classified as strains of *Acinetobacter* included both oxidase-positive and oxidase-negative species (Henriksen, 1952; Piéchaud, 1961). In 1967, Thornley published the results of an extensive investigation of both oxidase-positive and oxidase-negative bacteria, all considered strains of *Acinetobacter*. Acinetobacters have been difficult to classify in the past because they do not possess a sufficient number of unique phenotypic properties that enable them to be differentiated with certainty from other bacteria of similar appearance. In addition to being referred to as strains of *Achromobacter*, organisms subsequently demonstrated to be acinetobacters had been assigned at least 15 different names; those used most frequently include *“Bacterium anitratum”*, *“Herellea vaginicola”*, and *“Mima polymorpha”* (Baumann et al., 1968b). In a resolution based on classical taxonomic and genetic studies, the Subcommittee on the Taxonomy of *Moraxella* and Allied Bacteria suggested that the genus *Acinetobacter* should include only the oxidase-negative strains (Lessel, 1971). It was also proposed that the generic name *Achromobacter* be rejected (Hendrie et al., 1974). The strongest evidence that acinetobacters and moraxellas belong to the same family is that DNAs from streptomycin-resistant acinetobacters showed a weak, but consistently positive, transformation of *Moraxella catarrhalis* and *Moraxella osloensis* (Bøvre, 1967), and that relatively strong DNA–rRNA hybridization between the oxidase-positive and oxidase-negative organisms (Johnson et al., 1970) has been demonstrated. These results were supported by 16S rDNA sequence analysis (Pettersson et al., 1998).

The genus *Psychrobacter* contains most of the oxidase-positive strains of the original *Achromobacter* group. *Moraxella*-like psychrotrophic bacteria have been isolated from fish, poultry, and meat products (Gennari et al., 1992). Unlike the moraxellae and similar to some acinetobacters, some psychrobacters are able to form acid from glucose and other sugars. The demonstration of weak transformation of *M. osloensis* and other *Moraxella* species with DNA from streptomycin-resistant psychrotrophic strains (Bøvre and Hagen, 1981) established the relationship of these bacteria to the moraxellae. These organisms were subsequently classified as members of a new genus, *Psychrobacter* (Juni and Heym, 1986b).

Except for strains of *Acinetobacter* and *Psychrobacter*, all other members of the *Moraxellaceae* have been isolated as parasites of humans and other mammals. Several such organisms from sheep, cattle, and pigs have been studied (Bøvre and Hagen, 1981) and two of these, *M. caprae* (Kodjo et al., 1995) and *M. boevrei* (Kodjo et al., 1997), both isolated from goats, have been named. It seems most likely that there are many more species of the *Moraxellaceae* remaining to be discovered, particularly in less well-studied animals.

From studies of DNA–rRNA hybridization a new family, the *Moraxellaceae*, was proposed to accommodate the genera *Moraxella*, *Acinetobacter*, and *Psychrobacter* (Rossau et al., 1991). The family name *Moraxellaceae* is a most appropriate designation since it includes all organisms that have been shown to have genetic interactions with each other using the high-level-streptomycin resistance marker. The family name *Branhamaceae* was proposed to accommodate the spherical and rod-shaped species of *Moraxella* (Catlin, 1991). Unlike the family name *Moraxellaceae*, the proposed family name *Branhamaceae* fails to include *Acinetobacter* and *Psychrobacter*, genera that are clearly members of the same family. A summary of properties of individual members of some of the *Moraxellaceae* is given in Table BXII.γ.130.

Criteria for establishing membership in the *Moraxellaceae* Strains are considered to belong to the family *Moraxellaceae*, provided that preferably all, but at least the first, of the criteria listed below are fulfilled:

1. All strains of the family must show either a weak or a strong genetic interaction of the conserved high-level streptomycin resistance marker with at least one established *Moraxellaceae* strain. Since competence for natural transformation is widespread in the *Moraxellaceae*, there should be no difficulty in satisfying this criterion.
2. 16S rRNA gene sequence similarity of all strains within the family should be significantly greater than is found between a given strain and any other bacterium that does not satisfy criterion 1.
3. In DNA–rRNA hybridizations, using DNA from any member of the *Moraxellaceae* and rRNA from a strain being tested, $T_{m(e)}$ values should be significantly greater for rRNAs derived from all members of the family than the corresponding value obtained using rRNA from any other bacterial strain.

At the present time, available data support criteria 2 and 3. However, because of the heterogeneity of *Acinetobacter* and *Psychrobacter*, as demonstrated by wide variation in DNA base composition, large numbers of species (as determined by DNA–DNA homology), and fairly widespread 16S rRNA gene sequence differences within the *Moraxellaceae*, it is possible that strains belonging to the family that do not fulfill one, or both, of criteria 2 and 3 may be found.

Criteria for distinguishing genera in the *Moraxellaceae* A genus of the *Moraxellaceae* can be distinguished from other genera in the family if it can be determined that one or more of the properties listed below apply to all members of the genus:

1. Distinct phenotypic properties. (Example: only members of the genus *Acinetobacter* are oxidase negative.)
2. Very similar rRNAs, as determined by sequence similarities or by DNA–rRNA relatedness. (Examples: high 16S rRNA gene sequence similarity for strains of the species *M. lacunata*, *M. bovis*, and *M. nonliquefaciens* (Pettersson et al., 1998), all of which are members of the genus *Moraxella*, and unique $T_{m(e)}$ range for strains of the genus *Acinetobacter* and also for strains of the genus *M. osloensis* [Rossau et al., 1991]).
3. In quantitative transformation of the high-level streptomycin resistance marker, demonstration of a ratio of interstrain to intrastrain transformation equal to or greater than 10^{-4}, for a strain being tested and compared with at least one member strain of the genus. (Examples: strains of all species of *Moraxella*, all strains of *M. osloensis*, and all strains of *M. atlantae* [Bøvre and Hagen, 1981; Kodjo et al., 1997]).
4. Ability of DNAs from all strains of a genus to transform a conserved nutritional marker of a competent member of the genus. (Examples: transformation of a *trpE*⁻ auxotroph of *Acinetobacter*, strain BD413 [Juni, 1972], transformation of a *trpE*⁻ auxotroph of a competent strain of *M. osloensis* [Juni, 1974], and transformation of a hypoxanthine and thiamin auxotroph of a competent strain of *Psychrobacter* [Juni and Heym, 1980]).

Criteria for establishing named species in the *Moraxellaceae*

1. Strains of the same species should show 70% or greater DNA–DNA relatedness with 5°C or less ΔT_m (Wayne et al., 1987).
2. Strains of the same species may have one or more phenotypic properties that are unique for members of the species, as defined by DNA–DNA hybridization. (Example: selected phenotypic properties of the named species of *Acinetobacter*.)

Genera and species of *Moraxellaceae*

I. Genus *Moraxella*
  A. *M. lacunata*
    1. "*M. lacunata* subsp. *lacunata*"
    2. "*M. lacunata* subsp. *liquefaciens*"
  B. *M. bovis*
  C. *M. canis*
  D. *M. caprae*
  E. *M. catarrhalis*
  F. *M. caviae*
  G. *M. cuniculi*
  H. *M. equi*
  I. *M. nonliquefaciens*
  J. *M. ovis*

  Species Incertae Sedis

  A. *M. atlantae*
  B. *M. boevrei*
  C. *M. lincolnii*
  D. *M. osloensis*
  E. *M. phenylpyruvica*

II. Genus *Acinetobacter*
  A. *A. baumannii*
  B. *A. calcoaceticus*
  C. *A. haemolyticus*
  D. *A. johnsonii*
  E. *A. junii*
  F. *A. lwoffii*
  G. *A. radioresistens*
  H. *A. venetianus*
  I. Other species: 14 as yet unnamed species (DNA groups 3, 6, 9, 10, 11, TU13, TU14 (= BJ13), TU15, CTTU13, 1-3, BJ14, BJ15, BJ16, and BJ17)

III. Genus *Psychrobacter*
  A. *P. faecalis*
  B. *P. frigidicola*
  C. *P. glacincola*
  D. *P. immobilis*
  E. *P. marincola*
  F. *P. pacificensis*
  G. *P. proteolyticus*
  H. *P. submarinus*
  I. *P. urativorans*

Note concerning the significance of natural transformation in bacterial taxonomy Natural transformation, when it occurs, provides a unique mechanism for recombination of bacterial genes. Most early transformation studies made use of antibiotic resistance markers. Streptomycin resistance, a frequently employed genetic marker, can be expected to give somewhat different results compared with those obtained using other chromosomal markers. Single step mutation to high levels of streptomycin resistance (or dependence) results from specific base changes in DNA coding for the S12 (formerly P10) protein of the small ribosomal subunit (Ozaki et al., 1969). Since genes coding for ribosomal components (proteins and RNAs) have been shown to be highly conserved (Dubnau et al., 1965), transformation of a competent strain with a ribosomal marker DNA from any member of the same bacterial family is possible. Intergeneric transformation of such a marker is generally considerably weaker than intrageneric (interspecies) transformation. It has also been shown, using the streptomycin-resistance marker, that interspecies transformation is usually weaker than intraspecies transformation (Bøvre and Hagen, 1981). Extremely weak intergeneric transformation of the high-level streptomycin-resistance marker has, in the past, led to the conclusion that the interacting strains are members of the same genus. This view is no longer tenable in the light of more recent findings for the existence of several independent genera in the *Moraxellaceae*.

In contrast to ribosomal markers, nutritional markers appear to be limited to intrageneric (interspecies) transformation of competent strains. Studies of a variety of nutritional markers in competent strains have revealed that all of them can undergo intrastrain transformation. Only a relatively small number of them, however, are conserved in the sense that they can be transformed by DNAs from strains of all species of a particular genus. The reason for the conserved behavior of this latter class of nutritional markers is currently not understood. It has been proposed that the ability of DNA from one strain to transform another competent strain signifies that both strains are members of the same genus (Ravin, 1963). Using conserved nutritional markers this hypothesis has been verified for several genera of the *Moraxellaceae*: *Acinetobacter* (*trpE*$^-$ marker) (Juni, 1972), *Psychrobacter* (a hypoxanthine and thiamine marker) (Juni and Heym, 1980), and *M. osloensis* (*trpE*$^-$ marker) (Juni, 1974). The ability of DNAs from a large number of strains of *Oligella* (formally *Moraxella urethralis*) to transform a *trp* $^-$ marker has also been demonstrated (Juni, 1977). In these examples, transformation of the appropriate nutritional mutant by DNA from any strain of the genus has never failed. Furthermore, a false positive reaction with DNA from an organism that is not a member of the same genus has never been observed in these transformation assays. It would thus appear that the ability to transform conserved nutritional markers (but not conserved ribosomal markers) in competent strains of a bacterial genus might, in fact, be the best way to establish membership in that genus.

Using nonconserved nutritional markers, it has been shown that interstrain transformation takes place with high efficiency for strains of the *Moraxella* species *M. catarrhalis* (Juni, 1990), *M. nonliquefaciens* (Juni et al., 1987), and *M. bovis* (Juni et al., 1988). DNAs from other species of *Moraxella* failed to transform either of two *M. catarrhalis* auxotrophs (Juni, 1990). Auxotrophic mutants of *M. nonliquefaciens* and *M. bovis* were also transformed with lower efficiencies by DNAs from some, but not all, species of *Moraxella* (Juni et al., 1987, 1988).

It is possible to transform competent strains of any genus in the family for the ability to grow in the presence of streptomycin, using DNA from a streptomycin-resistant (or dependent) mutant of any strain of the family. Otherwise, the high-level streptomycin-resistance marker resembles conserved nutritional markers in its ability to transform any competent member of the genus from which the streptomycin-resistance marker was obtained. As with the case of conserved nutritional markers, interstrain transformation of the streptomycin-resistance marker can be less efficient than intrastrain transformation (Bøvre and Hagen, 1981). In-

tergeneric transformation of the high-level streptomycin-resistance marker probably occurs because of the conserved nature of all ribosomal genes, which are even more similar in sequence than conserved nutritional markers.

For most genetic markers, interfamily transformation has not been observed. In a rare exception, however, it has been shown that 23S rDNA from a variety of unrelated bacteria can stably transform any of the seven rDNA operons in competent *Acinetobacter* because of the highly conserved nature of rRNA genes (Strätz et al., 1996). It was also shown that the further the phylogenic distance (as determined from 16S rRNA gene sequence data), the lower the frequency of such interfamily transformation (Strätz et al., 1996).

Phylogenetic relationships of the *Moraxellaceae*

DNA–rRNA hybridization analysis DNA–rRNA hybridization and 16S rRNA (or rDNA) nucleotide sequencing of 1000 or more bases are two of the main procedures that have been used to obtain data for establishing phylogenetic relationships (Murray et al., 1990b). The (family) relationships of all genera of the *Moraxellaceae* were originally established by genetic transformation experiments (Bøvre and Hagen, 1981).

DNA–rRNA hybridization studies of the family *Neisseriaceae*, as this family was previously constituted, led to the conclusion that organisms presently considered to be members of the *Moraxellaceae* are not related to the *Neisseriaceae* (Rossau et al., 1986, 1989). Hybridization of rRNA from a strain of *Moraxella lacunata* and a strain of *Psychrobacter immobilis*, to DNAs from strains of all members of the *Moraxellaceae* resulted in a distinct cluster of $T_{m(e)}$ values ($T_{m(e)}$ is the temperature at which one-half of a DNA–rRNA duplex is denatured) ranging from 69.9 to 80.0°C. Significantly lower $T_{m(e)}$ values were obtained for DNAs from strains that were members of other families of rRNA superfamily I, of rRNA superfamily II, and of rRNA superfamilies V and VI (Rossau et al., 1991). $T_{m(e)}$ values for acinetobacters formed a distinct group. The other strains were separated into subgroups of a so-called *Moraxella* group (Rossau et al., 1991). The *Moraxella lacunata* subgroup included strains of the classical "*Moraxella lacunata* group" as well as the coccal species of *Moraxella*, which could not be distinguished from each other by this procedure.

Only three strains of *M. osloensis* were examined. They formed a distinct subgroup when their DNAs were hybridized to "*M. lacunata* subsp. *liquefaciens*" rRNA but were clustered together with the *M. lacunata* subgroup when these DNAs were hybridized to *Psychrobacter immobilis* rRNA (Rossau et al., 1991). Using *M. lacunata* rRNA and DNA from other strains, *M. phenylpyruvica* clustered with strains of *Psychrobacter*. When *Psychrobacter* rRNA was used for hybridization, however, strains of *M. phenylpyruvica* appeared to reside in a unique subcluster. The one strain of *M. atlantae* examined could be assigned to either the *Psychrobacter* or the *Moraxella lacunata* subgroup, depending upon which rRNA was used for hybridization (Rossau et al., 1991).

Although DNA–rRNA hybridization is a useful procedure for establishing membership in the *Moraxellaceae*, results from such studies do not necessarily provide the means for distinguishing genera, or species of a particular genus, within the family.

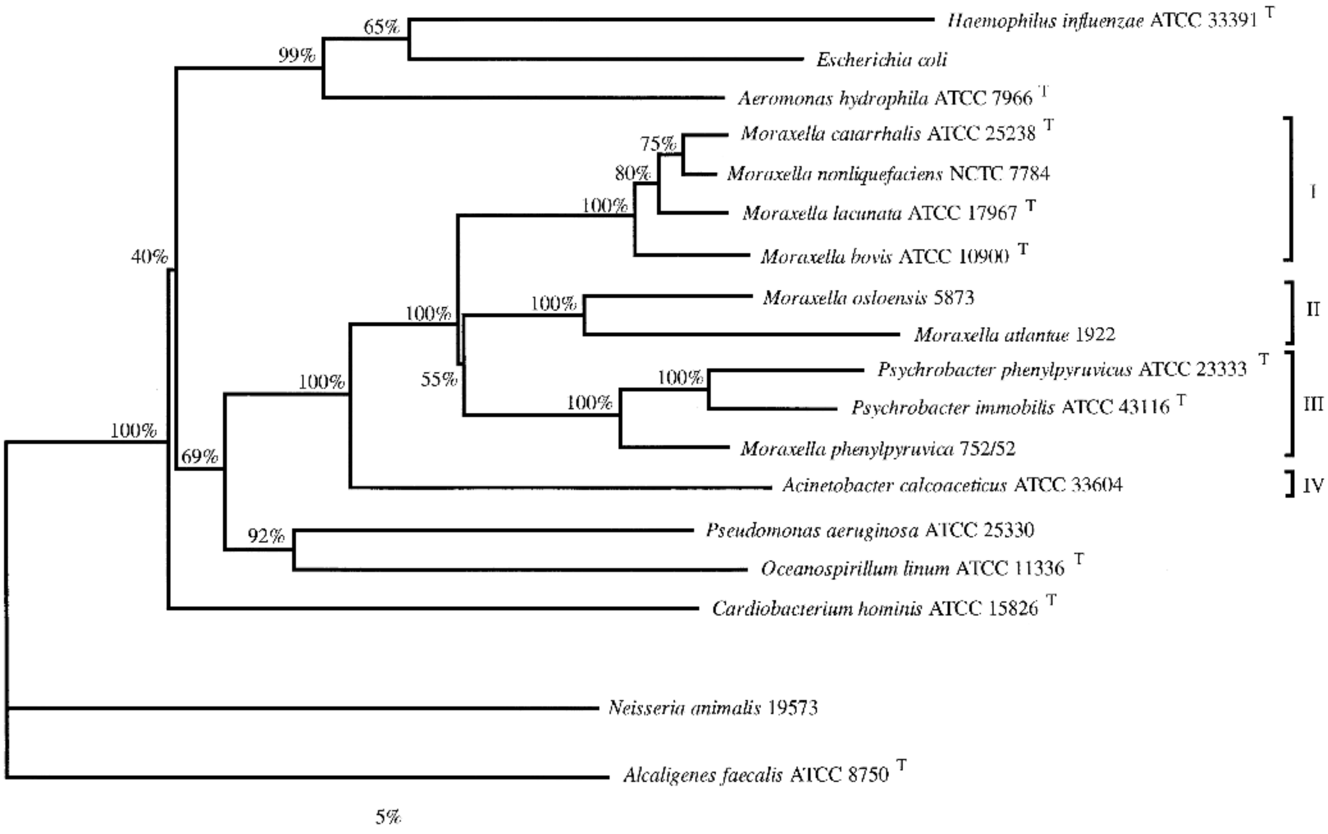

FIGURE BXII.γ.146. Phylogenetic tree based on distance matrix analysis of 1355 positions in the 16S rRNA genes for selected members of *Moraxellaceae*. (Reproduced with permission from B. Pettersson et al., International Journal of Systematic Bacteriology *48:* 75–89, 1998, ©International Union of Microbiological Societies.)

16S rRNA gene sequence analysis 16S rRNA gene sequence analysis is similar to DNA–rRNA hybridization in that it enables isolated strains to be recognized as members of the *Moraxellaceae*. With both procedures, it was possible to demonstrate that the genera *Acinetobacter*, *Moraxella*, and *Psychrobacter* are not members of the *Neisseriaceae* (Rossau et al., 1991; Enright et al., 1994).

A phylogenetic study of 33 strains, including 11 (previously designated) species of the family *Moraxellaceae*, by 16S rDNA sequence analysis (Pettersson et al., 1998) showed that the family *Moraxellaceae* formed a distinct clade consisting of four phylogenetic groups, as determined from branch lengths, bootstrap values, and signature nucleotides (Fig. BXII.γ.146). Group I contained the classical and coccal *Moraxella* species. Group II consisted of *Moraxella osloensis* and *Moraxella atlantae*. Group III contained strains of *Psychrobacter* and a single strain of *Moraxella phenylpyruvica*. Group IV contained two strains of *Acinetobacter*. The phylogenetic tree showed that the members of the *Moraxellaceae* constituted a monophyletic taxon forming a distinct line of decent within the *Gammaproteobacteria*. A phylogenetic tree for organisms belonging to group I is shown in Fig. BXII.γ.147.

16S rRNA nucleotides U and A in positions 514 and 537, respectively, flank a highly conserved oligonucleotide that should be useful for the development of diagnostic probes for detection of members of the *Moraxellaceae* (Pettersson et al., 1998). Phylogenetic conclusions regarding individual genera of the *Moraxellaceae* will be discussed below, along with the other features of each genus. Studies of other bacterial families have shown that information obtained through phylogenetic analysis of 16S rRNA does not necessarily parallel results obtained by DNA–DNA hybridization at the species level (Stackebrandt and Goebel, 1994).

As this volume was going to press, it was noticed that the genus *Enhydrobacter* (Staley et al., 1987) resembles a genus of the *Moraxellaceae*, based on 16S rRNA sequence similarity (sequence similarity was determined using the RDP Sequence Match program and comparing *Enhydrobacter aerosaccus* strain LMG 21877 = ATCC 27094^T (AJ550856) to the NCBI database). The nearest-neighbors of *Enhydrobacter aerosaccus* were *Moraxella osloensis* strains Ben 58 (X95304), 5873 (AF005190), PIV-10-1 (AJ505859), and AU1220 (AY043376) with S_{AB} values ranging from 0.956–0.973 and *M. osloensis* strain 3 (Y15855), S_{AB} = 0.893.

It should be noted, however, that *Enhydrobacter* DNA has a mol% G + C of 66, whereas the mol% G + C values of other genera in the family *Moraxellaceae* range from 38–50. In addition, *Enhydrobacter*, unlike all members of the *Moraxellaceae*, has several other unique properties, such as an extremely slow growth rate, growth at an optimum temperature of 37–39°C, ability to carry out sugar fermentations, and being gas-vacuolated. Although the relationship of *Enhydrobacter* 16S rRNA to that of *M. osloensis* suggests that *Enhydrobacter* may be a member of the *Moraxellaceae*, the several startlingly unusual properties of *Enhydrobacter* cast doubt on this conclusion.

It might be considered that 16S rDNA in *Enhydrobacter* may have been derived from *M. osloensis* by horizontal gene transfer or by mutation of 16S rDNA in an unrelated strain over eons of time resulting in the rRNA sequence in *Enhydrobacter* that is presently observed. It is also possible that a strain of *M. osloensis* may

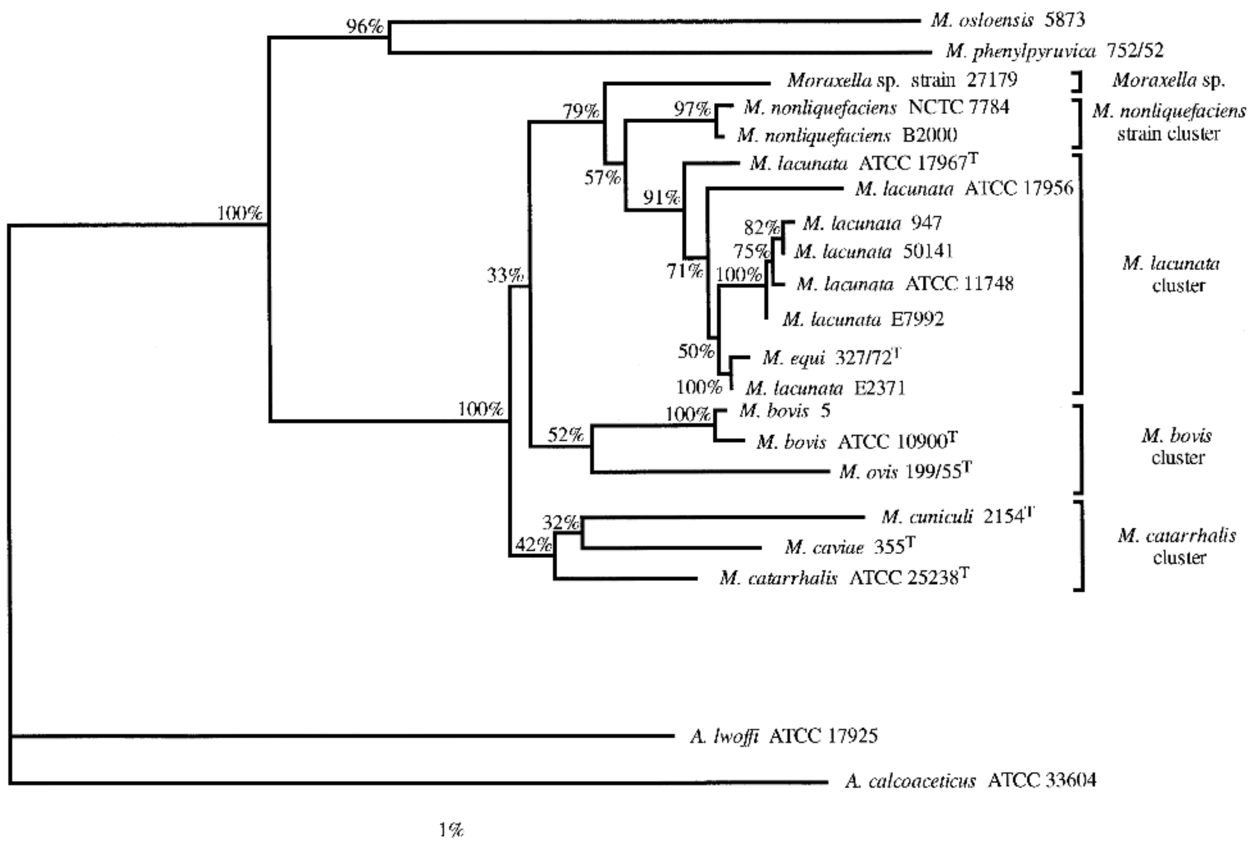

FIGURE BXII.γ.147. Phylogenetic tree based on distance matrix analysis of 1440 positions in the 16S rRNA genes of the moraxellae. (Reproduced with permission from B. Pettersson et al., International Journal of Systematic Bacteriology *48:* 75–89, 1998, ©International Union of Microbiological Societies.)

have undergone very extensive genetic modification of the many genes responsible for the unique phenotypes described above resulting in the organism now referred to as *Enhydrobacter*. In any case, this dilemma can be resolved readily by checking for ability of DNA from a high level streptomycin-resistant mutant of *Enhydrobacter* to transform competent strains of *M. osloensis*, or any of several other competent strains of several genera of the *Moraxellaceae* where even a weak, but reproducible, transformation would prove that *Enhydrobacter* is indeed a member of the *Moraxellaceae*. Also, *Enhydrobacter* DNA should be tested for ability to transform the genus-specific *trpE*$^-$ mutant (Juni, 1974) where, once again, a positive result would prove that *Enhydrobacter* is a member of the *Moraxellaceae*. Until such tests are performed, it is premature to consider that *Enhydrobacter* is a member of the *Moraxellaceae* based solely on 16S rRNA data.

Acknowledgments

This manuscript is dedicated to the memory of Kjell Bøvre, friend and colleague. It is largely because of his critical studies that we now have a much better understanding of the moraxellae.

Genus I. **Moraxella** *Lwoff 1939, 173, emend. Henriksen and Bøvre 1968, 391*[AL]

Elliot Juni and Kjell Bøvre

Mo.rax.el' la. M.L. dim. *-ella* ending; M.L. fem. n. *Moraxella* named after V. Morax, a Swiss ophthalmologist who pioneered the recognition of the type species.

Rods or cocci. The rods are often very short and plump, frequently approaching a coccus shape (1.0–1.5 × 1.5–2.5 μm); they usually occur in pairs and short chains (one plane of division). Variation in cell size, shape, and filament or chain formation is often seen in cultures, the pleomorphism being enhanced by lack of oxygen and by incubation temperatures above the optimum. **The cocci are usually smaller** (0.6–1.0 μm in diameter) and occur as single cells or in pairs with the adjacent sides flattened (differing planes of division); division in two planes at right angles to each other sometimes results in the formation of tetrads. Gram negative, but often with a tendency to resist Gram decolorization. Flagella are absent. Both rod-shaped and coccal species may be fimbriated. Swimming motility is absent, but surface-bound "twitching motility" has been observed in some rod-shaped species. **Aerobic, but some strains may grow weakly under anaerobic conditions.** May be encapsulated. Chemoorganotrophic. Most species are nutritionally fastidious and all grow on complex media; some are stimulated significantly by fatty acids (bile salts, Tween 80). Optimum temperature for growth, 33–35°C. **Colonies are not pigmented. Oxidase positive** (with either tetra- or dimethyl-*p*-phenylenediamine reagent). **Usually catalase positive. No acid is produced from carbohydrates.** Usually highly sensitive to penicillin. Parasitic on the mucous membranes of humans and other warm-blooded animals. Strains of the several species of this genus have been shown to be genetically closely related by transformation of the high-level streptomycin resistance marker (Bøvre and Hagen, 1981) as well as by transformation of nutritional markers (Juni et al., 1987, 1988; Juni, 1990). DNA–DNA hybridization studies have shown high relative interspecies binding ratios for DNAs from strains of the genus *Moraxella* (Tønjum et al., 1989). Species of *Moraxella* share 95% similarity in their 16S rRNA gene sequences.

The mol% G + C of the DNA is: 40.0–47.5 (T_m, Bd, HPLC).

Type species: **Moraxella lacunata** (Eyre 1900) Lwoff 1939, 173 (*Bacillus lacunatus* Eyre 1900, 5; (*Moraxella (Moraxella) lacunata* (Eyre 1900) Bøvre 1979, 404.)

List of species of the genus Moraxella

1. **Moraxella lacunata** (Eyre 1900) Lwoff 1939, 173[AL] (*Bacillus lacunatus* Eyre 1900, 5; (*Moraxella (Moraxella) lacunata* (Eyre 1900) Bøvre 1979, 404.)*
la.cu.na' ta. L. n. *lacuna* a shallow depression; M.L. fem. adj. *lacunata* pitted.

Two subspecies of *Moraxella lacunata* have been recognized (Henriksen, 1969).

The mol% G + C of the DNA is: 40.0–44.5.

Type strain: ATCC 17967, NCTC 11011.

GenBank accession number (16S rRNA): AF005160, AF005170, D64049.

a. **"Moraxella lacunata** *subsp.* **lacunata"**

Medium thick to plump rods, 0.8–1.2 μm in diameter, coccoid to distinctly bacillary, occurring predominantly in pairs and short chains. Frequently pleomorphic. May form narrow capsules. Colonies on blood agar are small (0.1–0.3 mm in diameter). Colonies are translucent to semiopaque. Pitting of the agar may be observed. No hemolysis occurs, but on heated blood (chocolate) agar, large dark zones around the colonies usually occur.

Strains may show improved growth on chocolate agar medium and may not grow on certain rich media without serum or oleic acid. They are unable to grow on medium MB, a defined medium that supports growth of strains of *M. bovis* (Juni et al., 1988). Other characteristics of

Editorial Note: Neither *"Moraxella lacunata* subspecies *lacunata"* nor *"Moraxella lacunata* subspecies *liquefaciens"* are validly published names.

the species are given in Table BXII.γ.130 of the description of the family *Moraxellaceae*. Human strains have been derived mainly from inflamed, as well as healthy, conjunctiva and from sites in the upper respiratory tract (Graham et al., 1990). They have occasionally been isolated from the blood. Attachment to epithelial tissues is mediated by type 4 pili (Ruehl et al., 1988), which are regulated by the *piv* gene. This gene encodes a site-specific DNA invertase (Marrs et al., 1990), the transcription of which is initiated at *pivp*, a σ^{70}-dependent promoter (Heinrich and Glasgow, 1997). The organism appears to be a significant causative agent of human conjunctivitis (and keratitis) and was more frequently isolated in the past. It is only rarely isolated at the present time.

The mol% G + C of the DNA is: 40.0–44.5 (Bd).

Type strain: none.

GenBank accession number (16S rRNA): AF005170.

Additional Remarks: There is presently no type strain of this subspecies; the previously listed type strain, ATCC 17967 (NCTC 11011), is actually a strain of *"M. lacunata* subsp. *liquefaciens"*. Strain ATCC 11748 (NCTC 10748) should be proposed as the neotype strain since it has typical properties of the species, as well as being competent for natural transformation.

b. **"Moraxella lacunata** *subsp.* **liquefaciens"**
li.que.fa' ciens. M.L. part. adj. *liquefaciens* dissolving.

This subspecies is very similar to *"M. lacunata* subsp. *lacunata"* in morphology and in its response to most conventional tests, but differs in being able to grow on media without serum and to liquefy the usual gelatin media. *"M. lacunata* subsp. *liquefaciens"* was first described as the cause of keratitis. It has also been isolated from cases of endocarditis and sinusitis. Less fastidious than *"M. lacunata* subsp. *lacunata"* (Bøvre, 1965c); can grow in a defined medium (medium MB) containing 11 growth factors (Juni et al., 1988). Colonies on blood agar medium have a greater diameter (~3 mm) than colonies of *"M. lacunata* subsp. *lacunata"*. Properties enabling further distinction between strains of *"M. lacunata* subsp. *liquefaciens"* and *"M. lacunata* subsp. *lacunata"* are discussed below. A number of isolates from the conjunctiva of healthy guinea pigs were shown to have the same morphological, cultural and biochemical reactions as *"M. lacunata* subsp. *liquefaciens"* (Ryan, 1964). Furthermore, quantitative transformation studies, using high-level streptomycin-resistance markers, revealed that two of these guinea pig isolates were very closely related to authentic strains of *"M. lacunata* subsp. *liquefaciens"* (Bøvre, 1965c). Because there are antigenic differences between guinea pig isolates and an authentic strain of *"M. lacunata* subsp. *liquefaciens"* (Ryan, 1964), it is possible that the animal strains represent another distinct subspecies of *M. lacunata*.

The mol% G + C of the DNA is: 41.5–43 (Bd).

Type strain: ATCC 17952, NCTC 7911 should be proposed as the neotype strain.

GenBank accession number (16S rRNA): AF005169.

Further comments The occurrence of genetically competent strains permits identification by quantitative genetic transformation (Bøvre and Hagen, 1981; Tønjum et al., 1992). Although *"M. lacunata* subsp. *lacunata"* and *"M. lacunata* subsp. *liquefaciens"* have many phenotypic similarities and cannot be differentiated readily based on 16S rRNA gene sequence analysis (Pettersson et al., 1998), it is possible to accomplish this by comparison of certain phenotypic properties. It has long been known that strains of *"M. lacunata* subsp. *lacunata"* are more nutritionally fastidious and generally have smaller colonies on blood agar medium than strains of *"M. lacunata* subsp. *liquefaciens"* (Bøvre, 1965c; Bøvre and Hagen, 1981). Studies of a collection of bacteria, received as strains of *M. lacunata*, showed that not all of these strains could grow on a defined medium (medium MB) suitable for growth of strains of *M. bovis* (Juni et al., 1986; 1988); one group of these strains (group 1) being able to grow on medium MB whereas strains of a second group (group 2) being unable to grow on this medium. It was subsequently shown that group 1 consisted of strains of *"M. lacunata* subsp. *liquefaciens"* whereas strains in group 2 consisted of strains of *"M. lacunata* subsp. *lacunata"* (Tønjum et al., 1992).

Furthermore, other studies of a collection of strains identified as *M. lacunata* based on results of classical phenotypic tests disclosed that these organisms fell into two classes based on their respective cellular fatty acid profiles (Moss et al., 1988). Profiles I and II are characteristic for strains of *"M. lacunata* subsp. *liquefaciens"* and *"M. lacunata* subsp. *lacunata"*, respectively. Many of the same strains were used in both the nutritional (Juni et al., 1988) and fatty acid studies (Moss et al., 1988).

Although there was some overlap, the clustering of strains of *"M. lacunata* subsp. *lacunata"* and *"M. lacunata* subsp. *liquefaciens"* into distinct groups was also apparent from total genomic DNA–DNA hybridization, (Tønjum et al., 1992). These two subspecies were also distinguished based on genetic variation of 12 enzyme loci (Tønjum et al., 1992). In quantitative transformation studies using the high-level streptomycin-resistant marker, it was shown that *"M. lacunata* subsp. *lacunata"* and *"M. lacunata* subsp. *liquefaciens"* were closely related but could, nevertheless, be distinguished from each other (Tønjum et al., 1992).

The different nutritional requirements and different cellular fatty acid patterns, as well as variation of enzyme loci of the subspecies, suggest that these two organisms normally occupy different ecological niches. *"M. lacunata* subsp. *lacunata"* may normally reside at a site so well supplied with nutrients that it has, over eons of time, evolved and lost considerable biosynthetic ability. By contrast, *"M. lacunata* subsp. *liquefaciens"* may reside at a site deficient in certain nutrients and has evolved to synthesize those growth factors not supplied at its normal host site, while losing the ability to synthesize growth factors not required at this site. This accounts for its relatively increased biosynthetic ability. Evolution in membrane structure, as indicated by different fatty acid compositions of the two subspecies, may result in membranes that, in some manner, contribute to the ability to compete successfully with other bacteria for access to a particular site. If these properties do, in fact, contribute to the ability to preferentially occupy certain sites, it would seem prudent to compare phenotypic properties, such

as those described above, when attempting to allocate bacteria to species since these may be the very factors that determine speciation. The subspecies nomenclature is retained pending a more precise definition of the terms species/subspecies as well as further possible findings regarding other different characteristics of the entities.

Phylogeny of the *Moraxella lacunata* cluster A phylogenetic study of the *Moraxellaceae* by 16S rDNA sequence analysis revealed four distinct groups (Pettersson et al., 1998) (Fig. BXII.γ.146). Strains of *Moraxella* were shown to reside in three clusters of group 1 (Fig. BXII.γ.147). A so-called *M. lacunata* cluster included 13 strains of "*M. lacunata* subsp. *lacunata*", "*M. lacunata* subsp. *liquefaciens*", and *M. equi*. Eight strains of this cluster had unique 16S rRNA gene sequences, and interstrain similarity values within the cluster ranged from 98.4 to 99.9% (Pettersson et al., 1998). Five strains of "*M. lacunata* subsp. *lacunata*", obtained from different geographic regions, clustered tightly together, and shared 99.8% 16S rRNA gene nucleotide similarity (Pettersson et al., 1998).

2. **Moraxella bovis** (Hauduroy, Ehringer, Urbain, Guillot and Magrou 1937) Murray 1948, 591[AL] (*Haemophilus bovis* Hauduroy, Ehringer, Urbain, Guillot and Magrou 1937, 247; *Moraxella (Moraxella) bovis* (Hauduroy, Ehringer, Urbain, Guillot and Magrou 1937) Bøvre 1979, 404.)
bo'vis. L. gen. n. *bovis* of cattle.

Rods, showing variation in shape, size and arrangement. The cells are often fimbriated and show "twitching motility." A distinct variation in colony type occurs. Freshly isolated strains form hemispherical to flat colonies (~1 mm in diameter in 48 h) on blood agar; they corrode the agar and often show surface spreading. These characteristics are associated with fimbriation of the cells and "twitching motility" (Bøvre and Frøholm, 1972b; Henrichsen et al., 1972; Pedersen et al., 1972). The texture of such colonies is often friable. Nonfimbriated variants occur spontaneously in cultures and form noncorroding, nonspreading colonies which are convex and usually larger than their corroding counterparts (often 3.0 mm after 48 h), and have a butyrous consistency. Fimbriated cells of collection strains may also form large colonies, but these may be less corroding than the colonies of fresh isolates. With few exceptions, bovine strains produce distinct hemolytic zones around colonies. Dark zones are produced on chocolate agar. Nutritionally fastidious. Other characteristics are listed in Table BXII.γ.130 of the description of the family *Moraxellaceae*.

Most frequently isolated from bovine eyes in cases of infectious keratoconjunctivitis, but has also been isolated from unaffected eyes and the nasal cavity of cattle, the eyes of sheep and mice, but not the eyes of rats, rabbits, or guinea pigs. Considered as potentially pathogenic for animals, dependent on accessory factors to elicit disease. Conjunctival colonization and disease development in UV-irradiated bovine eyes have been found associated with fimbriation of the bacteria (Pedersen et al., 1972).

Further comments Growth of most strains of *M. bovis* occurs in a defined medium containing 11 growth factors (Juni and Heym, 1986a). The cells are frequently transformable, genetic competence being associated with fimbriation (piliation) and corrosion (Bøvre and Frøholm, 1972a). A *M. bovis* pilin gene has been cloned and sequenced (Marrs et al., 1985; Rozsa and Marrs, 1991). Strains may be identified by quantitative genetic transformation of the high-level streptomycin resistance marker (Bøvre, 1965a, c), or qualitatively by transformation of an auxotrophic mutant of a competent strain (Juni et al., 1988). The species is slightly genetically heterogeneous, with interstrain transformation affinities as low as 10% of intrastrain transformation affinities (Bøvre, unpublished results). A so-called *M. bovis* cluster consisting of strains of *M. bovis* and *M. ovis* has been observed in phylogenetic studies involving 16S rRNA gene sequence analysis (Fig. BXII.γ.147); the 16S rRNA genes of *M. bovis* and *M. ovis* were 97.1–97.4% similar (Pettersson et al., 1998).

Two sequence-specific endonucleases (*Mbo*I and *Mbo*II) have been demonstrated in *M. bovis*, ATCC 10900 (Gelinas et al., 1977). The genes encoding the *Mbo*I restriction-modification enzymes are adjacent to each other with this gene cluster encoding two distinct methyl transferases (Ueno et al., 1993) and have been cloned and expressed in *E. coli*. An enzyme from *M. bovis* that methylates the *Mbo*II recognition sequence has been purified (McClelland et al., 1985). The two genes encoding this class II restriction-modification system are located adjacent to each other and have each been cloned separately in *E. coli* (Bocklage et al., 1991). Details of the interaction of the *Mbo*II restriction endonuclease with its DNA target site have been investigated (Sektas et al., 1995).

The mol% G + C of the DNA is: 42.5–43 (Bd).
Type strain: ATCC 10900.
GenBank accession number (16S rRNA): AF005182.

3. **Moraxella canis** Jannes, Vaneechoutte, Lannoo, Gillis, Vancanneyt, Vandamme, Verschraegen, Van Heuverswyn and Rossau 1993, 448[VP]
ca'nis. L. gen. n. *canis* of a dog.

Cells are cocci (diameter ~0.8–1.3 μm) and usually occur in pairs or short chains. Gram negative, but there may be a tendency to resist decolorization. A brown pigment may be observed on Mueller–Hinton agar. Cells are nonmotile in liquid medium. Chemoorganotrophic and aerobic. Mesophilic. Cell growth is usually observed on a medium containing mineral salts and ammonium acetate, on lactose– bromothymol blue agar, on eosine–methylene blue agar, on Mueller–Hinton medium, and on MacConkey agar at 37°C. Growth occurs on Mueller–Hinton agar at room temperature. No growth occurs in the presence of 6% NaCl or at 5°C. Usually indifferent to bile salts. Oxidase and catalase positive. Extracellular DNase, butyrase, esterase, and γ-glutamyl-aminopeptidase are produced. Phenylalanine deaminase, indole, urease, and carbonic anhydrase are not produced. No acid is produced from glucose. Tween 80 and starch are not hydrolyzed. Autoagglutination in physiological solution is usually not observed. Gelatin and serum are not liquefied. No hemolysis of human and sheep blood occurs. The major fatty acids are oleic acid ($C_{18:1\ \omega 9c}$) and palmitoleic acid ($C_{16:1\ \omega 7c}$). Isoheptadecanoic acid ($C_{17:0\ iso}$) is present in moderate amounts, and myristic acid ($C_{14:0}$) is absent. Typical characteristics are listed in Table BXII.γ.130 of the description of the family *Moraxellaceae*.

Isolated from the saliva of dogs or cats and occasionally

from humans (dog bite wounds or blood). Pathogenicity is not known.

Further comments Strains are frequently competent for genetic transformation. Transformation studies of strain NCTC 4103 (ATCC 23246), originally considered a strain of *M. catarrhalis*, showed that this strain interacted weakly with authentic strains of *M. catarrhalis* (Catlin and Cunningham, 1964). In an investigation involving transformation of nutritional mutants of *M. catarrhalis* and NCTC 4103, it was shown that strain NCTC 4103 is more closely related to *M. canis* than to *M. catarrhalis* (Juni, 1990). Significant levels of DNA–DNA relatedness (52–61%) were found between strain NCTC 4103 and strains of *M. canis*, and it has been suggested that strain NCTC 4103 occupies a position somewhere between *M. catarrhalis* and *M. canis* (Jannes et al., 1993). From the results of a polyphasic taxonomic investigation, it was concluded that strains of *M. canis* constitute a distinct cluster within the genus *Moraxella* (Jannes et al., 1993).

A review of the properties of *M. catarrhalis* appeared in 1992 (Doern, 1992).

The mol% G + C of the DNA is: 45.9–47.5 (T_m).

Type strain: N7, CCUG 8415A, LMG 11194.

4. **Moraxella caprae** Kodjo, Tønjum, Richard and Bøvre 1995,471[VP]

ca'prae. L. gen. n. *caprae* of a goat.

Gram negative. Medium to large straight rods with a tendency to grow as diplobacilli or in short chains. Nonmotile, aerobic, and grow well at temperatures between 30 and 37°C. Colonies are grayish white, smooth, and convex, vary in size from 1 to 1.5 mm, and are surrounded by a wide area of hemolysis after 36–48 h of aerobic incubation on 5% blood agar plates. Grow poorly on nutrient agar. Oxidase and catalase positive. All strains hydrolyze Tween 80 and tributyrin and reduce nitrate. No acid is produced from carbohydrates. All strains are nonproteolytic (Loeffler slant and gelatin negative). Indole and urease reactions are also negative. The main features that distinguish *M. caprae* from *M. bovis* are reduction of nitrate and absence of proteolysis. Other characteristics are listed in Table BXII.γ.130 of the description of the family *Moraxellaceae*. The clinical significance of this organism is not known. All strains were isolated from the nasal cavity of healthy goats.

Further comments Strains of *M. caprae* have a high degree of genetic affinity to *M. bovis*, as shown by quantitative and qualitative genetic transformation assays, and exhibit high DNA–DNA relative binding ratios to each other, but lower levels of DNA relatedness to all other species of *Moraxella* (Kodjo et al., 1995). None of the eight strains of *M. caprae* tested was competent for genetic transformation.

The mol% G + C of the DNA is: 40–41.5 (HPLC).

Type strain: CCUG 33296, NCTC 12877.

5. **Moraxella catarrhalis** (Frosch and Kolle 1896) Henriksen and Bøvre 1968, 391[AL] (*Mikrokokkus catarrhalis* Frosch and Kolle *in* Flügge 1896, 15; *Branhamella catarrhalis* (Frosch and Kolle 1896) Catlin 1970, 157; *Moraxella (Branhamella) catarrhalis* Bøvre 1979, 404.)

ca.tarrh.a'lis. Gr. adj. *catarrhus* downflowing, catarrh; M.L.adj. *catarrhalis* of catarrh.

Cocci; division in two planes at right angles to each other and tetrad formation may be observed. May be fimbriated. Colonies are approximately 2.0 mm in diameter in 48 h, opaque, hemispherical, becoming considerably larger and convex, almost flat, on prolonged incubation. They usually have a friable texture and can be shifted around and picked from the agar without losing their semi-convex shape and without adherence to the agar. They are nonhemolytic. Extracellular DNase is produced. Other characteristics are listed in Table BXII.γ.130 of the description of the family *Moraxellaceae*.

Previously, as a rule, highly sensitive to penicillin, but strains resistant because of β-lactamase production are now generally encountered. Frequently isolated from the human nasopharynx, which appears to be its main natural habitat (Murphy, 1996). Has also been isolated from inflammatory secretions of the middle ear and maxillary sinus, from bronchial aspirate in bronchitis and pneumonia, and occasionally from systemic infections. The organism is most often considered to be a well-adapted parasite, but it is also a significant cause of disease in both the upper and lower respiratory tracts. It is responsible for otitis media and sinusitis in children and infants (Murphy, 1996; Enright and McKenzie, 1997; Catlin, 1990).

Further comments *M. catarrhalis* has been shown to possess several outer membrane proteins; the outer membrane protein profiles of this organism are highly conserved (Murphy, 1996). It produces a rough-type lipopolysaccharide attached to a lipid A moiety, and lacks high-molecular-mass O-polysaccharide chains (Johnson et al., 1976). There are at least three serotypes of *M. catarrhalis* lipopolysaccharide (Vaneechoutte et al., 1990).

The cells are frequently competent for genetic transformation and are easily identified by transformation procedures. In a qualitative transformation assay, in which nutritional mutants of a competent strain of *M. catarrhalis* were transformed to prototrophy with homologous wild-type DNA, DNAs from 20 independently isolated strains of *M. catarrhalis* all transformed these mutants with the same efficiency (Juni, 1990). In quantitative transformations, comparing ratios of interstrain to intrastrain transformation of the high-level streptomycin-resistance marker, a competent strain of *M. catarrhalis* showed extremely poor transformation (ratios $<5 \times 10^{-5}$) with DNAs from representative strains of most species of *Moraxella*. The exception was *M. cuniculi*, where a ratio of 1×10^{-3} was obtained (Bøvre and Hagen, 1981). In another study of transformation of the high-level streptomycin-resistance marker, an affinity ratio $>10^{-4}$ for *M. catarrhalis* and *M. bovis* was observed (Kodjo et al., 1997).

The amino acids glycine and arginine are the principal growth factors in a defined medium for all strains of *M. catarrhalis* (Juni et al., 1986).

The species appears genetically homogeneous, but one deviating strain, NCTC 4103 (ATCC 23246), has been detected (Catlin and Cunningham, 1964; Bøvre, 1965b, 1980; Bøvre and Hagen, 1981). Strain NCTC 4103 was originally reported to show a significant level (≤59%) of DNA–DNA hybridization with *M. catarrhalis* (Rossau et al., 1991), but these results could not be reproduced in a subsequent study (Jannes et al., 1993).

Phylogenetic investigations based on 16S rRNA gene sequence analysis place *M. catarrhalis*, *M. cuniculi*, and *M. caviae* together in a somewhat diverse cluster (Pettersson et

al., 1998). A review of the properties of *M. catarrhalis* appeared in 1992 (Doern, 1992).

The mol% G + C of the DNA is: 40–43 (Bd).

Type strain: Ne 11, ATCC 25238, NCTC 11020.

GenBank accession number (16S rRNA): AF005185.

6. **Moraxella caviae** (Pelczar 1953) Henriksen and Bøvre 1968, 391[AL] (*Neisseria caviae* Pelczar 1953, 744; *Moraxella (Branhamella) caviae* (Pelczar 1953) Bøvre 1979, 404.)
ca' vi.ae. M.L. fem. n. *Cavia* generic name of the guinea pig; M.L. gen. n. *caviae* of *Cavia*.

Cocci commonly arranged in pairs with adjacent sides flattened; division in two planes at right angles to each other. Tetrad formation may be observed. The colonies are low, conical, and have a diameter of approximately 2.5 mm in 48 h. They are semiopaque and have a butyrous consistency. Weak hemolysis may be observed, and in this respect, the colonies may resemble those of *M. ovis*.

Sensitive to penicillin, but in some studies the organism has been shown to resist 0.1 U/ml penicillin. Other characteristics are listed in Table BXII.γ.130 of the description of the family *Moraxellaceae*. Isolated from the pharynx and mouth of healthy guinea pigs.

Further comments All strains examined are noncompetent for genetic transformation. In quantitative transformation of the high-level streptomycin-resistance marker to competent strains of *M. catarrhalis* and *M. cuniculi*, the ratios of interstrain to intrastrain transformation were extremely low (2×10^{-5} and 5×10^{-5}, respectively), but a higher ratio of 5×10^{-4} for transformation of *M. ovis* (Bøvre and Hagen, 1981) was found. Similar transformation studies involving DNA from streptomycin-resistant *M. caviae* resulted in extremely low interactions with competent strains of *M. bovis* (Henriksen, 1973). Phylogenetic studies of 16S rRNA gene sequences place one strain of *M. caviae* in the same, somewhat unstable, cluster, which includes *M. catarrhalis* and *M. cuniculi* (Pettersson et al., 1998). It would appear that *M. caviae* might be the most distantly related species of *Moraxella*.

The mol% G + C of the DNA is: 44.5–47.5 (Bd).

Type strain: ATCC 14659, CCUG 355, NCTC 10293.

7. **Moraxella cuniculi** (Berger 1962) Bøvre and Hagen 1984, 355[VP] (Effective publication: Bøvre and Hagen 1981, 1522) (*Neisseria cuniculi* Berger 1962, 455.)
cun.i' cu.li. L. gen. n. *cuniculi* of the rabbit.

Cocci commonly arranged in pairs with adjacent sides flattened; division in two planes at right angles to each other. Tetrad formation may be observed. The colony size in 48 h is similar to, or slightly smaller than, that of *M. catarrhalis*. The colonies are conical, opaque, and often friable. Nonhemolytic. Isolated from the mouths of healthy rabbits. No evidence of pathogenicity. Other characteristics are listed in Table BXII.γ.130 of the description of the family *Moraxellaceae*.

Further comments Using the high-level streptomycin-resistance marker, ratios of interstrain to intrastrain transformation of 2×10^{-3}, 2×10^{-4}, and 1×10^{-4} for interaction with *M. catarrhalis*, *M. ovis*, and *M. lacunata*, respectively, were obtained (Bøvre and Hagen, 1981); these results verify that *M. cuniculi* is a species of the genus *Moraxella*. Only low level DNA–DNA hybridization between *M. cuniculi* and either *M. ovis* or *M. caviae* could be demonstrated (Véron et al., 1993). The type strain is competent for genetic transformation, making genetic identification of new isolates possible.

The mol% G + C of the DNA is: 44.5 (Bd).

Type strain: ATCC 14688, NCTC 10297.

8. **Moraxella equi** Hughes and Pugh 1970, 457[AL]
e' qui. L. gen. n. *equi* of the horse.

Nonmotile diplococcus. Colonies on blood agar are 0.5–1.0 mm in diameter, resembling *M. bovis*, but are nonhemolytic and butyrous. Other properties resemble those of *M. bovis*. Oxidase and catalase positive. Produces an alkaline reaction in several carbohydrate fermentation media, grows well on Herellea agar, unlike *M. bovis* which reportedly fails to grow on Herellea agar (Hughes and Pugh, 1970). Liquefies gelatin at 37°C, does not produce ornithine or lysine decarboxylases, does not reduce nitrate to nitrite, does not produce H_2S or indole, and does not grow on Simmons citrate medium, KCN medium, or urea broth. Precipitin lines indistinguishable from those with control homologous antiserum were produced when *M. equi* cells were tested against three *M. bovis* antisera (Hughes and Pugh, 1970).

Isolated from the eyes of two groups of horses and ponies that had signs of conjunctivitis and erosion of the epithelium of their eyelid margins. Becomes established when introduced into equine eyes but not into bovine eyes, in contrast to *M. bovis*, which does not survive in equine eyes (Hughes and Pugh, 1970).

Further comments *M. equi* has shown overlapping affinities in streptomycin-resistance transformation with some bovine isolates of *M. bovis* (Bøvre, unpublished results); an interstrain to intrastrain transformation ratio of 8×10^{-2} was found for interaction with the type strain of *M. bovis* (Kodjo et al., 1995). *M. equi* was indistinguishable from strains of *"M. lacunata* subsp. *liquefaciens"* in ability to grow on a defined medium containing 11 growth factors, and in transformation of nutritional mutants of *M. bovis* (Juni et al., 1988), such transformations being significantly less efficient than those observed with DNAs from strains of *M. bovis* (Juni et al., 1988). Furthermore, the 16S rRNA gene of *M. equi* has a sequence similarity of 99.9% to that of a strain of *"M. lacunata* subsp. *liquefaciens"* (Pettersson et al., 1998). Nevertheless, in DNA–DNA hybridization and multilocus enzyme electrophoresis studies *M. equi* and *M. bovis* are virtually indistinguishable (Tønjum et al., 1992). *M. equi* and *M. bovis* do not show a close relationship to *"M. lacunata* subsp. *liquefaciens"* in DNA–DNA hybridization (Tønjum et al., 1992). These findings confirm that *M. equi* is a unique *Moraxella* species. It might be considered that *M. equi* first appeared when DNA from either *M. bovis* or *"M. lacunata* subsp. *liquefaciens"* was transferred from one to the other and integrated into the chromosome of the recipient strain, resulting in a hybrid strain. Such a strain may have survived because it is better suited to occupy certain specific sites in the horse. Currently only a single strain of *M. equi* (ATCC 25576) is available. Further studies, involving isolation of moraxellae from horses in different geographical regions, are required to determine whether *M. equi* is universally distributed.

The mol% G + C of the DNA is: not reported.

Type strain: ATCC 25576.

9. **Moraxella nonliquefaciens** (Scarlett 1916) Lwoff 1939, 175[AL] (*Bacillus duplex non liquefaciens* Scarlett 1916, 107; *Moraxella (Moraxella) nonliquefaciens* Bøvre and Henriksen 1967a, 134.)

non.li.que.fa' ci.ens. L. pref. *non* not; L. part. adj. *liquefaciens*-dissolving; L. part. adj. *nonliquefaciens* not dissolving.

Rods, showing variation in shape, size, and arrangement. The colony size and colony type variation in relation to fimbriation and "twitching motility" are similar to that described for *M. bovis*, but the corroding colonies of freshly isolated strains may often be larger and more spreading (Bøvre et al., 1970; Bøvre and Frøholm, 1972b; Henrichsen et al., 1972). Colonies are translucent to semiopaque. Some strains are very mucoid. Cell walls of nonmucoid strains often contain polysaccharide that is chemically and immunologically identical to capsular polysaccharide of serogroup B meningococci (Bøvre et al., 1983). No hemolysis occurs on blood agar. Other characteristics are listed in Table BXII.γ.130 of the description of the family *Moraxellaceae*.

M. nonliquefaciens is nutritionally fastidious; 22 independently isolated strains were able to grow in a defined medium containing nine amino acids and three vitamins (Juni et al., 1984). It fails to grow on Hugh and Leifson's OF medium. Previously, as a rule, highly sensitive to penicillin, but strains resistant because of β-lactamase production are now often encountered. Most frequently isolated from the nasal cavity, which is probably the main natural habitat. Also found in other samples from the respiratory tract, including bronchial aspirates in chronic bronchitis and upper respiratory disease (Graham et al., 1990), the latter in small children. It is considered a well-established parasite of humans with good adaptation to the host and, although rarely reported, may play a role, similar to *M. catarrhalis*, as an agent of disease. It has been found in individuals with endophthalmitis (Ebright et al., 1982; Lobue et al., 1985) and occasionally in blood in systemic disease (Brorson et al., 1983; Tønjum et al., 1992).

Further comments The cells are frequently transformable, with competence for genetic transformation being associated with fimbriation of cells and with corroding, spreading colonies (Bøvre and Frøholm, 1972a). Strains of *M. nonliquefaciens* have type 4 pilin genes (*tfa*) (Tønjum et al., 1991). *M. nonliquefaciens* strains can be identified by quantitative (Bøvre, 1964, 1965a, c) and qualitative (Juni et al., 1987) genetic transformation. The species is genetically homogeneous (Bøvre and Henriksen, 1967a). Strains of *M. nonliquefaciens* have high interstrain 16S rRNA gene sequence similarities (99.8%) and can be distinguished from other strains of the *M. lacunata* cluster by such analysis (Pettersson et al., 1998).

The mol% G + C of the DNA is: 40–44 (Bd).

Type strain: 4663/62, ATCC 19975, NCTC 10464.

10. **Moraxella ovis** (Lindqvist 1960) Henriksen and Bøvre 1968, 391[AL] (*Neisseria ovis* Lindqvist 1960, 165; *Moraxella (Branhamella) ovis* (Lindqvist 1960) Bøvre 1979, 404.)
o' vis. L. gen. n. *ovis* of the sheep.

Cocci commonly arranged in pairs with adjacent sides flattened; division in two planes at right angles to each other. Tetrad formation may be observed. Colonies on blood agar are ~2.5 mm in diameter in 48 h, low convex, becoming almost flat after longer incubation. They are grayish white and slightly smaller and more opaque than the largest colony forms of *M. bovis*. The colonies are friable or soft, and are usually surrounded by a narrow zone of clear hemolysis. Nonhemolytic variants may arise spontaneously in cultures, and primarily nonhemolytic strains (genetically confirmed as belonging to the species) have been isolated directly from sheep and cattle (and a horse). Other characteristics are listed in Table BXII.γ.130 of the description of the family *Moraxellaceae*

Isolated from the conjunctiva of sheep and cattle and from upper respiratory sites in sheep (and a horse). Frequently found in cultures from eyes in infectious keratoconjunctivitis of sheep, and often found together with *M. bovis* in cases of such disease in cattle. Considered to be of low pathogenicity, most frequently occurring as a harmless parasite.

Further comments The strains are frequently competent for genetic transformation and can be easily identified by quantitative transformation (Bøvre and Hagen, 1981). Demonstrated to be a species of *Moraxella* by virtue of transformation of the high-level streptomycin-resistance marker (Bøvre and Hagen, 1981) as well as by transformation of an auxotrophic mutant of *M. bovis* (Juni et al., 1988). Other closely related coccal and rod-shaped moraxellae, not yet described, have been isolated from sheep and cattle and these must be taken into consideration when identifying *M. ovis*, as well as *M. bovis*, in these animals (Bøvre, 1980; Bøvre and Hagen, 1981). Strains of *M. ovis* grow on a defined medium (medium MB) suitable for growth of strains of *M. bovis* (Juni et al., 1988). There is a significant amount of DNA–DNA hybridization between *M. ovis* and *M. bovis* (Tønjum et al., 1989). The 16S rRNA genes of *M. ovis* and *M. bovis* have been shown to be 97.1–97.4% similar (Pettersson et al., 1998).

The mol% G + C of the DNA is: 44.5–46.5 (Bd).

Type strain: 199/55, ATCC 33078, NCTC 11227.

GenBank accession number (16S rRNA): AF005186.

Species Incertae Sedis[1]

1. **Moraxella atlantae** Bøvre, Fuglesang, Hagen, Jantzen and Frøholm 1976, 520[AL] (*Moraxella (Moraxella) atlantae* Bøvre 1979, 404.)
at.lan' tae. M.L. gen. n. *atlantae* of Atlanta, the American city where strains of the species were first recognized as a distinct group by Elizabeth O. King.

This group is comprised of strains originally designated *Moraxella atlantae*. Rods, showing variation in shape and size. There is little tendency to form chains. Cells are often fimbriated and may show "twitching motility." Colonies are small (0.2–0.5 mm in diameter, occasionally up to 1 mm) in 48 h on either blood agar or chocolate agar. Agar corrosion and spreading of colonies may be seen. Permanent dissociation of such colonies formed by fimbriated cells into nonfimbriated, noncorroding variants has not been observed. Colonies are semiopaque and may appear slightly pink, probably due to blood pigment accumulation. Nonhemolytic. Bile salts (or Tween 80) stimulation of growth occurs with levels up to 1%. Penicillin sensitive, but usually resists 0.05 U/ml penicillin. Other characteristics are listed in Table BXII.γ.130 of the description of the family *Moraxellaceae*.

1. Although originally considered to be species of *Moraxella*, each of the five species listed in this section appears to represent an independent genus of the *Moraxellaceae*.

Only rarely isolated. Found in human blood, cerebrospinal fluid, and spleen. The natural habitats and pathogenicity are not yet defined.

Further comments The strains are often competent for genetic transformation and can be identified by transformation methods (Bøvre et al., 1976). The cellular lipid composition closely resembles that of *M. phenylpyruvica*; however, *M. atlantae* differs by containing true waxes (Bøvre et al., 1976; Bryn et al., 1977). Although previously considered a species of *Moraxella*, this organism constitutes a unique genus in the family *Moraxellaceae*, based on the following evidence: 1. Ratios of interstrain to intrastrain transformation of the high-level streptomycin-resistance marker for all other strains in the family tested are $\leq 2 \times 10^{-5}$ (Bøvre and Hagen, 1981). 2. There is only weak DNA–DNA hybridization with *M. phenylpyruvica* and no significant level with other members of the family (Tønjum et al., 1989). 3. Can be differentiated from other *Moraxellaceae* species by the presence of mannose in its whole-cell monosaccharide pattern (Jantzen et al., 1974). 4. 16S rRNA gene sequence similarity with other members of the *Moraxellaceae* is highest for *M. osloensis* (93%) and is lower for other members of the family (Pettersson et al., 1998).

M. atlantae should be given a new genus designation.

The mol% G + C of the DNA is: 46.5–47.5 (Bd).

Type strain: ATCC 29525, CDC 5118, NCTC 11091.

2. **Moraxella boevrei** Kodjo, Richard, and Tønjum 1997, 120[VP]
boev' re.i. L. gen. n. *boevrei* of Bøvre, in honor of Kjell Bøvre.

This group is comprised of strains originally designated *Moraxella boevrei*. Cells are thin rods to coccus-like structures and have a tendency to occur as diplobacilli or in short chains. Colonies on blood agar are gray-white, rough, and small (diameter after 48 h, 0.5 mm) and are surrounded by a wide area of hemolysis. Isolates are nonmotile, aerobic, and mesophilic. Growth occurs in an aerobic atmosphere (preferably containing 5% CO_2) on 5% sheep or human blood agar plates or chocolate agar plates. Growth does not occur or occurs weakly on nutrient agar. The oxidase and catalase reactions are strongly positive. All strains hydrolyze Tween 80 and reduce nitrate. No acid is produced from carbohydrates. All strains are proteolytic (Loeffler slants and gelatin positive). Indole and urease reactions are negative. The only conventional characteristic that distinguishes *M. boevrei* from *M. bovis* is the reduction of nitrate. Otherwise, all other conventional and hydrolytic enzymes of *M. boevrei* and *M. bovis* are identical. Other characteristics are listed in Table BXII.γ.130 of the description of the family *Moraxellaceae*.

Isolated from the nasal flora of goats. Pathogenicity has not been demonstrated.

Further comments The strains are competent for genetic transformation and can be identified by quantitative transformation of the high-level streptomycin-resistance marker. The basis for considering *M. boevrei* to be a new genus includes the following: 1. Using *M. boevrei* DNA with *M. bovis*, *M. lacunata*, *M. atlantae*, and *M. catarrhalis* as recipients, ratios of interstrain to intrastrain transformation to streptomycin resistance were less than 5×10^{-5} to 6.5×10^{-5}. 2. There is little or no DNA–DNA hybridization of *M. boevrei* with most other species of *Moraxellaceae* and other Gram-negative bacteria tested. 3. The results of rDNA restriction pattern analysis showed that the strains of *M. boevrei* were similar to each other and different from 10 other member strains of the *Moraxellaceae* (Kodjo et al., 1997).

It should be noted, however, that DNA–DNA hybridization resulted in relative binding ratios of 12–23 between *M. boevrei* and strains of *M. bovis*, *M. nonliquefaciens*, and *M. ovis* as compared with ratios of 58 to >100 among *M. boevrei* isolates (Kodjo et al., 1997). In view of these findings, *M. boevrei* may actually be a distantly related species of the genus *Moraxella* (*sensu stricto*). Pending further studies to establish the precise taxonomic position of *M. boevrei*, this entity is presently considered a possibly unique genus of the *Moraxellaceae*, based on the criteria used to classify members of this family.

The mol% G + C of the DNA is: 41–41.5 (HPLC).

Type strain: 88365, ATTC 700022, CIP 104716, CCUG 35435, NCTC 12925.

3. **Moraxella lincolnii** Vandamme, Gillis, Vancanneyt, Hoste, Kersters, and Falsen 1993, 479[VP]
lin' col.ni.i. N.L. gen. n. *lincolnii* of K. Lincoln, a Swedish microbiologist.

This group is comprised of strains originally designated *Moraxella lincolnii*. Cells are nonmotile, coccus-like to plump rods 1–1.5 × 1.5–2.5 μm. They often occur in pairs and may form short chains. After 2 d incubation, colonies are whitish, smooth, convex, and circular and have a diameter of 1–3 mm. The colonies of some strains may have a flattened edge. No hemolysis and no production of pigment or odor. Aerobic. Optimal growth occurs at 28–33°C. Growth also occurs at 36–37°C but not at 42°C. Growth occurs in the absence of NaCl; no growth occurs in the presence of 1.5% NaCl. Oxidase and catalase activities are present. All strains are susceptible to penicillin (10 μg discs). Most strains reduce nitrite but fail to reduce nitrate. Acid is not produced from D-glucose, D-fructose, maltose, or sucrose. Lactate cannot be used as a carbon source. No denitrification, liquefaction of gelatin, proteolysis on Loeffler slants, hydrolysis of Tween 80, or indole production. No urease, DNase, or β-galactosidase activity. The major fatty acids are $C_{10:0}$, $C_{12:0\ 3OH}$, $C_{16:1\ \omega7c}$, $C_{16:0}$, $C_{18:1\ \omega9c}$, and $C_{18:0}$. Other characteristics are listed in Table BXII.γ.130 of the description of the family *Moraxellaceae*.

Has been isolated mainly from the respiratory tract of humans. Its clinical significance, if any, is unknown.

Further comments Assignment of these organisms to *Moraxellaceae* is based on the results of DNA–rRNA hybridization studies in which DNAs from strains of *M. lincolnii* were hybridized with radioactively labeled rRNA from *M. lacunata* (Vandamme et al., 1993). $T_{m(e)}$ values of 74.4–74.8°C obtained are well within the range for all members of the *Moraxellaceae* ($T_{m(e)}$ range: ~70–80.0°C [Rossau et al., 1991]). Further studies are required to establish possible relationships to other members of the family.

M. lincolnii will require a new genus designation should further investigations verify that it is, indeed, a distinct genus of the *Moraxellaceae*.

The mol% G + C of the DNA is: 44 (T_m).

Type strain: CCUG 9405, LMG 5127.

4. **Moraxella osloensis** Bøvre and Henriksen 1967a, 131[AL] (*Moraxella (Moraxella) osloensis* Bøvre 1979, 404.)

os.lo.en′sis. M.L. adj. *osloensis* pertaining to Oslo, Norway, where the species was first recognized.

This group is comprised of strains originally designated *Moraxella osloensis*. Rods, showing variation in size, shape, and arrangement similar to that of the genus *Moraxella* (*sensu stricto*). The cells may be indistinguishable from cocci in some specimens or when freshly isolated. A distinct rod shape occurs with pronounced formation of fusiform cells when cultured in sublethal concentrations of penicillin; diplocells may sometimes appear like "waterbuffalo horns" (Bøvre, unpublished). Intracellular inclusions of poly-β-hydroxybutyrate are usually formed, especially when the nitrogen source is limiting.

Colonies are 2.0–2.5 mm in diameter in 48 h and are semiopaque. They do not exhibit colony type variation.

Strains usually grow in mineral media with ammonium ions and acetate, but one genetically verified exception has been found. Highly or, most often, moderately sensitive to penicillin, but resistant strains which possess β-lactamase have been found. Other characteristics are listed in Table BXII.γ.130 of the description of the family *Moraxellaceae*. Isolated from the upper respiratory tract, genitourethral specimens, blood, cerebrospinal fluid, and pyogenic manifestations in joints, bursae, and other sites from humans. Not yet isolated with certainty from nonhuman sources. Usually considered a harmless parasite, but significant pathogenicity is possible.

Further comments Although originally designated as members of *M. nonliquefaciens*, two strains (19116/51 and 752/52) of the 22 studied were considered to represent two new taxonomic groups, based on quantitative transformation studies using the high-level streptomycin-resistance marker (Bøvre, 1964). Further studies of strains similar to strain 19116/51 led to the designation of *M. osloensis* (Bøvre, 1965d; Bøvre and Henriksen, 1967a). Strains are frequently competent for genetic transformation and procedures for their identification by transformation are readily performed (Bøvre, 1965d; Bøvre et al., 1977; Juni, 1974). Although previously considered to be a species of *Moraxella*, this organism constitutes a unique genus in the family *Moraxellaceae*, based on the following evidence: 1. Ratios of interstrain to intrastrain transformation of the high-level streptomycin-resistance marker for all other strains in the family tested (Bøvre and Hagen, 1981) are $\leq 4 \times 10^{-5}$. 2. Except for a weak reaction with DNA from a strain of *M. phenylpyruvica* (752/52), there is no detectable DNA–DNA hybridization with DNA from most members of the family (Tønjum et al., 1991). 3. DNAs from strains of *M. osloensis* have a unique average intergroup $T_{m(e)}$ value (75.6°C) when hybridized with rRNA from "*M. lacunata* subsp. *liquefaciens*", ATCC 17952 (Rossau et al., 1991). 4. A *trpE* $^{-}$ mutant of *M. osloensis* was transformed to prototrophy only by DNAs from strains of *M. osloensis* (Juni, 1974). 5. Unique cellular fatty acid composition (Jantzen et al., 1974; Bøvre et al., 1977; Moss et al., 1988). 6. Ability to grow on a defined medium containing a single organic carbon and energy source with an ammonium salt as the nitrogen source (Bøvre and Henriksen, 1967a; Juni, 1974). A specific endonuclease, *Mos*I, has been purified from *M. osloensis*, ATCC 19976, and shown to recognize the same sequence as *Mbo*I (Gelinas et al., 1977).

Phylogenetic analysis of 16S rRNA gene sequences has shown that *M. osloensis* and *M. atlantae* form a common and distinct clade of the *Moraxellaceae* (Pettersson et al., 1998) (Fig. BXII.γ.147). Strains of *M. osloensis* and *M. atlantae* were shown to be distantly related to each other, their 16S rRNA genes displaying 93.4% similarity and ≤93% similarity, respectively, to other members of the *Moraxellaceae* (Pettersson et al., 1998).

M. osloensis should be given a new genus designation.

The mol% G + C of the DNA is: 43–46 (Bd).

Type strain: ATCC 19976, CDC A1920, NCTC 10465.

Additional Remarks: A frequently used (transformable) reference strain is CDC 5873.

5. **Moraxella phenylpyruvica** Bøvre and Henriksen 1967b, 344[AL] Epit. spec. cons. Opin. 42, Jud. Comm. 1971, 107 (*Moraxella (Moraxella) phenylpyruvica* Bøvre 1979, 404.)
phe.nyl.py.ru′vi.ca. M.L. n. *acidum phenylpyruvicum* phenylpyruvic acid; M.L. fem. adj. *phenylpyruvica* pertaining to phenylpyruvic acid, the product of deamination of phenylalanine by this organism.

This group is comprised of strains originally designated *Moraxella phenylpyruvica*. Rods, showing variation in shape, size, and arrangement. The colonies are relatively small (0.9–1.0 mm in diameter) in 48 h on blood agar. They often appear semiopaque with a very slight pink hue, probably due to blood pigment accumulation. Nonhemolytic. Phenylalanine deaminase and urease positive, but strains negative for one or, very rarely, both activities may occur. Grows distinctly, but slowly, at 4–10°C. Usually grows at high salt or bile concentrations; the minimum inhibitory concentrations are usually 7.5–9.0% NaCl and 5% bile salts (Oxoid). Bile salt (Tween 80) stimulation of growth occurs, with levels up to 4% (Snell et al., 1972; Bøvre et al., 1976). Although usually highly sensitive to penicillin, several strains of human and animal origin have been found to be penicillin resistant due to β-lactamase production. Other characteristics are listed in Table BXII.γ.130 of the description of the family *Moraxellaceae*.

Isolated from human blood and cerebrospinal fluid, the genitourethral tract, and from other sites and specimens of humans; also isolated from the genital tract and brain of sheep and cattle, the intestine of a goat, and the genital tract of pigs. Pathogenicity for humans, and perhaps animals, has not been assessed adequately, although judging from its sources of isolation this species may be a significant potential pathogen.

Further comments Strains competent for genetic transformation have not yet been found, but genetic relationships to other taxa of the family *Moraxellaceae* have been detected by the use of strains as DNA donors in transformation. The cellular lipid composition is unique among recognized *Moraxellaceae* species in that true waxes are absent; in other respects, the lipid composition resembles that of *M. atlantae* (Jantzen et al., 1974; Bøvre et al., 1976; Bryn et al., 1977; Moss et al., 1988). Although previously considered a species of *Moraxella*, this organism constitutes a unique genus in the family *Moraxellaceae*, based on the following evidence: 1. Ratios of interstrain to intrastrain transformation of the high-level streptomycin-resistance marker for all other strains in the family tested are equal to, or less than, 2×10^{-5} (Bøvre and Hagen, 1981). 2. There is only slight DNA–DNA hybridization with *M. osloensis* and *M. at-*

lantae, and nondetectable levels with other members of the family (Tønjum et al., 1989). 3. A streptomycin-dependent marker of *M. phenylpyruvica*, which had been transformed into the competent strain of *Acinetobacter* (a rare occurrence), was transformed to streptomycin independence by DNAs from 35 strains of *M. phenylpyruvica;* DNAs from other members of the *Moraxellaceae* were inactive (Juni, 1990).

M. phenylpyruvica may be heterogeneous since strains 752/52 and ATCC 23333 T have a 16S rRNA gene sequence similarity of only 95.9% (Pettersson et al., 1998). Both of these strains react in the same positive manner in transformation of an *M. phenylpyruvica* streptomycin-dependent marker located in the competent strain of *Acinetobacter*, indicating a strong relationship (Juni, 1990).

M. phenylpyruvica should be given a new genus designation.*

The mol% G + C of the DNA is: 42.5–43.5 (Bd).

Type strain: ATCC 23333, CDC 2863, NCTC 10526.

**Editorial Note:* Bowman et al. (1996) have proposed the transfer of *Moraxella phenylpyruvica* to the genus *Psychrobacter* as *Psychrobacter phenylpyruvicus.*

Genus II. **Acinetobacter** *Brisou and Prévot 1954, 727*[AL]

ELLIOT JUNI

A.ci.ne' to.bac.ter. Gr. adj. *akinetos* unable to move; M.L. n. *bacter* the masculine form of the Gr. neut. n. *bactrum* a rod; M.L. masc. n. *Acinetobacter* nonmotile rod.

Rods 0.9–1.6 × 1.5–2.5 µm, becoming spherical in the stationary phase of growth. Colonies are generally nonpigmented and are mucoid when the cells are encapsulated. Cells commonly occur in pairs and in chains of variable length. Do not form spores. Gram negative but occasionally difficult to destain. Swimming motility does not occur but the cells display "twitching motility", presumably because of the presence of fimbriae. Aerobic, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. Most strains do not reduce nitrate to nitrite. Most strains grow between 20 and 37°C, having temperature optima of 33–35°C. Some strains cannot grow at 37°C. **Oxidase negative. Catalase positive.** Grow well on most complex media. Most strains grow in defined media containing a single carbon and energy source, such as acetate or lactate, using ammonium or nitrate salts, or one of several common amino acids, as a supply of nitrogen. Frequently amino acids such as glutamic acid or aspartic acid can serve as a single source of carbon, energy, and nitrogen in a defined mineral medium. With rare exceptions, they display no growth factor requirements. Most frequently saprophytic, occurring naturally in soil, water, sewage, and foods such as raw vegetables. Can also reside, possibly indigenously, on the human skin and in the human respiratory tract. Can cause nosocomial infections such as bacteremia, secondary meningitis, pneumonia, and urinary tract infections in humans.

The mol% G + C of the DNA is: 38–47.

Type species: **Acinetobacter calcoaceticus** (Beijerinck 1911) Baumann, Doudoroff and Stanier 1968b, 1538 emend. Bouvet and Grimont 1986, 238 (*Micrococcus calcoaceticus* Beijerinck 1911,1067.)

FURTHER DESCRIPTIVE INFORMATION

Habitat Acinetobacters occur naturally in soil and water (Baumann, 1968) and are present in sewage (Warskow and Juni, 1972). It has been estimated that at least 0.001% of the total culturable, heterotrophic, aerobic population in soil and water are acinetobacters (Baumann, 1968). Acinetobacters have been demonstrated to associate with soybean root nodules in relatively large numbers (Wong et al., 1986). They have been shown to occur in raw, washed, and frozen vegetables (Gennari and Stegagno, 1986), in fresh, frozen, and stored fish products (Gennari and Stegagno, 1985), and in spoiled meat, milk, and cheese (Gennari et al., 1992). Body sites, such as the skin and respiratory tract, also appear to harbor certain acinetobacters (Bergogne-Bérézin and Towner, 1996).

General Physiology

CELL STRUCTURES Rapidly growing cells tend to be plump rods, whereas cells in the stationary phase of growth are spherical and have a somewhat smaller diameter than the rods (Baumann et al., 1968b). An occasional rod-shaped cell can frequently be observed in a microscopic field of stationary phase cells. Cells occur typically in pairs, and occasionally in chains. Many strains are encapsulated and capsules may be seen readily in India ink wet mounts. Colonies are generally nonpigmented and are mucoid when the cells are encapsulated.

Electron microscopy of thin sections of cells has revealed a cell wall ultrastructure that is typical of Gram-negative bacteria (Breuil et al., 1975; Scott et al., 1976). The peptidoglycan contains muramic acid, glucosamine, alanine, D-glutamic acid, and *meso*-diaminopimelic acid (Martin et al., 1973; Horisberger, 1977). Unlike the cell walls of several Gram-negative bacteria, the murein of one strain of *Acinetobacter* had an unusually high proportion of cross-linked peptide side chains (Quintela et al., 1995). It is known that antibodies against *Chlamydia* cross-react with *Acinetobacter* (Brade and Brunner, 1979). Nurminen et al. (1984) present evidence that this cross reaction involves a lipopolysaccharide component; other findings suggest that *Chlamydia* antiserum reacts with the cell wall of *Acinetobacter* (Espinosa et al., 1996).

When originally investigated, one strain of *Acinetobacter* was shown to possess a lipopolysaccharide containing D-glucose, glucosamine, galactosamine, lipid A, ethanolamine, fatty acids, phosphate, and protein (Adams et al., 1970). Lipopolysaccharide composition is not the same in all strains studied (Borneleit and Kleber, 1991). Numerous investigations have elucidated the structures of O-antigen lipopolysaccharides from a variety of *Acinetobacter* strains (Vinogradov et al., 1997; Haseley and Wilkinson, 1997; Haseley et al., 1997, 1998; and other references to be found in these papers). It has been suggested that because of the presence of deoxy sugars, amino acids, and branched polymers, *Acinetobacter* O-antigens display a marked hydrophobicity, which is consistent with the ability of acinetobacters to grow on hydrophobic substrates (Haseley et al., 1997).

Evolution of acinetobacters has resulted in a large variety of surface antigens, many of them capsular, on different strains. A

serologic system for identification of strains by immunofluorescent staining revealed 28 serovars among strains capable of forming acid aerobically from glucose, as well as a series of other serovars among acinetobacters that do not form acid from glucose (Marcus et al., 1969). The capsular polysaccharide of one strain of *Acinetobacter* has been shown to interact with antisera prepared against group B and group G streptococci, as well as with antipneumococcal type XX serum (Heidelberger et al., 1969).

Outer membranes of *A. calcoaceticus* and *A. radioresistens* have been analyzed and found to contain several unique proteins ranging in molecular weight from 12,000 to 50,000 daltons (Fischer et al., 1984; Nishimura et al., 1986a). The major outer membrane protein of *A. calcoaceticus* has a molecular weight of 38,000 daltons, in contrast to that of *A. radioresistens*, which has two major outer membrane proteins with molecular weights of 39,000 and 42,000 daltons, respectively (Nishimura et al., 1986a). Two other studies, which examined larger numbers of strains, showed a good correlation between outer membrane cell envelope protein patterns and DNA–DNA hybridization groups (Ino and Nishimura, 1989; Dijkshoorn et al., 1990).

Metabolism Nitrite and nitrate can serve as nitrogen sources for acinetobacters, and these organisms possess an assimilatory nitrate reductase (Jyssum and Joner, 1965). Although most acinetobacters are not able to reduce nitrate to nitrite in the conventional nitrate reduction assay, a few strains can do so (Riley and Weaver, 1974); these strains are unable to grow anaerobically with nitrate as the terminal electron acceptor (Juni, 1978). Since all acinetobacters are oxidase negative, they lack cytochrome *c* (Baumann et al., 1968a). However, they do contain cytochromes *b*, *o*, and occasionally *d* and P-450, as well as flavoproteins, and appear to have a normal electron transport system (Asperger and Kleber, 1991).

Enzymes of the tricarboxylic acid cycle have been shown to be present in acinetobacter cell-free extracts. The presence of NADP-isocitrate dehydrogenase has been demonstrated (Weitzman, 1991). The absence of an NAD-isocitrate dehydrogenase, which is typical for most bacteria, and the relatively slow growth rate with acetate as the sole carbon source, indicate that for acinetobacters, as well as for the vast majority of bacteria, the tricarboxylic acid cycle is more important in the synthesis of amino acids (specifically aspartate, glutamate, and proline) and porphyrin than it is in general cellular respiration. Enzymes of the glyoxylate cycle have been demonstrated in *Acinetobacter* and all evidence verifies the obligate requirement of this cycle for growth with two-carbon compounds such as acetate as sole carbon and energy source (Juni, 1978). The enzymes of the Embden–Meyerhof pathway, for conversion of phosphoenolpyruvate to hexose phosphates, are present in *Acinetobacter* and are used for gluconeogenesis from C_4-dicarboxylic acids, but not for the degradation of sugars (Taylor and Juni, 1961).

Relatively few strains can use D-glucose as a carbon source for growth (Baumann et al., 1968b; Juni, 1972). One strain that can use glucose as a carbon source has been shown to catabolize it via the Entner–Doudoroff pathway, involving the key enzymes 6-phosphogluconate dehydratase and 2-keto-3-deoxy-6-phosphogluconate aldolase (Taylor and Juni, 1961). Many acinetobacters that are unable to grow on glucose contain an aldose dehydrogenase and are able to acidify glucose media rapidly (gluconic acid being formed), as well as media containing other sugars such as D-xylose, L-arabinose, D-galactose, D-mannose, L-rhamnose, maltose, lactose, and cellobiose (Hauge, 1960); this enzyme is responsible for the positive diagnostic test for the production of acid from glucose. Strains of *Acinetobacter* able to form acid from glucose have been demonstrated to produce two glucose dehydrogenases, a soluble and a membrane-bound enzyme (Matsushita et al., 1989; Duine et al., 1982). The two glucose dehydrogenases are distinct enzymes; the membrane-bound form appears to be the only enzyme used by intact cells for the oxidation of glucose (Duine, 1991). Both enzymes use pyrroloquinoline quinone (PQQ, methoxatin) as a coenzyme (Duine, 1991). Genes involved in synthesis of PQQ and coding for membrane-integrated quinoprotein glucose dehydrogenase in *Acinetobacter* have been cloned in *E. coli* (Goosen et al., 1987, 1989a, b; Cleton-Jansen et al., 1989; Dewanti and Duine, 1998).

Growth and nutrition Most strains of *Acinetobacter* can grow in a simple mineral medium containing a single carbon and energy source such as ethanol, acetate, lactate, pyruvate, malate, or α-ketoglutarate. Ammonium and nitrate salts serve as nitrogen sources. Some organic compounds, such as amino acids, can serve as single sources of carbon, energy, and nitrogen. Rare strains have growth factor requirements; such strains frequently revert spontaneously to prototrophy when cultured in the laboratory (Warskow and Juni, 1972). Acinetobacters resemble saprophytic pseudomonads in being able to use a wide variety of organic compounds as carbon, energy, and/or nitrogen source for growth in mineral media, and generally oxidize such compounds to completion. Utilizable organic nutrients include certain sugars, fatty acids, aliphatic alcohols, unbranched hydrocarbons, dicarboxylic acids, amino acids, and many aromatic and alicyclic compounds (Baumann et al., 1968b); the spectrum of compounds utilized is frequently species specific (Bouvet and Grimont, 1986). Acinetobacters, normally associated in relatively large numbers with soybean root nodules, have also been shown to obtain energy for growth by oxidizing H_2, which is released by the nodules (Wong et al., 1986). Some strains can utilize a single hexose, D-glucose, and the pentoses D-ribose, D-xylose, and L-arabinose. Other carbohydrates, disaccharides, and sugar alcohols (including glycerol) are not used. There is no evidence that acinetobacters can obtain energy for growth by fermentation. Since acinetobacters are nonmotile, growth in liquid media requires vigorous aeration. Growth can take place from pH 5.0 to 8.0, with a pH optimum for growth of approximately 6.5 (Baumann, 1968; Juni, 1982).

Biochemistry Because of their ability to metabolize many organic compounds, acinetobacters normally synthesize a wide variety of degradative enzymes. Most metabolic and genetic studies in *Acinetobacter* have been directed towards elucidating the pathways involved, as well as regulation of expression of the relevant enzymes. Since aromatic compounds are available through normal breakdown of dead plant and animal tissues, it is not surprising to find that acinetobacters can degrade organic compounds such as benzoate, *p*-hydroxybenzoate, mandelate, quinate, and tryptophan (Fewson, 1991).

The normal soil and water habitats of acinetobacters, coupled with their ability to degrade a wide variety of organic compounds, make it likely that acinetobacters can be used for bioremediation. Although toxic to most microorganisms, aromatic compounds such as salicylate, halogenated aromatics, and phenol (Schirmer et al., 1997) can be degraded by acinetobacters, occasionally by strains harboring specific degradative plasmids (Fewson, 1991).

Because of their ability to utilize hydrocarbons, acinetobacters

are capable of playing a role in the degradation of crude oil. It has been demonstrated that certain acinetobacters elaborate and excrete polymers that emulsify hydrocarbons, such as oils, thus making these substances available for degradation in an aqueous environment (Gutnick et al., 1991; Navon-Venezia et al., 1995). Acinetobacters that degrade alkanes are frequently isolated from areas contaminated with petroleum. Various aspects of alkane metabolism have been investigated (Asperger and Kleber, 1991; Maeng et al., 1996; Parche et al., 1997; Ratajczak et al., 1998). Many acinetobacters possess the ability to degrade alkanes by pathways that, in some cases, involve rubredoxin, rubredoxin reductase, and cytochrome P-450 (Asperger and Kleber, 1991; Geissdörfer et al., 1995).

Some acinetobacters elaborate an extracellular lipase, as determined by hydrolysis of Tween 80 (Baumann et al., 1968b) and other lipids (Breuil and Kushner, 1975; Fischer, 1986; Kok et al., 1995a,b, 1996). Strains that show hemolysis on blood agar plates excrete phospholipase (Lehmann, 1971, 1973).

Early studies of pathways for degradation of aromatic compounds in *Acinetobacter* demonstrated that these compounds are generally converted to β-ketoadipate, and that succinate and acetyl CoA are the products of degradation of β-ketoadipate (Stanier and Ornston, 1973). Evolution of genes for the β-ketoadipate pathway has been reviewed (Ornston and Neidle, 1991). There is evidence for supraoperonic clustering on the chromosome of certain genes involved in aromatic catabolism, where the product of one gene is further metabolized by a second gene in an independent and closely located transcriptional operon (Ornston and Neidle, 1991; Averhoff et al., 1992). An apparent DNA slippage structure has been proposed to explain the extensive evolutionary divergence of *pcaD* and *catD*, genes that encode identical catalytic activities in *Acinetobacter* but are located in different regions of the chromosome (Hartnett and Ornston, 1994). Evidence has been presented for gene conversion in the nonreciprocal genetic exchange involved in repair of defective *pcaIJF* by nucleotide sequences of a functional *catIJF* gene in *Acinetobacter* (Kowalchuk et al., 1995), a process that requires a functional *recA* gene (Gregg-Jolly and Ornston, 1994). Transcriptional activation of aromatic genes, similar to *LysR* type activation (Collier et al., 1998), as well as other transcriptional activators, has been reported (DiMarco and Ornston, 1994; Gerischer et al., 1998). Using a mutant of *Acinetobacter* sp. strain ADP1 that was unable to grow on benzene as the sole carbon source, since it lacked both transcriptional activators of the *cat* genes, it was demonstrated that spontaneous mutants able to grow with benzoate carried 10–20 amplified chromosomal regions (amplicons), each encompassing the *cat* genes (Reams and Neidle, 2003).

It has been demonstrated that certain features of aromatic amino acid biosynthesis are unique and characteristic for all acinetobacters (Byng et al., 1985).

Acinetobacter chromosomes have been reported to encode genes for synthesis of several restriction endonucleases and, most probably, their corresponding modification enzymes. These include *AccI* and *AccII* (Roberts, 1985), *AccIII* (Kita et al., 1985), *AlwNI* (Morgan et al., 1987), *AcII* (Degtyarev et al., 1992), *AjoI* (Nowak et al., 1994), *AspM* (Zelinskaia et al., 1996), and *AccBSI* (Abdurashitov et al., 1997). The genes of the *AccI* restriction-modification system have been sequenced following cloning and expression in *E. coli* (Kawakami et al., 1991).

Polyphosphate has been shown to be accumulated in wastewater by some acinetobacters (Gutnick et al., 1991; Kortstee et al., 1994). These organisms appear to be responsible for removing inorganic phosphate from sewage through their association with activated sludge (Fuhs and Chen, 1975; Buchan, 1983); the presence of K^+ seems to be essential for phosphate uptake (Van Groenestijn et al., 1988). A strain from activated sludge was demonstrated to accumulate large amounts of inorganic polyphosphate (3.7–5.7 mg P/100 mg dry weight of cells) and has been identified as *A. johnsonii* (Bonting et al., 1992). It has been suggested that a polyphosphate-synthesizing system is encoded on a 20-kb plasmid (Bayly et al., 1991). A strain of *A. johnsonii* that accumulates inorganic phosphate under aerobic conditions was shown to contain a high-affinity phosphate-uptake system that is induced in the absence of inorganic phosphate (Van Veen et al., 1993; Kortstee et al., 1994). A polyphosphate kinase gene from strain ADP1 (BD413) has been isolated and shown to be induced by phosphate starvation (Geissdörfer et al., 1998). Inorganic polyphosphate can serve as an energy reserve, as can poly-β-hydroxybutyrate and simple wax esters, all of which have been shown to accumulate in many strains of *Acinetobacter* (Fixter and Sherwani, 1991).

Studies of amino acid transport in *Acinetobacter* have revealed that alanine, lysine, and proline are taken up and concentrated by high affinity systems that are coupled to membrane-bound glucose dehydrogenase (Van Veen et al., 1994).

A phosphotyrosine-protein phosphatase from *A. johnsonii*, which specifically dephosphorylates an endogenous protein kinase known to autophosphorylate at multiple tyrosine residues in the inner membranes of this organism, has been studied and shown to be a member of the phosphotyrosine-protein phosphatase family (Grangeasse et al., 1998).

Mutarotase, an enzyme that catalyzes the anomeric interconversion of D-glucose and other aldoses, has been demonstrated in *Acinetobacter*; its gene has been cloned and expressed in *E. coli* (Gatz et al., 1986), and the nucleotide sequence of the gene directing the synthesis of this enzyme has been determined (Gatz and Hillen, 1986).

Genetics It is to be expected that a relatively large part of the *Acinetobacter* chromosome will code for enzymes involved in degradative pathways, because of the large number of organic compounds that can be degraded by these organisms. A measure of the percentage of the chromosome devoted to these activities comes from the studies of Gutnick et al. (1969), where it was shown that for about 600 organic compounds screened as possible carbon and nitrogen sources for *Salmonella typhimurium* LT-2, an organism previously considered to have only a limited number of possible carbon and energy sources, about 100 utilizable compounds were found. It might be expected that the portion of the chromosomes of *Acinetobacter* strains devoted to the genes controlling synthesis of enzymes involved in degrading organic compounds must be considerably greater than the 10% estimated for *S. typhimurium* (Gutnick et al., 1969).

Using plasmids, it has been possible to mobilize the *Acinetobacter* chromosome and conjugally transfer chromosomal genes to a recipient strain (Towner and Vivian, 1976b). In this manner, it has been demonstrated, using a series of genetic markers, that the *Acinetobacter* chromosome is circular (Towner and Vivian, 1976a) and loci of 23 different mutations were mapped on a circular linkage group (Towner, 1978). The orientation and precise location of more than 40 genes have been physically mapped on the circular chromosome of *Acinetobacter* sp. strain EBF/65, which has been shown to consist of 3780 ± 191 kb (Gralton et al., 1997). Analysis of codon usage in *Acinetobacter* structural genes

has revealed that all possible triplet codons are used, some preferentially (White et al., 1991).

Transformation Genetic exchange in *Acinetobacter* can be mediated by transformation, transduction, and conjugation (Vivian, 1991). Although rare, competence for genetic transformation in *Acinetobacter* has been observed in two strains (Juni and Janik, 1969; Ahlquist et al., 1980). Two clinically isolated strains of *Acinetobacter* were reported to be weakly competent (Bergan and Vaksvik, 1983). Nutritional, as well as antibiotic resistance, markers are readily transformed in competent strain BD413, and transformation of a *trpE*$^-$ auxotroph of this strain to prototrophy can be accomplished specifically by DNAs from acinetobacters (Juni, 1972). Genes involved in capsule biosynthesis of a competent strain have been studied by transformation (Juni and Janik, 1969). A partial mapping of genes directing synthesis of enzymes for the tryptophan biosynthetic pathway in *Acinetobacter* has been accomplished using transformation (Sawula and Crawford, 1972). A genetic analysis of the genes for proline biosynthesis has also been reported (Ginther, 1978). Natural transformation has been useful in the analysis of catabolic pathways in *Acinetobacter* (Kloos et al., 1995).

Using natural transformation in *Acinetobacter*, it has been possible to introduce randomly mutated genes, resulting from errors produced during PCR replication, into the chromosome of a competent recipient strain without prior cloning of PCR fragments (Kok et al., 1997). It has been demonstrated that plant DNA can be taken up and recombinationally incorporated into suitable plasmids resident in competent *Acinetobacter* (de Vries and Wackernagel, 1998; Gebhard and Smalla, 1998). A general method, where randomly mutated PCR products are transformed into competent *Acinetobacter* and captured by marker-replacement recombination in a plasmid resident in the transformation recipient, has been described (Melnikov and Youngman, 1999).

Physiological characterization of natural transformation in *Acinetobacter* has been reported (Palmen et al., 1993). The DNA uptake process in *Acinetobacter* does not make use of specific sequence recognition for binding and uptake of DNA (Lorenz et al., 1992; Palmen et al., 1993). Investigations of the molecular basis for DNA uptake in competent strains of *Acinetobacter* have implicated elements in the assembly of the type IV pilus (Palmen and Hellingwerf, 1997; Link et al., 1998), findings that are consistent with earlier observations correlating competence and piliation in other bacteria (Bøvre and Frøholm, 1971).

Phages Lytic phages for acinetobacters are isolated readily from sewage (Blouse and Twarog, 1966; Twarog and Blouse, 1968; Herman and Juni, 1974). A generalized transducing phage (P78) specific for one strain of *Acinetobacter* has been isolated and demonstrated to lysogenize the host strain (Herman and Juni, 1974). Weigle reactivation has been demonstrated for UV-irradiated temperate phage P78, suggesting that *Acinetobacter* possesses an inducible DNA repair pathway (Berenstein, 1982). Ultraviolet light was shown to induce temperate prophage P78 (Berenstein, 1986). Several *Acinetobacter* phages have been classified according to structural characteristics of phage heads and tails (Ackermann et al., 1994).

Plasmids More than 80% of all acinetobacters isolated harbor multiple plasmids (Hartstein et al., 1988; Gerner-Smidt, 1989; Seifert et al., 1994b), some of which are cryptic (Hunger et al., 1990; Minas and Gutnick, 1993; Seifert et al., 1994b); others carry antibiotic resistance markers (Murray and Moellering, 1979; Hinchliffe and Vivian, 1980; Gerner-Smidt, 1989; Garcia et al., 1996). Transmissible antibiotic resistance in *Acinetobacter* has been shown to be associated with plasmids that belong to broad host-range incompatibility groups (Towner, 1991). Plasmids from many incompatibility groups have been transferred to *Acinetobacter*, by conjugation or mobilization, where most of them are not completely stable (Towner, 1991). By making use of the ability of P1 incompatibility plasmid RP4 to mobilize the *Acinetobacter* chromosome, it was first demonstrated that the chromosomal DNA is circular (Towner and Vivian, 1976a; Towner, 1978). Some *Acinetobacter* plasmids encode genes involved in degradation of certain organic compounds (Winstanley et al., 1987, 1991; Fujii et al., 1997). Plasmid-mediated heavy metal resistance in *Acinetobacter* has been reported (Towner, 1991). A shuttle plasmid for *Acinetobacter* and *Escherichia coli* was constructed by ligation of a cryptic *Acinetobacter* plasmid and pBR322; the *trpE* gene of *Acinetobacter* was cloned in this vector (Hunger et al., 1990). The same shuttle vector was used to construct a gene bank of *Acinetobacter* chromosomal DNA (Hunger et al., 1990). Three cryptic plasmids have been observed in competent strain BD413 and two of these, when ligated with pUC19, resulted in shuttle vectors that replicated in both *Acinetobacter* and in *Escherichia coli* (Minas and Gutnick, 1993). Plasmids have been introduced into strain BD413 by natural transformation (Singer et al., 1986; Hunger et al., 1990). The means by which resident plasmids were originally introduced into isolated strains are not known.

Transposable elements Some acinetobacters carry transposons on their chromosomes and these encode antibiotic resistance genes (Towner, 1991). Studies of the gene for chloramphenicol acetyltransferase (CAT) in a strain of *A. baumannii* revealed that this chromosomal gene is part of a transposon similar to Tn*2670* from plasmid NR1; the 5′ end of the cloned CAT gene is linked to IS *1* and the 3′ end is linked to components of Tn *21* (Elisha and Steyn, 1991). A newly discovered insertion sequence, IS*1236*, which resembles IS*3*, has been discovered in *Acinetobacter* sp. strain BD413 (ADP1) where it exists in seven copies (Gerischer et al., 1996). Transposon Tn *3171*, which may be identical to Tn*7*, was shown to be incorporated in the chromosome of *Acinetobacter* in a nonrandom fashion (Towner, 1983). When introduced into *Acinetobacter* on a suicide plasmid, Tn*5* was shown to insert nonrandomly into the chromosome at a limited number of sites (Singer and Finnerty, 1984). However, Tn *5* has been inserted into a variety of cloned fragments of *Acinetobacter* DNA that can be transformed into strain BD413 (Doten et al., 1987; Goosen et al., 1987; Reddy et al., 1989; Gregg-Jolly and Ornston, 1994). When present in *Acinetobacter*, Tn *5* confers low-level resistance to streptomycin due to the presence of a Tn*5*-encoded streptomycin phosphotransferase (O'Neill et al., 1984). Low transposition frequencies for Tn*7* and Tn*10* to the *Acinetobacter* chromosome have been reported (Ely, 1985). Several different kinds of mutations in an *Acinetobacter* strain were produced by introduction of a derivative of Tn *10* (mini-Tn*10* PttKm) (Leahy et al., 1993).

Integrons, genetic elements that integrate cassettes encoding antibiotic resistance, have been demonstrated to be present in the majority (48 of 59 strains) of clinical isolates of *A. baumannii* biotype 9 (Gonzalez et al., 1998).

Pathogenesis and antibiotic susceptibility Although considered normally nonpathogenic, acinetobacters are causative agents of nosocomial infections, particularly in debilitated individuals and those residing in intensive care units (Bergogne-

Bérézin and Towner, 1996). From 1971 to 1981, species of *Acinetobacter* accounted for 1.4% of all nosocomial infections in a university hospital in the United States (Larson, 1984). Infection with *Acinetobacter* has been shown to result in septicemia, meningitis, endocarditis, brain abscess, lung abscess, pneumonia, empyema, urinary tract infections, skin and wound infections, as well as other clinical manifestations (Glew et al., 1977; Bergogne-Bérézin and Towner, 1996). There appears to be a clear association between hospital instrumentation, such as the use of mechanical ventilators, endotracheal and gastric tubes, vascular catherization, lumbar punctures, myelography, ventriculography, indwelling urinary catheterization, and penetrating keratoplasty, as well as the fitting of contact lenses and subsequent infection with *Acinetobacter*. Evidence has been presented indicating that nosocomial infection with *Acinetobacter* has a distinct seasonal variation (Retailliau et al., 1979).

Although acinetobacters are frequently isolated from several areas of the human body, there is some uncertainty as to whether they are present as contaminants rather than as commensals. Bacteria able to survive and multiply in human tissue must have a mechanism for sequestering iron. Several different siderophores are synthesized by acinetobacters (Smith et al., 1990; Echenique et al., 1992; Actis et al., 1993; Okujo et al., 1994; Yamamoto et al., 1994); a high affinity iron transport system has been demonstrated in a strain of *A. baumannii* (Echenique et al., 1992).

Virtually all acinetobacters can grow in simple mineral media containing one of a large number of organic carbon and energy sources (Warskow and Juni, 1972; Baumann, 1968), a characteristic not usually observed for bacteria whose normal habitat is an animal site. It therefore seems likely that, although some of these bacteria can act as opportunistic pathogens, they should probably not be considered as part of the indigenous microflora. The finding that acinetobacters are frequently isolated from the skin of hospital inpatients (Al-Khoja and Darrell, 1979; Seifert et al., 1997) can account for the occurrence of nosocomial infections with strains of this organism. Although isolated readily from the hands of hospital personnel, there is no evidence for persistent colonization with *Acinetobacter* (Buxton et al., 1978). Of the 20 or more recognized *Acinetobacter* genomic species (DNA groups) and named species, *A. baumannii* and the unnamed groups 3 and 13 *sensu* Tjernberg and Ursing (TU) are the ones most frequently isolated from hospitalized patients (Dijkshoorn et al., 1993; Seifert et al., 1993b).

High rates of antibiotic resistance, frequently to multiple drugs, are found in *Acinetobacter* spp. (Bergogne-Bérézin and Towner, 1996). Unlike most of the *Moraxellaceae*, acinetobacters are generally resistant to penicillin. Growth of most strains is not inhibited by 1 U/ml of penicillin G and the majority of strains are resistant to 100 U/ml (Baumann et al., 1968a). Since the 1970s, there has been an increase in the number of antibiotics, particularly the older antibiotics, to which hospital-isolated acinetobacters have become resistant. Most strains of *A. baumannii* now show resistance to aminopenicillins, ureidopenicillins, cephalosporins, cephamycins, many aminoglycosides-aminocyclitols, chloramphenicol, and tetracyclines (Bergogne-Bérézin and Towner, 1996). Currently, imipenem appears to be the most effective drug, although imipenem-resistant strains have been isolated already (Tankovic et al., 1994; Lytikäinen et al., 1995).

Taxonomic relationships of acinetobacters

***Assignment of isolated strains to the genus* Acinetobacter** The following phenotypic properties are generally used to assign isolated strains to the genus *Acinetobacter*: Gram-negative coccobacilli, oxidase negative, aerobic (nonfermenting), nonmotile, and, for most strains, negative nitrate reduction.

The ability of DNA from strains of *Acinetobacter* to transform a conserved *trpE*$^-$ mutant of the naturally competent BD413 strain to prototrophy (Juni, 1972) has never failed to be demonstrated during the many years since the introduction of this test. Several hundred independently isolated strains have already been identified with this assay. Transformation of *trpE*$^-$ has been shown to be genus specific and no exceptions have been reported. The specificity of this assay has been confirmed in a clinical setting (Brooks and Sodeman, 1974).

A genus-specific 16S rRNA-targeted oligonucleotide probe has been used to detect acinetobacters (Wagner et al., 1994b).

DNA–rRNA hybridization The highly conserved nature of 16S rRNA makes it useful for recognition of generic relationships among isolated bacterial strains. In DNA–rRNA hybridization studies, employing rRNA from *Acinetobacter calcoaceticus* ATCC 23055^T and filter-fixed DNAs from 23 strains of *Acinetobacter*, $T_{m(e)}$ (midpoint of thermal elution) values from 75.5 to 79.5°C were obtained (Van Landschoot et al., 1986). Similar studies, where DNAs from five established strains of *Acinetobacter* were hybridized with rRNA from *Moraxella lacunata*, resulted in hybrids having $T_{m(e)}$ values ranging from 71 to 73°C; corresponding values ranging from 73.1 to 80°C were obtained using DNAs from strains of all other genera in the *Moraxellaceae* (Rossau et al., 1991). When DNA–rRNA hybridizations were performed using the same five established strains of *Acinetobacter* and rRNA from *Psychrobacter immobilis*, $T_{m(e)}$ values ranging from 69.9 to 71.7°C were obtained; this range being unique for the five strains of *Acinetobacter* (Rossau et al., 1991). In both of these studies, corresponding DNA–rRNA hybridizations using DNA from bacteria not in *Moraxellaceae* resulted in $T_{m(e)}$ values from 53.5 to 67.5°C.

In studies employing rRNA from *A. calcoaceticus* ATCC 23055^T, it was proposed that two strains previously designated as *Pseudomonas cruciviae* and *Pseudomonas pavonacea* were "probably not members of the genus *Acinetobacter*", since although $T_{m(e)}$s of their hybrids (75.5°C and 76.0°C, respectively) indicated that they belong to the *Acinetobacter* rRNA branch, these strains differed significantly in phenotypic properties from some typical *Acinetobacter* species (Van Landschoot et al., 1986). The finding that DNA from each of these atypical strains transformed *Acinetobacter* strain BD413 *trpE*$^-$ to prototrophy (Juni, unpublished results) proves that these strains are indeed acinetobacters, and serves to confirm the significance of $T_{m(e)}$, as well as transformation, for identification of acinetobacters.

Acinetobacter *species and DNA groups delineated by DNA–DNA hybridization* It has been suggested, and generally accepted, that bacterial species be defined primarily on the basis of DNA reassociation, wherein members of a particular species show approximately 70% or greater DNA–DNA relatedness and with 5°C or less ΔT_m (Wayne et al., 1987). It was also recommended that genomic species that cannot be identified by phenotypic properties should not be given a species name. Early DNA–DNA hybridization studies of 45 strains of *Acinetobacter*, using a nitrocellulose filter method, distinguished groups with members that showed 50%, or greater, relatedness to one of five reference strains, and a sixth group consisted of strains showing less than 50% relatedness to any of the reference strains (Johnson et al., 1970). The results of this investigation have been correlated with hybridizations studies using the S1 nuclease method where,

within species, the levels of DNA relatedness to reference strains ranged from 62 to 95%, with ΔT_m values of less than 3.5°C (Bouvet and Grimont, 1986). To date, extensive DNA–DNA hybridization investigations have revealed the existence of approximately 21 species of *Acinetobacter* (Bouvet and Grimont, 1986; Bouvet and Jeanjean, 1989; Tjernberg and Ursing, 1989; Gerner-Smidt and Tjernberg, 1993). Six species were named (and assigned species numbers) in one study (Bouvet and Grimont, 1986), and a seventh species, *A. radioresistens*, was named by another laboratory (Nishimura et al., 1988). The other genomic (DNA) groups, which could not be differentiated by phenotypic methods, or contained fewer than 10 strains, were assigned a number. It should be noted that genomic species 13–15 of Bouvet and Jeanjean (1989) and Tjernberg and Ursing (1989) were described independently, and in order to avoid confusion, it is current practice to add the suffices BJ or TU to denote the groups of the respective studies. Genomic species 13 BJ and DNA group 14 TU have one reference strain in common, and have been considered one genomic species, while the other groups are apparently distinct.

Numerous reports refer to strains that cannot be allocated to any of the described (genomic) species. Since almost all of the acinetobacters studied were derived from hospital sources and because the most common habitats of these organisms are soil and water, it seems likely that many naturally occurring strains have yet to be isolated and that the current listing is probably not complete.

A distinct correlation between the PAGE-types of the outer membrane proteins and several *Acinetobacter* DNA relatedness groups has been reported (Ino and Nishimura, 1989; Dijkshoorn et al., 1990).

Although the highly competent strain BD413, a soil derivative, was originally reported to be a strain of *A. calcoaceticus*, phenotypic characterization (Bouvet and Grimont, 1986), studies of outer membrane protein patterns (Ino and Nishimura, 1989), and 16S rDNA sequence analysis (Strätz et al., 1996) suggest that this strain may, in fact, belong to a unique species. Furthermore, phylogenetic analysis of nucleotide sequences of *gyrB* genes revealed that strain BD413 was not strongly linked to any currently recognized genomic species (Yamamoto and Harayama, 1996) and may, in fact, represent a new genomic species (Yamamoto et al., 1999).

A group of *n*-alkane-degrading *Acinetobacter* strains have been described as members of a new species, *"A. venetianus"*; these strains harbored plasmids containing genes homologous to *alkBFGH* of *Pseudomonas oleovorans*, which encode the enzymatic steps of *n*-alkane oxidation (Di Cello et al., 1997). It has been shown that the oil-degrading *Acinetobacter* strain RAG-1 is a member of this species and that all strains of *"A. venetianus"* have a unique restriction pattern of amplified 16S rDNA and share similarities in DNA–DNA hybridization and biochemical characteristics (Vaneechoutte et al., 1999).

It is most likely that *Acinetobacter* species, particularly those which include many virtually identical independently isolated strains, consist of organisms that have evolved to survive in some particular ecological niche(s). In each instance, the particular genetic constitution of strains of a species may represent an arrangement that is especially advantageous to the survival of those strains in their natural niche; the similarity of such arrangements in isolated strains may account for the observed high levels of DNA–DNA hybridization. It is possible that mutations in 16S rDNA may not interfere with the ability of strains of a particular species to retain a selective advantage for occupation of their normal niche, thus accounting for frequent lack of correlation between data from DNA–DNA hybridization and 16S rDNA sequence analysis, as described below.

16S rDNA analysis 16S rRNA gene sequences from single strains of 21 reported *Acinetobacter* (genomic) species have been shown to have binary similarities of more than 94% and to constitute a phylogenetically coherent group of organisms within the *Gammaproteobacteria* (Ibrahim et al., 1997; Rainey et al., 1994a) (Figs. BXII.γ.148 and BXII.γ.149). Most strains of *Acinetobacter* were found to belong to one of five clusters (Fig. BXII.γ.149). Cluster I included DNA groups 2 and TU13; cluster II included DNA groups 3, CTTU13, and 1-3; cluster III included DNA groups 6, 8, and 9; cluster IV included DNA groups BJ15 through BJ17; and cluster V included DNA groups 1, BJ14, 10, and 11 (Ibrahim et al., 1997). Several DNA groups (4, 5, 7, 12, TU14, and TU15) are not associated significantly with any of the five clusters. Although reassociation of DNA from group 10 to DNA from group 11 is low (Bouvet and Grimont, 1986), strains from these groups have almost identical 16S rDNA sequences (Ibrahim et al., 1997). Neither study (Ibrahim et al., 1997; Rainey et al., 1994a) had complete correspondence between DNA–DNA hybridization values and clustering of 16S rDNA sequences, similar to observations for other groups of bacteria (Stackebrandt and Goebel, 1994). The finding that two authentic strains of *A. calcoaceticus* have 16S rRNAs with a similarity coefficient (S_{AB}) of only 0.66 (Byng et al., 1985) is yet another demonstration of the lack of correspondence of data obtained by DNA–DNA hybridization and 16S rRNA gene sequences.

Although there appear to be unambiguous sequence differences in the highly variable regions of the 16S rDNAs of each of the 21 DNA groups examined (Ibrahim et al., 1997), it seems premature to use these signatures for absolute species identification until more strains from each DNA group are analyzed in a similar manner. In addition, since the *Acinetobacter* chromosome encodes at least seven rRNA operons (Strätz et al., 1996; Gralton et al., 1997) it is possible that one, or more, of the rDNA sequences might have experienced mutational and recombinational changes during evolution of individual members of a species (Sneath, 1993).

Phylogenetic studies involving* GYRB, RPOD, *and* RECA *genes It has been suggested that the resolution of 16S rRNA-based phylogenetic analysis is not sufficient to distinguish closely related genomic species, because of the extremely slow rate of base substitution in 16S rDNAs (Yamamoto and Harayama, 1996). Genes that code for proteins evolve more rapidly than the genes coding for rRNA. It has been proposed that the highly conserved nature of type II DNA topoisomerase genes makes them excellent candidates for studying bacterial diversity (Huang, 1996). The DNA topoisomerase *gyrB* of acinetobacters has been subjected to phylogenetic analysis based on nucleotide sequences of these genes and the corresponding amino acid sequences of the gene products (Yamamoto and Harayama, 1996). It was shown that the percentage of nucleotide substitutions in the *gyrB* genes of 15 strains of *Acinetobacter* varied from 0.3 to 30.4%, but that the percentage of substitutions in the corresponding amino acid sequences was between 0.5 and 13.3%, indicating that nucleotide substitution which results in amino acid substitution is less frequent than synonymous substitution (Yamamoto and Harayama,

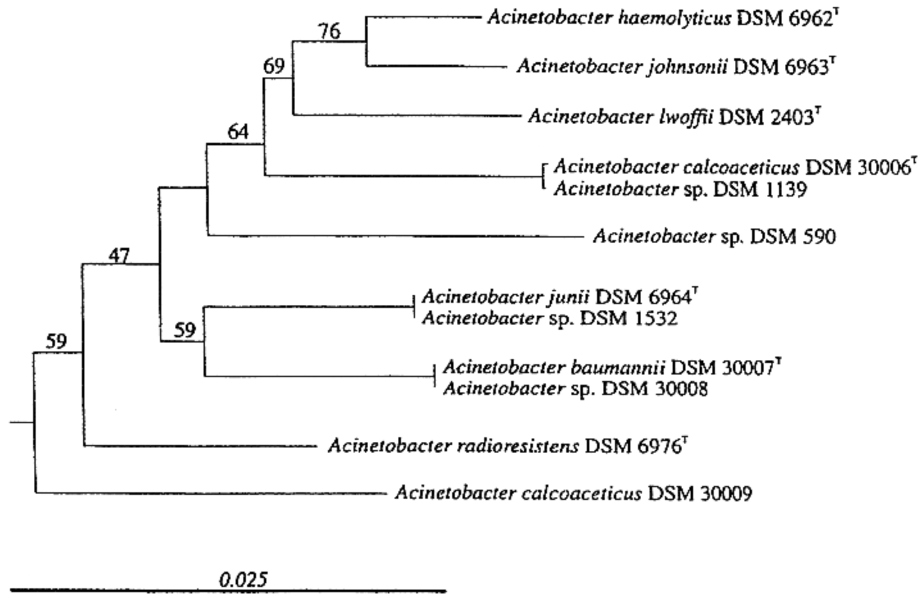

FIGURE BXII.γ.148. Intrageneric relationships of the genus *Acinetobacter* as determined by 16S rDNA sequence analysis. (Reproduced with permission from F.A. Rainey et al., FEMS Microbiology Letters. *124:* 349–354, 1994, ©Elsevier Science B.V.)

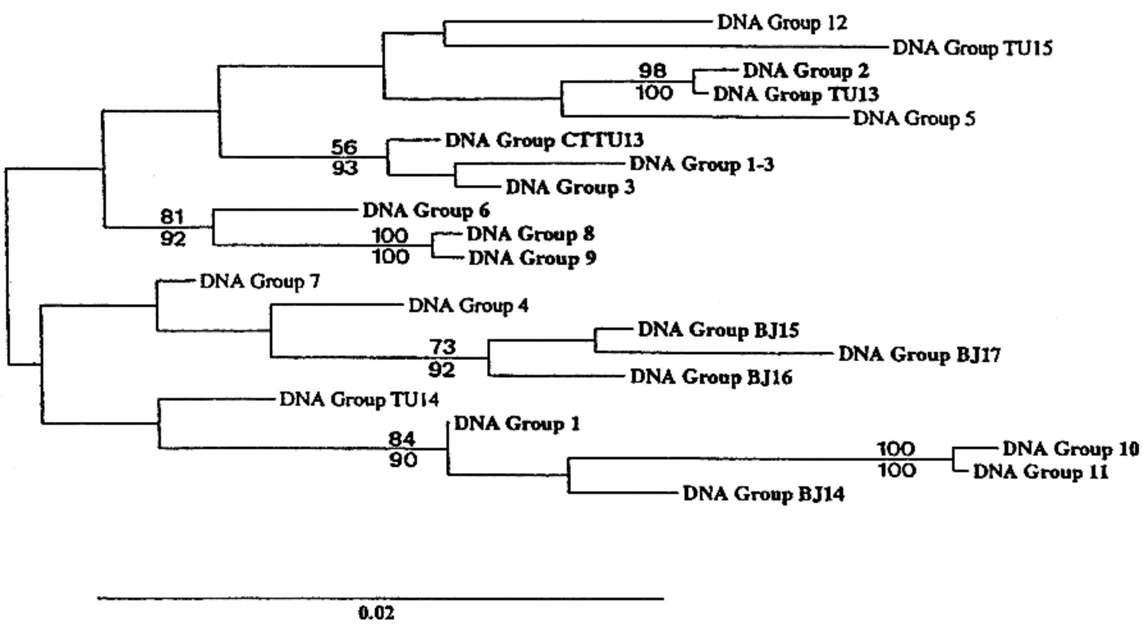

FIGURE BXII.γ.149. Unrooted phylogenetic dendrogram constructed for 21 strains representing all known DNA groups described for the genus *Acinetobacter*. (Reproduced with permission from A. Ibrahim et al., International Journal of Systematic Bacteriology *47:* 837–841, 1997, ©International Union of Microbiological Societies.)

1996). The results of phylogenetic analysis using *gyrB* nucleotide sequences was consistent with those using DNA–DNA hybridization and phenotypic comparisons.

In a more extensive investigation using 49 *Acinetobacter* strains, 46 of which had previously been classified into 18 genomic species using the results of DNA–DNA hybridization, it was shown that the phylogenetic grouping of such strains based on *gyrB* genes was almost congruent with that based on DNA–DNA hybridization studies (Yamamoto et al., 1999) (Fig. BXII.γ.150). Three strains that had not been characterized previously by DNA–DNA hybridization appeared to belong to two new genomic species (Fig. BXII.γ.150). Since minor discrepancies existed in the grouping of strains of genomic species 8, 9, and BJ17, the phylogenetic tree for these strains was reconstructed from the sequence of *rpoD*, the structural gene for RNA polymerase σ^{70} factor (Yamamoto et al., 1999); this tree was completely congruent with the grouping based on DNA–DNA hybridization (Fig. BXII.γ.150).

Using *Acinetobacter recA* obtained by polymerase chain reaction amplification, it was possible to distinguish 17 genomic species

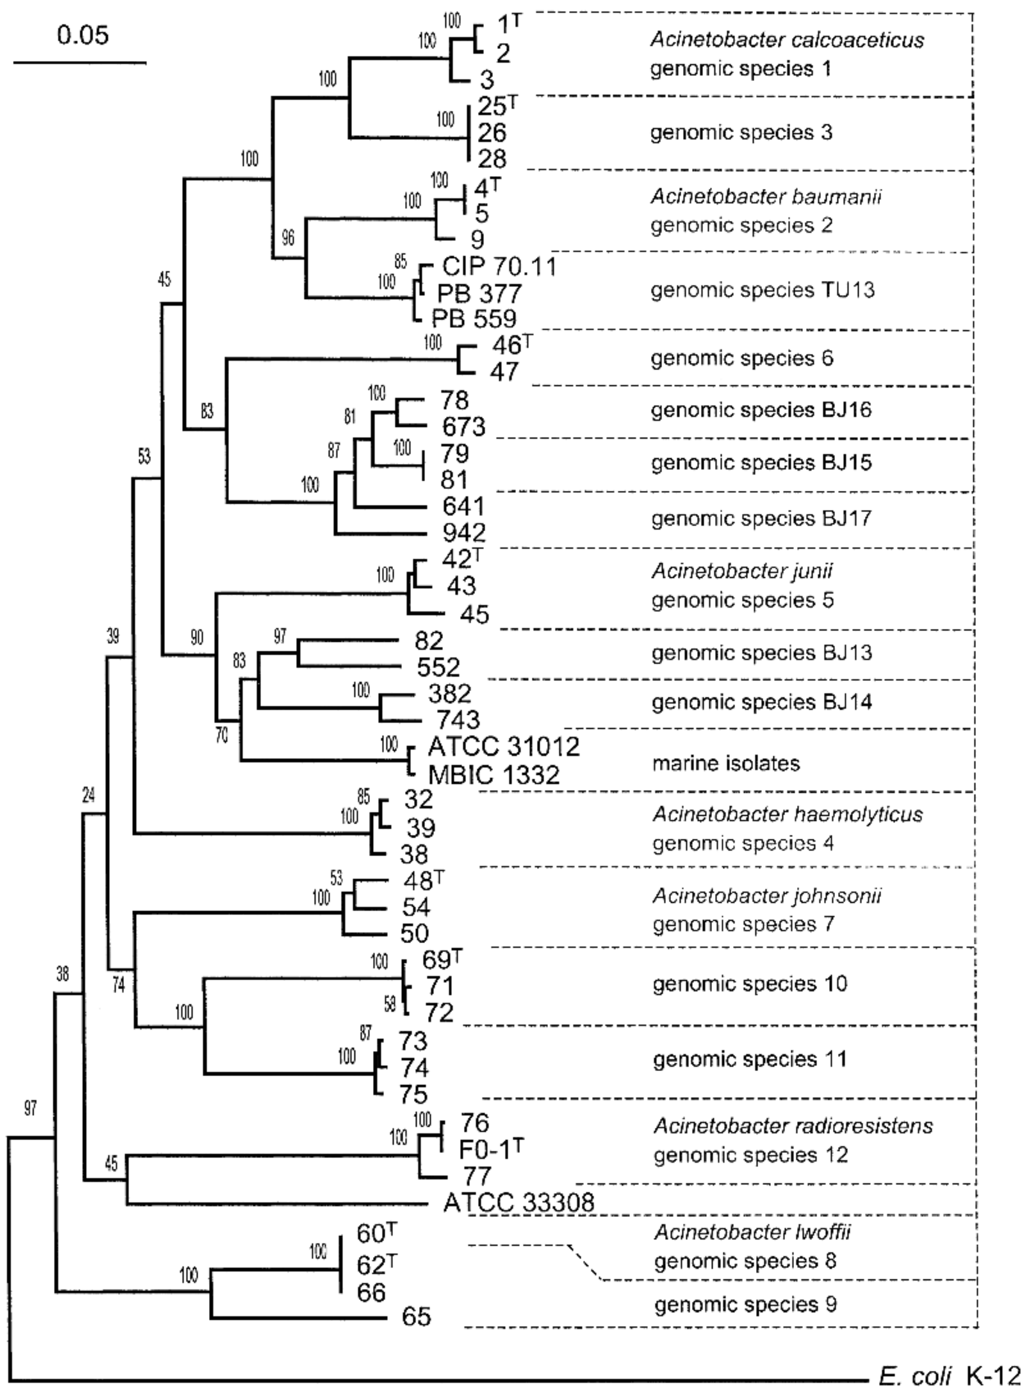

FIGURE BXII.γ.150. Phylogenetic trees of 49 *Acinetobacter* strains from the nucleotide sequences of the *gyrB* genes. Reproduced with permission from S. Yamamoto et al., International Journal of Systematic Bacteriology *49:* 87–95, 1999, ©International Union of Microbiological Societies.)

by restriction fragment length polymorphism analysis with two restriction enzymes (Nowak et al., 1995).

Methods used for* Acinetobacter *(genomic) species identification The recognition of distinct DNA relatedness groups within the genus *Acinetobacter* has raised interest in the ecology and pathology of the different groups. A great many approaches to identification of these (genomic) species by methods easier to perform than DNA–DNA hybridization have been taken. Table BXII.γ.131 presents phenotypic properties that frequently make it possible to distinguish strains from most of 19 DNA groups. It should be noted though, that phenotypic systems, including nutritional and physiological tests (Bouvet and Grimont, 1986, 1987b; Gerner-Smidt et al., 1991; Kämpfer et al., 1993) or test galleries of commercial systems (Soddell et al., 1993; Bernards et al., 1995, 1996), do not allow for identification of all DNA groups. In particular, using phenotypic properties, it is difficult to discriminate between the closely related (genomic) species *A. calcoaceticus* (DNA group 1), *A. baumannii* (DNA group 2), and

the unnamed groups 3 and 13TU, sometimes referred to as the *A. calcoaceticus-A. baumannii* (Acb) complex. Table BXII.γ.132 lists phenotypic properties that permit some differentiation of the species of this complex.

Other methods used for species identification of acinetobacters (Dijkshoorn, 1996) are based on structural characteristics of strains and include serotyping (Traub and Leonhard, 1994), fatty acid compositional analysis (Kämpfer, 1993), outer membrane protein patterns (Ino and Nishimura, 1989; Dijkshoorn et al., 1990), and enzyme electrophoresis (Bouvet and Jeanjean, 1995). None of these methods has been completely successful for assignation of isolated strains to the currently described (genomic) species.

Due to the difficulties in phenotypic identification, and given the clinical relevance of some genomic species, a variety of molecular methods has been explored for their usefulness in identification of *Acinetobacter* species. These methods include ribotyping (Gerner-Smidt, 1992; Dijkshoorn et al., 1993), amplified rDNA restriction analysis (ARDRA) (Vaneechoutte et al., 1995; Dijkshoorn et al., 1998; Jawad et al., 1998) and AFLP™ (amplified fragment length polymorphism) (Janssen et al., 1997), 16S-23S rDNA spacer analysis (Dolzani et al., 1995; Nowak et al., 1995), and tRNA spacer fingerprinting (Ehrenstein et al., 1996).

Typing methods Primarily because of an interest in tracing strains of *Acinetobacter* involved in nosocomial infections and epidemic spread, a great effort has been made to distinguish strains. Early phenotypic methods used to allocate strains to definitive types include phage typing (Bouvet et al., 1990) and bacteriocin typing (Andrews, 1986). Other phenotypic methods include biotyping (Bouvet and Grimont, 1987b), multilocus enzyme electrophoretic typing (Picard et al., 1989; Thurm and Ritter, 1993), cell envelope protein typing (Dijkshoorn et al., 1987), antibiotic susceptibility typing (Dijkshoorn et al., 1993; Seifert et al., 1993a; Marcos et al., 1994; Lytikäinen et al., 1995), and serotyping (Traub and Leonhard, 1994; Pantophlet et al., 1998). Antibiogram typing is widely used in screening for strain identity, although gain or loss of resistance genes may lead to false conclusions. Biotyping has been shown to be a practical method for allocating strains of the Acb complex to as many as 19 biotypes (Bouvet and Grimont, 1987b; Bouvet et al., 1990) and has ena-

bled the recognition of specific types from different countries (Marcos et al., 1994; Dominguez et al., 1995; Ratto et al., 1995).

Rapid developments in molecular biology have led to the application of numerous DNA-based typing methods for *Acinetobacter* strain identification, including discrimination of strains of the Acb complex. These include plasmid DNA fingerprinting (Gerner-Smidt, 1989; Seifert et al., 1994b), ribotyping (Gerner-Smidt, 1992), PCR fingerprinting methods with detection of amplification products by agarose gel electrophoresis (Reboli et al., 1994) or automated laser fluorescence (Webster et al., 1996), pulsed field gel electrophoresis (Tankovic et al., 1994), and selective amplification of restriction fragments by AFLP™ (Janssen and Dijkshoorn, 1996; Janssen et al., 1997). Nosocomial acinetobacters can be very similar; therefore, it is current practice to use a combination of methods for strain identification (Dijkshoorn et al., 1993; Struelens et al., 1993; Seifert et al., 1994a; Lytikäinen et al., 1995). By application of such a polyphasic strategy, including ribotyping, protein electrophoretic typing, AFLP™, biotyping and antibiogram typing, it was possible to recognize and differentiate two highly similar strains found in different NW European hospitals and countries (Dijkshoorn et al., 1996). It was shown recently that multiply-resistant strains with features similar to these two clones are also common in the Czech Republic (Nemec et al., 1999). It is not yet known whether these strains are also responsible for outbreaks in other parts of the world.

Analysis of 170 acinetobacter strains isolated from various foods revealed that although strains belonging to almost every species were represented, 46% were identified as *A. johnsonii* and 15% as *A. lwoffii* (Gennari and Lombardi, 1993). A majority (78%) of *Acinetobacter* strains isolated from activated sludge, in a pilot-scale treatment of sewage for enhanced removal of phosphate, was identified as *A. johnsonii* (Duncan et al., 1988).

Study of quantitative transformation of the high-level streptomycin-resistance marker Since quantitative transformation of the high-level streptomycin-resistance marker was instrumental in elucidation of the taxonomic relationships within the *Moraxellaceae* (Bøvre and Hagen, 1981), similar studies with 54 clinical isolates and 17 reference strains of *Acinetobacter*, using competent strain BD4 as the recipient, were initiated (Bergan and Vaksvik, 1983). Ratios of interstrain to intrastrain transformation of 0.06–6.4% were obtained, DNAs from streptomycin-resistant mutants of 13 of the clinical isolates failing to transform the competent streptomycin-sensitive strain. Although these studies were limited, the results obtained suggest that evolutionary change in ribosomal protein S12 (*StrA*) in the genus *Acinetobacter* may be as extensive as that found in the genus *Moraxella* (Bøvre and Hagen, 1981).

Enrichment and Isolation Procedures

Isolation of acinetobacters can be accomplished using ordinary laboratory media such as heart infusion agar, brain heart infusion agar, or trypticase soy agar. Although many acinetobacters grow well at 37°C, the optimum growth temperature for most strains is 33–35°C. Acinetobacters having lower optimum temperatures and unable to grow at 37°C have been reported (Breuil et al., 1975). A general enrichment procedure for isolation of acinetobacters from soil and water involves inoculation of 20 ml of an acetate-mineral medium with 5 ml of a water sample, or of a filtered 10% soil suspension, followed by vigorous aeration during incubation at 30°C, or at room temperature (Baumann, 1968). Aeration is especially favorable for enrichment of nonmotile acinetobacters since, in a nonaerated culture, motile oxygen-consuming pseudomonads tend to move to the surface layer, thereby decreasing the amount of oxygen diffusing into the interior of the liquid volume. Acinetobacters have a slightly acid pH optimum for growth, and aeration at a pH from 5.5 to 6.0 favors enrichment of these organisms from soil and water samples (Baumann, 1968; Juni, 1982). Presumptive identification of colonies of *Acinetobacter* growing on any medium involves a demonstration of nonmotile coccobacilli in a wet mount, an oxidase-negative reaction, and a Gram-negative stain (Warskow and Juni, 1972). When these criteria are satisfied, definitive identification can be achieved through use of the transformation assay (Juni, 1972).

Selective media for isolation of acinetobacters from environmental and clinical sources are available and include Herellea

Agar (Difco) (Mandel et al., 1964) and Leeds *Acinetobacter* Medium (Jawad et al., 1994).

Maintenance Procedures

Cultures of *Acinetobacter* can be maintained on heart infusion agar plates (Difco) stored in plastic bags (to delay evaporation and drying) at room temperature for periods as long as six months before being transferred (Marcus et al., 1969). This procedure is not recommended, however, since it has been observed that the ability to use certain carbon sources is lost, probably because of spontaneous mutation, when cultures are transferred infrequently in this manner (Juni, unpublished). Storage at low temperatures, or by lyophilization, appears to be best for preservation of properties initially observed for a particular strain. Cultures can be conveniently stored by preparing a heavy suspension of organisms in buffer, or in broth, and adding 0.5 ml of this suspension to 1.0 ml of sterile glycerol in a screw-capped test tube. After mixing, this suspension is stored at approximately −65°C. Since 67% glycerol remains liquid at temperatures above −46°C, a stored culture can be sampled conveniently by withdrawing a loopful, or 0.1 ml, of the glycerol stock and streaking this material directly on a heart infusion, or other suitable medium, plate without significant warming of the glycerol suspension.

Acknowledgments

I would like to thank Lenie Dijkshoorn for invaluable assistance in preparation of the section dealing with taxonomy of acinetobacters.

List of species of the genus Acinetobacter

1. **Acinetobacter calcoaceticus** (Beijerinck 1911) Baumann, Doudoroff and Stanier 1968b, 1538[AL] emend. Bouvet and Grimont 1986, 238 (*Micrococcus calcoaceticus* Beijerinck 1911, 1067.)

cal.co.a.ce′ ti.cus. L. n. *calx* chalk; L. n. *acetum* acetic acid; M.L. n. *calcoaceticus* calcium acetate, which was used by Beijerinck in the enrichment medium from which he isolated the organism.

Characteristics as given for the genus. Colonies on trypticase soy agar are circular, convex, smooth, and slightly opaque with entire margins; colonies are 0.5–1.5 mm in diameter after 24 h and 2.5–3.5 mm in diameter after 48 h at 30°C. Good growth occurs at 15–37°C in one day. No growth occurs at 41°C and above. Nitrates are not reduced to nitrites in complex medium. Grows on citrate (Simmons). Acid is produced from D-glucose. γ-Glutamyltransferase is produced, but β-xylosidase is not produced. Horse or sheep blood is not hemolyzed; gelatin is not hydrolyzed.

The following compounds are utilized as sole sources of carbon and energy: L-phenylalanine, L-histidine, phenylacetate, malonate, azelate, β-alanine, *trans*-aconitate, L-arginine, L-ornithine, DL-lactate, 2,3-butanediol, DL-4-aminobutyrate, glutarate, L-aspartate, and L-tyrosine. D-malate and histamine are not utilized. L-Leucine is utilized by some strains.

Isolated from soil.

Genomic species 1.

The mol% G + C of the DNA is: 40–42 (T_m).

Type strain: ATCC 23055, CIP 81.08, DSM 30006.

GenBank accession number (16S rRNA): X81661, Z93434.

2. **Acinetobacter baumannii** Bouvet and Grimont 1986, 239[VP]

bau.ma′ ni.i. M.L. gen. *baumannii* in honor of Paul and Linda Baumann.

Characteristics as given for the genus. Colonies on trypticase soy agar are circular, convex, smooth, and slightly opaque with entire margins and sometimes have a butyrous aspect. Colonies are 1.5–2.0 mm in diameter after 24 h and 3.0–4.0 mm in diameter after 48 h at 30°C. Good growth occurs at 15–44°C. Occasional strains may require methionine for growth on minimal medium. Nitrates are not reduced to nitrites in complex medium (exceptions occur). Acid is produced from D-glucose by most strains. Strains which produce acid from D-glucose also produce β-xylosidase. γ-Glutamyltransferase is produced by most strains. Horse or sheep blood is not hemolyzed; gelatin is not hydrolyzed. Citrate (Simmons) is utilized by prototrophic strains. The following compounds are utilized: DL-lactate, glutarate, L-aspartate, L-tyrosine, ethanol, 2,3-butanediol, and DL-4-aminobutyrate. The following compounds are utilized by most strains: L-phenylalanine and phenylacetate (growth on L-phenylalanine is associated with growth on phenylacetate in this species), L-histidine, azelate, D-malate, L-leucine, β-alanine, *trans*-aconitate, L-arginine, and L-ornithine. Histamine is not utilized.

Isolated from human clinical specimens or the natural environment. Most *Acinetobacter* strains isolated from nosocomial infections belong to this species.

Genomic species 2.

The mol% G + C of the DNA is: 40–43 (T_m).

Type strain: ATCC 19606, CIP 70.34, DSM 30007.

GenBank accession number (16S rRNA): X81660.

3. **Acinetobacter haemolyticus** Bouvet and Grimont 1986, 239[VP]

hae.mo.ly′ ti.cus. Gr. n. *haema* blood, dissolving.

Characteristics as given for the genus. Colonies on trypticase soy agar are circular, convex, smooth, and slightly opaque with entire margins and sometimes have a sticky consistency. Colonies are 1.5–2.0 mm in diameter after 48 h at 30°C. Good growth occurs at 15–37°C. No growth occurs at 41°C. Nitrates are not reduced to nitrites in complex medium (exceptions occur). On horse or sheep blood agar, colonies are surrounded by a clear zone which is limited by a dark red ring after 24 h at 37°C or after 48 h at 30°C. Gelatin is hydrolyzed (exceptions occur). Some strains produce acid from D-glucose and produce β-xylosidase. Some strains produce γ-glutamyltransferase. Most strains grow on Simmons citrate agar.

DL-4-Aminobutyrate is utilized by all strains. The following compounds are utilized by most strains: L-histidine, D-malate, L-leucine, ethanol, and L-arginine. The following compounds are not utilized: DL-lactate, azelate, histamine, β-alanine, 2,3-butanediol, and L-ornithine.

Isolated from clinical specimens and the environment.

Genomic species 4.

The mol% G + C of the DNA is: 40–43 (T_m).

Type strain: Strain Mannheim 2446/60, B40, ATCC 17906, CIP 64.3, DSM 6962, NCTC 10305.

GenBank accession number (16S rRNA): X81662.

4. **Acinetobacter johnsonii** Bouvet and Grimont 1986, 239[VP]

john′ so.ni.i. M.L. gen. *johnsonii* in honor of John L. Johnson.

Characteristics as given for the genus. Colonies on tryptocase soy agar are circular, convex, smooth, and slightly opaque with entire margins; colonies are 1.0–1.5 mm in diameter after 24 h and 2.0–3.0 mm in diameter after 48 h at 30°C. Good growth occurs at 15 to 30°C; no growth occurs at 37°C. Nitrates are not reduced to nitrites in complex medium (exceptions occur). Acid is not produced from D-glucose; β-xylosidase and γ-glutamyltransferase are not produced. Horse or sheep blood is not hemolyzed; gelatin is not hydrolyzed. No growth factor is required (in a few cases methionine is required). Grows on Simmons citrate. DL-Lactate and ethanol are utilized as sole sources of carbon and energy.

The following compounds are utilized by many strains: malonate, D-malate, L-aspartate, L-tyrosine, 2,3-butanediol, L-arginine, L-ornithine, and DL-4-aminobutyrate. The following compounds are not utilized: glutarate, L-phenylalanine, phenylacetate, L-histidine, azelate, L-leucine, histamine, β-alanine, and *trans*-aconitate.

Isolated from clinical specimens, activated sludge, foods, and eviscerated chickens.

Genomic species 7.

The mol% G + C of the DNA is: 44–45 (T_m).

Type strain: ATCC 17909, CIP 64.6, DSM 6963, NCTC 10308.

GenBank accession number (16S rRNA): X81663.

5. **Acinetobacter junii** Bouvet and Grimont 1986, 239[VP]
ju′ni.i. M.L. gen. *junii* in honor of Elliot Juni.

Characteristics as given for the genus. Colonies on tryptocase soy agar are circular, convex, and smooth with entire margins. Colonies are 1.0–1.5 mm in diameter and translucent after 24 h and 2.0–2.5 mm in diameter and slightly opaque after 48 h at 30°C. Good growth occurs at 15–37°C; occasionally growth occurs at 41°C. No growth occurs at 44°C. No growth factor is required. Nitrates are not reduced to nitrites in complex media. Acid is not produced from D-glucose. β-Xylosidase and γ-glutamyltransferase are not produced. Horse or sheep blood is not hemolyzed; gelatin is not hydrolyzed.

Citrate (Simmons) is occasionally utilized. DL-Lactate, L-histidine, D-malate, and ethanol are utilized as sole sources of carbon and energy. The following compounds are utilized by many strains: L-aspartate, L-leucine, L-tyrosine, L-arginine, and DL-4-aminobutyrate. The following compounds are not utilized: glutarate, L-phenylalanine, phenylacetate, malonate, azelate, histamine, β-alanine, 2,3-butanediol, *trans*-aconitate, and L-ornithine.

Isolated from human clinical specimens.

Genomic species 5.

The mol% G + C of the DNA is: 42 (T_m).

Type strain: Mannheim 2723/59, ATCC 17908, CIP 64.5, DSM 6964, NCTC 10307.

GenBank accession number (16S rRNA): X81664.

6. **Acinetobacter lwoffii** (Audureau 1940) Brisou and Prévot 1954, 727[AL] emend. Bouvet and Grimont 1986, 238.
lwof.fi.i. M.L. gen. *lwoffii* in honor of Andre Lwoff.

Characteristics as given for the genus. Colonies on tryptocase soy agar are circular, convex, smooth, and slightly opaque with entire margins; colonies are 1.0–1.5 mm in diameter after 24 h and 3.0–4.0 mm in diameter after 48 h at 30°C. Good growth occurs at 15–37°C in one day. No growth occurs at 41°C and above. Nitrates are not reduced to nitrites in complex medium. No growth occurs on citrate (Simmons). Acid is not produced from D-glucose; β-xylosidase and γ-glutamyltransferase is not produced. Horse or sheep blood is not hemolyzed; gelatin is not hydrolyzed.

Azelate and DL-lactate are utilized as sole sources of carbon and energy. The following compounds are not utilized: L-phenylalanine, L-histidine, malonate, L-aspartate, L-leucine, histamine, β-alanine, 2,3-butanediol, glutarate, *trans*-aconitate, and L-arginine. Some strains can utilize phenylacetate, L-tyrosine, ethanol, L-ornithine, and DL-4-aminobutyrate.

Habitat unknown.

Genomic species 8.

The mol% G + C of the DNA is: 46 (T_m).

Type strain: ATCC 15309, CIP 64.10, DSM 2403, NCTC 5866.

GenBank accession number (16S rRNA): X81665.

7. **Acinetobacter radioresistens** Nishimura, Ino, and Iizuka 1988, 210[VP]
ra.di.o.re.sis′tens. L. n. *radius* ray, beam; L. part. adj. *resistens* resisting; M.L. part. adj. *radioresistens* ray resisting, because of high resistance to gamma-ray irradiation.

Cells are rods 0.6–0.7 × 0.8–1.0 μm. Pleomorphic. A plump form is 0.8–0.9 ×1.2–1.8 μm; elongate cells (15 μm or more long) occur in young cultures; and coccoid cells (0.6–0.9 μm in diameter) occur in old cultures. The cells occur singly or in pairs. Nonsporeforming, nonencapsulated, nonmotile, non-acid fast, Gram negative. Colonies on nutrient agar smooth, entire, convex, glistening, opaque, and yellowish white to pale yellow. A pellicle is formed on the surface of nutrient broth.

Metabolism is strictly respiratory. Catalase is produced. Cytochrome oxidase is not produced. Nitrate is reduced to nitrite in succinate-nitrate medium but not in Casitone-nitrate medium. Indole and hydrogen sulfide are not produced. Tween 80 is hydrolyzed. Lysine and ornithine decarboxidase, pheylalanine deaminase, arginine dihydrolase, gelatinase, and urease are not produced. Hemolysis on sheep blood agar is negative. Growth occurs in media containing 5% NaCl. Good growth occurs at 27–31°C. Growth occurs at 42°C. L-Arabinose, D-ribose, D-xylose, D-galactose, D-glucose, D-fructose, D-mannose, L-rhamnose, D-glucosamine, D-cellobiose, lactose, maltose, melibiose, sucrose, and raffinose are not oxidized and are not assimilated. Acetate, fumarate, DL-lactate, L-malate, malonate, succinate, hexadecane, heptadecane, octadecane, eicosane, ethanol, *n*-butanol, L-alanine, L-glutamate, L-leucine, and L-proline are assimilated. Citrate, gluconate, decane, nonadecane, methanol, *n*-propanol, isopropanol, ethanolamine, β-alanine, DL-phenylalanine, L-histidine, L-isoleucine, DL-norleucine, DL-serine, L-threonine, dulcitol, *i*-inositol, D-mannitol, and D-sorbitol are not assimilated.

Highly resistant to gamma-ray irradiation (D_{10} value, 125 to 220 krads under air equilibrium in 0.067 M phosphate buffer). Resistant to benzylpenicillin (100 IU).

The major cellular fatty acids are the even-numbered straight-chain acids $C_{18:1}$, $C_{16:1}$, and $C_{16:0}$. The ubiquinone system is Q-9.

Isolated from cotton and from soils.

Assigned to genomic species 12 (Tjernberg and Ursing, 1989).

The mol% G + C of the DNA is: 44.1–44.8 (T_m).
Type strain: Strain FO-1, DSM 6976, IAM 13186.
GenBank accession number (16S rRNA): X81666.

8. **"Acinetobacter venetianus"** Di Cello, Pepi, Baldi and Fani 1997, 245.
venetianus. venetianus because it was isolated from the Venice lagoon

Characteristics are as given for the genus. Strains tested (2) are β-hemolytic on sheep blood agar. Growth occurs at 37°C but not at 41°C or 44°C. Aerobic acidification of glucose on OF medium is negative. β-Xylosidase is not produced. Strains test positive for gelatinase production; caprate, malate, and citrate hydrolysis; and assimilation of acetate, alanine, caprate, valerate, citrate, histidine, and 3-hydroxybutyrate. There is no growth on rhamnose, *N*-acetylglucosamine, ribose, inositol, fucose, sorbitol, arabinose, propionate, 5-ketogluconate, glycogen, *m*-hydroxybutyrate, and 2-ketogluconate.

Strains grow on fuel oil and the *n*-alkanes (C_{10}, C_{14}, and C_{20}), and their respective oxidation products as sole carbon sources. Strains harbor plasmids that encode the enzyme activities required for oxidation of alkanes and dehydrogenation of aliphatic alcohols.

Isolated from lagoons and other waters that are contaminated with fuel oil or other products derived from petroleum.

The mol% G + C of the DNA is: 43.6–43.9 (T_m).
Deposited strain:
GenBank accession number (16S rRNA): X80825 (for strain RAG-1).
Additional Remarks: No type strain has been designated. Strains investigated include VE-C3, RAG-1, and T4.

Other Organisms

The following genomic groups have been recognized by virtue of possessing unique DNA–DNA hybridization groups. They are not yet named because none of them has been shown to display a set of phenotypic properties that distinguish them from the other species of *Acinetobacter*. Some of the phenotypic properties of these genomic species are shown in Tables BXII.γ.131 and BXII.γ.132.

Unnamed genomic species of *Acinetobacter*: 3, 6, 9, 10, 11, TU13, TU14 (= BJ13), TU15, CTTU13, 1-3, BJ14, BJ15, BJ16, and BJ17.

Genus III. **Psychrobacter** *Juni and Heym 1986b, 389*[VP]

Elliot Juni

Psy.chro' bac.ter. Gr. adj. *psychros* cold; M.L. masc. n. *bacter* rod; M.L. masc. n. *Psychrobacter* a rod that grows at low temperatures.

Rods or cocci, 0.9–1.3 × 1.5–3.8 µm. Rods can vary in length from extremely short (coccobacilli) to relatively long. For some strains the rods tend to be somewhat swollen. Also observed to grow as cocci or coccobacilli. Nonpigmented. Colonies on heart infusion agar are usually cream-colored, smooth, and opaque. Gram negative; the stain frequently tends to be retained. Nonmotile, and aerobic. **Most strains are psychrotrophic; they are able to grow at 5°C, have temperature optima near 20°C, and generally are unable to grow at 35–37°C.** Strains able to grow well at 35–37°C usually cannot grow at 5°C. Grow well on most common complex media. Most strains can grow on a mineral-agar medium containing a single carbon and energy source and ammonium salts as the nitrogen source. Some strains form acid aerobically from D-glucose, D-mannose, D-galactose, L-arabinose, D-xylose, and L-rhamnose. They are **halotolerant and grow in the presence of 6.5% or greater NaCl**. Many strains are radiation resistant. **Oxidase positive. Catalase positive.** Many strains are **competent for natural genetic transformation**. Have been isolated from the open sea, the deep sea, sea ice, ornithogenic soils, skins and gills of fish, skins of poultry, various food products, irradiated foods, air contaminants, and from a variety of human sources. Not known to be clinically significant. Cultures of *Psychrobacter* can be maintained in the same manner as for cultures of *Acinetobacter*, as described above.

The mol% G + C of the DNA is: 41–50.7.

Type species: **Psychrobacter immobilis** Juni and Heym 1986b, 388.

Further descriptive information

Bacterial strains that were oxidase positive and psychrotrophic (subsequently shown to be psychrobacters) were proposed as members of the *Moraxellaceae* because of weak but distinct genetic interactions with authentic *Moraxella* species, involving the high-level streptomycin-resistance marker (Bøvre and Hagen, 1981). Based on 16S rRNA gene sequence information, *Psychrobacter immobilis* has been placed in group III (of four groups) of the family *Moraxellaceae* (See Fig. BXII.γ.146 of the description of the family *Moraxellaceae.*) (Pettersson et al., 1998). Nine distinct species of *Psychrobacter* have been revealed from analysis of phenotypic properties, DNA–DNA hybridization, and 16S rRNA sequences (see Fig. BXII.γ.151) (Bowman et al., 1996, 1997a, 1997d; Maruyama et al., 2000; Denner et al., 2001a; Kämpfer et al., 2002a; Romanenko et al., 2002a). 16S rRNA sequences having similarities of 93.9–99.9% have been reported for strains of all species of *Psychrobacter* (Bowman et al., 1996, 1997d; Denner et al., 2001a; Kämpfer et al., 2002a; Romanenko et al., 2002a). Based on the extent of 16S rDNA similarity, psychrobacters are more closely related to the moraxellae than they are to the acinetobacters (Bowman et al., 1996; Pettersson et al., 1998) (Fig. BXII.γ.146). The wide range of DNA composition of psychrobacters (mol% G + C 41–50.7) provides evidence for heterogeneity of the genus.

It has been reported (Romanenko et al., 2002a) that strains of *P. submarinus* and *P. marincola* have 99.9% similarity in 16S rRNA sequences but showed DNA–DNA reassociation of only 15% similarity. Furthermore, the mol% G + C of the DNAs of these strains differed by 3.9%. These data indicate that *P. submarinus* and *P. marincola* must have a long history of independent evolution, from a presumed common ancestor, in spite of conservation of the sequences of their respective 16S rRNAs. By contrast, it was demonstrated (Denner et al., 2001a) that 16S rRNA similarities between *P. proteolyticus* and those of *P. glacincola*

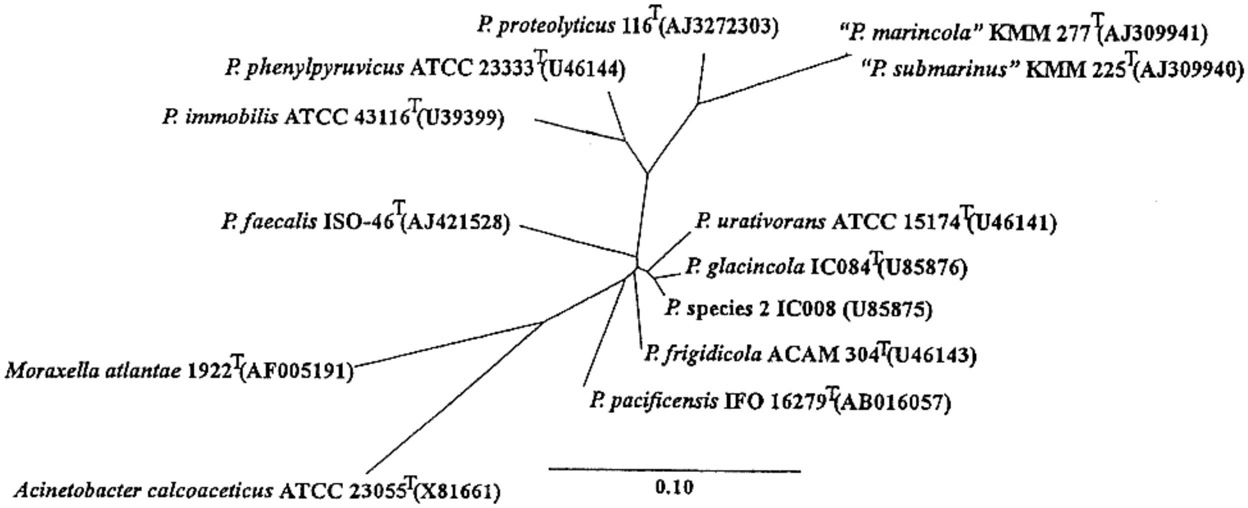

FIGURE BXII.γ.151. Phylogenetic tree for the species of the genus *Psychrobacter*. (Reproduced with permisson from P. Kämpfer et al., Systematic and Applied Microbiology *25:* 31–36, 2002, ©Urban & Fischer.)

and *P. urativorans* were 97.4 and 96.9%, respectively, whereas the corresponding DNA–DNA reassociation values were 62.2 and 35.9%, respectively. It is clear, as already noted (Stackebrandt and Goebel, 1994), that the relative evolutionary stability of 16S rRNA does not mirror corresponding stability of chromosomal DNA.

The organism originally designated as *"Micrococcus cryophilus"* (McLean et al., 1951) has been shown to be a psychrobacter (Juni and Heym, 1980), *P. urativorans* (Bowman et al., 1996).

The relatively large individual cells of many *Psychrobacter* strains are in contrast to the smaller sizes of most other Gram-negative bacteria. Major fatty acid profiles include $C_{16:1\ \omega7c}$, 35–47%; $C_{17:1\ \omega8c}$, 3–7%; and $C_{18:1\ \omega9c}$, 37–70% (Nishimura et al., 1979; Moss et al., 1988; Bowman et al., 1996). A novel fatty acid, $C_{12:1\ \omega9c}$, has been shown to be present in *P. immobilis* (Moss and Daneshvar, 1992). Contain wax esters (Gallagher, 1971; Russell and Volkman, 1980; Bowman et al., 1996, 1997d). The major ubiquinone of *Psychrobacter* contains eight isoprene units (Q8) (Moss et al., 1988). Cell membranes resemble those of other Gram-negative bacteria (Thorne, et al., 1973).

Most strains grow well at room temperature on plates of a variety of complex media. Strains of *P. frigidicola* grow best at 14–16°C; some fail to grow at room temperature and may be considered psychrophilic. Growth in liquid media requires aeration. Most psychrobacters can grow on mineral media containing sodium lactate and/or monosodium glutamate and an ammonium salt as the source of nitrogen. Many organic compounds can serve as sole carbon and energy sources for growth of psychrobacters (Shaw and Latty, 1988). The growth lag phase in such mineral media is decreased by addition of amino acids and, frequently, Tween 80 (Juni, 1992). Psychrobacters are aerobic and appear to contain all the enzymes of the tricarboxylic acid cycle (Tai and Jackson, 1969). They have been isolated from foods following gamma-ray irradiation at 300 and 500 krad (Ito et al., 1976), but strains isolated from nonirradiated foods are frequently radiation sensitive (Ito and Iizuka, 1983). They have also been isolated from sea life and the deep sea (Georgala, 1958; Maruyama et al., 2000; Denner et al., 2001a; Romanenko et al., 2002a), the skin of chickens (Lahellec et al., 1975), food products (Shaw and Latty, 1988; Gennari et al., 1992), Antarctic ornithogenic soils (Bowman et al., 1996), Antarctic sea ice (Bowman et al., 1997d), and a bioaerosol originating from pigeon feces (Kämpfer et al., 2002a).

DNAs from strains of all species of *Psychrobacter* tested are able to transform a hypoxanthine and thiamine auxotroph (ATCC 43117), of a competent *Psychrobacter immobilis* strain (ATCC 43116), for ability to grow on a defined medium (Juni and Heym, 1980). DNAs from strains of all other members of the *Moraxellaceae* fail to transform this auxotroph to prototrophy; the transformation assay appears to be genus specific. Approximately one-third of strains isolated from humans and previously classified as CDC group EO-2 were shown to be psychrobacters, based on their phenotypic properties and the results of the transformation assay (Hudson et al., 1987).

DNA–rRNA hybridization studies have shown that *Moraxella phenylpyruvica* is more closely related to psychrobacters than to the other members of the *Moraxellaceae* (Rossau et al., 1991). The overall levels of 16S rDNA sequence similarity between one strain of *M. phenylpyruvica* and the several species of *Psychrobacter* was shown to be 93–96% (Bowman et al., 1996, 1997d; Denner et al., 2001a; Kämpfer et al., 2002a). *M. phenylpyruvica* also resembles *Psychrobacter* in being able to grow (slowly) at 4°C and tolerate NaCl concentrations up to 9%, and it has been proposed that *M. phenylpyruvica* be transferred to the genus *Psychrobacter* as *Psychrobacter phenylpyruvicus* comb. nov. (Bowman et al., 1996). There are three lines of evidence suggesting that *M. phenylpyruvica* is, in fact, not a species of *Psychrobacter*. 1. DNAs from strains of *M. phenylpyruvica* fail to transform the hypoxanthine and thiamine auxotroph of *Psychrobacter* to prototrophy (Juni and Heym, 1980), this assay being genus specific for all strains of *Psychrobacter* tested. 2. In a transformation assay that makes use of a streptomycin-dependent marker from a strain of *M. phenylpyruvica* that was transformed into the competent *Acinetobacter* strain BD413 (a rare transformant), it was shown that DNAs from 34 independently isolated strains of *M. phenylpyruvica* (including strain ATCC 23333^T, the type strain of *P. phenylpyruvicus*) all transformed the streptomycin-dependent *Acinetobacter* to streptomycin-independence (Juni, 1990). DNAs from strains of *Psychrobacter* were inactive (Juni, unpublished results). 3. There are

characteristic differences in fatty acid composition between strains of *Psychrobacter* and strains of *M. phenylpyruvica* (Moss et al., 1988; Bowman et al., 1996, 1997d) and, unlike *Psychrobacter* and other members of the *Moraxellaceae*, *M. phenylpyruvica* does not possess true waxes (Bowman et al., 1996). In the description of *M. phenylpyruvica* (listed under species of the genus *Moraxella*), it is suggested that strains bearing this designation are members of a unique genus of the family *Moraxellaceae*.

A *Psp*PI type-II restriction-modification system of a strain of *Psychrobacter* has been investigated; the gene encoding the *Psp*PI methyltransferase has been cloned, expressed in *E. coli*, and its nucleotide sequence has been determined (Rina et al., 1997).

List of species of the genus Psychrobacter

1. **Psychrobacter immobilis** Juni and Heym 1986b, 388[VP].
im.mo' bi.lis. L. adj. *immobilis* motionless.

Plump rods or coccobacilli frequently showing diploforms, 0.9–1.3 μm in diameter. Nonmotile. Aerobic. Gram positive. Oxidase and catalase positive. Most strains grow on a defined medium with a single carbon and energy source and a mineral or organic source of nitrogen (i.e., an amino acid such as glutamate). Many organic compounds can serve as carbon and energy sources. Most strains form acid aerobically from D-glucose, D-mannose, D-galactose, L-arabinose, D-xylose, and L-rhamnose and use some of these compounds as carbon and energy sources for growth. Phenylalanine is deaminated. Other phenotypic characteristics appear in Table BXII.γ.133.

The mol% G + C of the DNA is: 44–47 (T_m).

Type strain: ATCC 43116, CCUG 9708, DSM 7229, LMG 7091, LMG 7203.

GenBank accession number (16S rRNA): U39399.

2. **Psychrobacter faecalis** Kämpfer, Albrecht, Buczolits and Busse 2002b, 1438[VP] (Effective publication: Kämpfer, Albrecht, Buczolits and Busse 2002a, 35.)
fae.ca' lis. L. n. *faex, faecis* dregs; M.L. adj. *faecalis* fecal.

Aerobic, cells are straight rods 0.8–1.2 × 1–2 μm and occur singly; they are nonmotile, Gram negative, oxidase- and catalase-positive. Colonies are circular, slightly raised, and beige with entire margins on nutrient agar. Grows well at 4–36°C on different complex media; no growth was found at 45 and 55°C on nutrient agar. No growth occurs on Salmonella-Shigella Agar. H_2S is not produced. Indole production, growth on Simmons citrate, urease, arginine dihydrolase, lysine decarboxylase, and ornithine decarboxylase, were all negative. No acid production from the following sugars could be detected: glucose, lactose, sucrose, D-mannitol, dulcitol, salicin, adonitol, inositol, sorbitol, L-arabinose, raffinose, L-rhamnose, maltose, D-xylose, trehalose, cellobiose, methyl-D-glucoside, erythritol, melibiose, D-arabitol, and D-mannose. The following compounds are not utilized as sole sources of carbon: L-arbutin, cellobiose, D-galactose, gluconate, D-maltose, D-mannose, α-D-melibiose, L-rhamnose, D-ribose, sucrose, salicin, D-trehalose, D-xylose, adonitol, *i*-inositol, D-sorbitol, glycerol, D-fructose, D-mannitol, maltitol, putrescine, *trans*-aconitate, mesaconate, adipate, azelate, itaconate, suberate, β-alanine, L-phenylalanine, L-serine, L-proline, L-histidine, L-tryptophan, 3-hydroxybenzoate, and phenylacetate. Ubiquinone Q-8 is the major quinone type, in addition to small amounts of ubiquinone Q-9 and Q-7; spermidine is the major polyamine. The polar lipid profile is characterized by the presence of phosphatidylethanolamine, phosphatidylglycerol, and diphophotidylglycerol. The fatty acids $C_{18:1\ \omega 9c}$, $C_{17:1\ \omega 8c}$, $C_{16:1\ \omega 7c}$, $C_{15:0\ iso\ 2OH}$, and $C_{12:0\ 3OH}$ are produced. Isolated from an aerosol originating from pigeon feces. Other phenotypic characteristics appear in Table BXII.γ.133.

The mol% G + C of the DNA is: not determined.

Type strain: Iso-46, DSM 14664, CIP 107288.

GenBank accession number (16S rRNA): AJ421528.

3. **Psychrobacter frigidicola** Bowman, Cavanagh, Austin and Sanderson 1996, 847[VP].
fri' gid.i.col.a. L. adj. *frigidus* cold; L. n. *cola* dweller; M.L. n. *frigidicola* cold dweller.

Cells are coccoid, 1.5–2.0 μm in diameter; occur in pairs, tetrads, or rarely in short chains. Aerobic. Nonmotile. No growth factors are required. Able to grow in the absence of NaCl but growth is stimulated by 0.25–0.30 M NaCl. Can tolerate up to 9% NaCl. Optimal temperature for growth 14–16°C. Maximum temperature for growth 19–22°C. Phenylalanine and tryptophan are deaminated. Urease, nitrate reduction, and production of acid from carbohydrates are negative. Isolated from ornithogenic soils from Antarctica. Other phenotypic characteristics appear in Table BXII.γ.133.

The mol% G + C of the DNA is: 41–42 (T_m).

Type strain: ACAM 304, CCUG 34377.

GenBank accession number (16S rRNA): U46143.

4. **Psychrobacter glacincola** Bowman, Nichols and McMeekin 1997e, 1274[VP] (Effective publication: Bowman, Nichols and McMeekin 1997d, 214.)
gla.cin.co' la. L. n. *glacies* ice; L. *incola* inhabitant; M.L. n. *glacincola* the ice inhabitant.

Cells are coccoidal with a diameter of 1.0–1.5 μm. Nonmotile. Colonies are up to 4 mm in diameter, circular, have an entire edge, low convex elevation, butyrous consistency, and an off-white color. No fluorescent pigments formed. Seawater is required for optimal growth but most strains will grow at between 0 and 2.1 M NaCl. Optimal growth occurs at 19–22°C. Growth factors are not required. Fail to utilize or form acid from carbohydrates. Utilize nitrate and ammonium salts as nitrogen sources. Some strains produce urease and reduce nitrate to nitrite. Tween 40 and Tween 80 are hydrolyzed. Phenylalanine is not deaminated. Isolated from Antarctic ice. Other phenotypic characteristics appear in Table BXII.γ.133.

The mol% G + C of the DNA is: 43–44 (T_m).

Type strain: ACAM 483, DSM 12194.

GenBank accession number (16S rRNA): U46145.

5. **Psychrobacter marincola** Romanenko, Schumann, Rohde, Lysenko, Mikhailov and Stackebrandt 2002a, 1296[VP]
ma.rin.co' la. L. gen. n. *maris* of the sea; L. n. *incola* inhabitant; N.L. n. *marincola* inhabitant of the sea.

Aerobic, Gram negative, nonmotile nonpigmented, nonsporeforming, coccoidal cells, 0.7–1.0 μm in diameter. Oxidase- and catalase-positive. Colonies on nutrient agar are whitish, circular with an entire edge, convex, 1–2 mm in diameter. No fluorescent pigments are formed. Moderately halophilic. Seawater is required for growth; can grow at 0.5–

[e]Data for *P. pacificensis* from Maruyama et al., 2000.

[f]Data for *P. proteolyticus* from Denner et al., 2001a.

15.5% (w/v) NaCl. Growth occurs at 7–35°C, with an optimum at 25–28°C. Does not grow at 4, 37, or 40°C. The pH range for growth is 5.5–9.5, with optimum growth at 6.5–8.5. Negative for Simmons citrate test, Voges–Proskauer reaction, ONPG test, H_2S production and denitrification. Susceptible to ampicillin (10 µg), benzylpenicillin (10 U), gentamycin (10 µg), kanamycin (30 µg), carbenicillin (25 µg), lincomycin (15 µg), oleandomycin (15 µg), polymyxin (300 U), streptomycin (30 µg), tetracycline (30 µg) and neomycin (15 µg). The major fatty acid is $C_{18:1\ \omega 9c}$. The phospholipids are phosphatidylethanolamine, phosphatidylglycerol, phosphatidylinositol and phosphatidylserine. Isolated from internal tissues of the ascidian *Polysyncraton* sp., collected in the Indian Ocean. Other characteristics appear in Table BXII.γ.133.

The mol% G + C of the DNA is: 50.7 (T_m).

Type strain: KMM277, DSM 14160.

GenBank accession number (16S rRNA): AJ309941.

6. **Psychrobacter pacificensis** Maruyama, Honda, Yamamoto, Kitamura and Higashihara 2000, 845[VP]
pa.ci.fi.cen′sis. M.L. adj. *pacificensis* pertaining to the Pacific Ocean.

Strains are aerobic, Gram negative, nonmotile, nonpigmented, nonsporulating, oxidase-positive, catalase-positive coccobacilli 1.0–1.5 µm long and about 1 µm wide. Strains produce many fimbriae as appendages, but no flagella. Circular, convex, off-white colonies with a complete edge occur on agar plates containing polypeptone and yeast extract. No fluorescent pigments formed. Seawater or NaCl at about 3% is required for optimal growth, with most strains not growing at 0 or 8% NaCl. It takes 1–2 weeks to reach stationary phase at 4°C, but isolates give growth yields at 4°C comparable to those at 20°C. Optimal growth at about 25°C, with the maximum growth temperature being 38°C. Acid is formed aerobically from glucose, xylose and arabinose. Urease is positive, but phenylalanine deaminase and tryptophan deaminase are negative. The species is negative for the following biochemical tests: glucose fermentation, indole production, esculin hydrolysis, gelatin liquefaction, and arginine dihydrolase. Strains use L-histidine and DL-malate as sole carbon and energy sources. Some strains use acetate, L-alanine, 3-hydroxybutyrate, lactate, malonate and suberate, but none use *p*-hydroxybutyrate, citrate, gluconate, propionate, L-serine or *n*-valerate. The major fatty acid is $C_{18:1\ \omega 9c}$ and Q-8 is the major quinone. Isolated from 6,000 m deep seawater in the Japan Trench off Hachijo Island, Japan. Other characteristics appear in Table BXII.γ.133.

The mol% G + C of the DNA is: 43–44 (HPLC).

Type strain: NIHB P2K6.

GenBank accession number (16S rRNA): AB016057.

7. **Psychrobacter proteolyticus** Denner, Mark, Busse, Turkiewicz and Lubitz 2001b, 1619.[VP] (Effective publication: Denner, Mark, Busse, Turkiewicz and Lubitz 2001a, 51.)
pro.te.o.ly' ti.cus. M.L. n. adj. *proteolyticus,* proteolytic.

Cells are Gram negative, nonpigmented, nonmotile, nonsporeforming, rod-shaped to coccoidal, and 0.5–1.25 μm wide by 1.0–2.5μm long. Colonies on complex standard media are cream-colored, circular, entire, convex, and of butyrous consistency; diameters are as large as 1.0 mm after 2 d incubation at room temperature. The following biochemical tests are positive: oxidase, catalase, urease, alkaline phosphatase, C4 esterase, C8 esterase, lipase, leucine arylamidase, valine arylamidase, acid phosphatase, and naphthol-AS-BI-phosphohydrolase. Gelatin, casein, and tributyrin are hydrolyzed whereas esculin, starch, and DNA are not. The following biochemical tests are negative: arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, C14 lipase, cystine arylamidase, trypsin, chymotrypsin, α-galactosidase, β-galactosidase, β-glucuronidase, α-glucosidase, β-glucosidase, α-mannosidase, α-fucosidase, H_2S production, nitrate reduction, and indole production. Citrate is used as a single carbon source. Acid is produced from the carbohydrates: glucose, rhamnose, melibiose, amygdalin, and arabinose. No acid is produced from the carbohydrates: mannitol, inositol, sorbitol, and saccharose. Ubiquinone-8 is the main respiratory lipoquinone. Phosphatidylethanolamine, phosphatidylglycerol, and diphosphatidylglycerol are the major polar lipids. The predominant nonpolar fatty acids are: $C_{18:1\ \omega9c}$ and $C_{16:1\ c}$; $C_{17:1\ \omega8c}$, $C_{16:0}$, $C_{18:0}$, and $C_{12:0}$ are present in minor amounts. The predominant 2-hydroxy fatty acid is $C_{12:0\ 2OH}$. Isolated from a stomach specimen of an Antarctic krill. Other phenotypic characteristics appear in Table BXII.γ.133.

The mol% G + C of the DNA is: 43.6 (HPLC).
Type strain: 116, CIP 106830, DSM 13887.
GenBank accession number (16S rRNA): AJ272303.

8. **Psychrobacter submarinus** Romanenko, Schumann, Rohde, Lysenko, Mikhailov and Stackebrandt 2002a, 1296[VP]
sub.ma.ri' nus. L. prep. *sub* under; L. adj. *marinus* of the sea; N.L. adj. *submarinus* from under the sea.

Aerobic, Gram negative, nonmotile, nonpigmented, nonsporeforming, ovoid cells, 1.6–1.9 μm long and 0.7–1.0 μm in diameter. Oxidase- and catalase-positive. Colonies on nutrient agar are whitish, circular with an entire margin, convex, 2–3 mm in diameter. No fluorescent pigments are formed. Moderately halophilic. Seawater is required for growth; growth occurs in the presence of 0.5–15.5% (w/v) NaCl. Temperature range for growth is 4–35°C, with an optimum at 25–28°C. Does not grow at 37 or 40°C. pH range for growth is 5.5–9.5 with optimum growth at 6.5–8.5. The strain is negative for Simmons citate test, ONPG test, acetoin production, H_2S production, and denitrification. Susceptible to ampicillin (10 μg), gentamicin (10 μg), kanamycin (30 μg), carbenicillin (25 μg), polymyxin (300 U), streptomycin (30 μg), and neomycin (15 μg). Resistant to benzylpenicillin (10 U), lincomycin (15 μg), oleandomycin (15 μg), tetracycline (15 μg). The major fatty acid is $C_{18:1\ \omega9c}$. The phospholipids are phosphatidylethanolamine, phosphatidylglycerol, diphosphatidylglycerol, phosphatidylinositol, and phosphatidylserine. Other characteristics appear in Table BXII.γ.133.

The mol% G + C of the DNA is: 46.7 (T_m).
Type strain: KMM 225, DSM 14161.
GenBank accession number (16S rRNA): AJ309940.

9. **Psychrobacter urativorans** Bowman, Cavanagh, Austin and Sanderson 1996, 847[VP]
u.ra.ti.vor' ans. M.L. n. *uratum* salt of uric acid; M.L. part. adj.*vorans* devouring; M.L. part. adj. *urativorans* uric acid devouring.

Cells are coccoid, 1.5–2.0 μm in diameter, and occur in pairs and tetrads. Nonmotile. Aerobic. No growth factors are required. Growth is inhibited by 1% bile. Tolerates 9% NaCl. Growth is not stimulated by NaCl. Optimal temperature for growth 18–20°C. Maximum temperature for growth 25–27°C. Does not deaminate phenylalanine or tryptophan. Acid is not produced from carbohydrates. Strains may produce urease and reduce nitrate to nitrite. Other phenotypic characteristics appear in Table BXII.γ.133.

The mol% G + C of the DNA is: 44–46 (T_m).
Type strain: ACAM 534, ATCC 15174, CCUG 4982, DSM 20429.
GenBank accession number (16S rRNA): U46141.

Family III. *Incertae Sedis*

Genus I. **Enhydrobacter** *Staley, Irgens and Brenner 1987, 290[VP]*

JAMES T. STALEY AND DON J. BRENNER

En.hy' dro.bac.ter. Gr. adj. *enhydros* aquatic Gr. neut. n. *bacter* masc. form of Gr. neut. n. *bacterion* a rod; N.L. masc. n. *Enhydrobacter* aquatic rod.

Coccobacillary to rod-shaped cells, 0.5–0.7 × 1.0–5.0 μm. **Unicellular; pairs and short chains occur.** No resting stages known. **Gram negative. Facultative aerobic.** Chemoheterotrophic. **Oligotrophic. Grow very slowly.** Sugars are fermented anaerobically, and organic acids are used aerobically. Growth occurs on mineral medium with D-glucose as the sole carbon source and inorganic ammonium compounds as the sole nitrogen sources. No growth on nutrient agar, Clark–Lubs medium or EMB agar. Vitamins are required by the type strain when grown on defined media. Oxidase and catalase positive. Type strain isolated from the oxygen-depleted zone of a eutrophic lake.

The mol% G + C of the DNA is: 66.

Type species: **Enhydrobacter aerosaccus** Staley, Irgens and Brenner 1987, 290.

Further descriptive information

A recent analysis of 16S rRNA sequences indicated that *Enhydrobacter aerosaccus* is closely related to *Moraxella osloensis* (Thompson et al., 2003a). The genus *Enhydrobacter* has therefore been placed in the family *Moraxellaceae* as a *genus incertae sedis*; no further testing has been done to relate it to or to differentiate it from other genera in this family.

Unlike other described members of aeromonads, *Enhydrobacter aerosaccus* is a true oligotrophic bacterium that grows very slowly on typical media used for cultivation of *Proteobacteria*. Biochemical reactions on Hugh–Leifson medium take 30–60 days at room temperature.

This monospecific genus most closely resembles members of the genus *Aeromonas* in that it grows on a defined medium with D-glucose as the sole carbon source and uses ammonium salts as the sole nitrogen sources for growth. Like *Aeromonas* spp., *Enhydrobacter* can use some amino acids such as L-alanine, L-serine, and L-arginine as carbon sources for growth. The type strain of *E. aerosaccus* is nonmotile, a feature that is also found in some species of *Aeromonas*, such as *A. salmonicida*.

However, *E. aerosaccus* differs from *Aeromonas* spp. in several ways. The mol% G + C content of the DNA is 66, considerably higher than the 57–63% found in *Aeromonas* spp. Furthermore, it does not grow on typical media used for cultivation of *Aeromonas* spp., such as methyl red–Voges–Proskauer (Clark–Lubs) medium, EMB medium, nutrient agar, and King A and King B media. Furthermore, *E. aerosaccus* is gas vacuolate, a property not found in any *Aeromonas* spp.

Finally, DNA–DNA reassociation experiments indicate that *Enhydrobacter* is sufficiently distantly related to *Aeromonas* to justify the creation of a separate genus (Staley et al., 1987).

Enrichment and Isolation Procedures

The sole strain of this genus has been isolated from a eutrophic lake, Wintergreen Lake, near Kalamazoo, Michigan (Van Ert and Staley, 1971). A dilute peptone enrichment culture is made using 100 ml of lake water from the thermocline of the oxygen-depleted zone (< 1 mg/l dissolved O_2), supplemented with 10 mg of sterile Bacto Peptone (Difco laboratories, Detroit, MI). After incubation for 18 days at room temperature, 0.1 ml of a 1:100 dilution is spread on plates containing 0.01% peptone with mineral salts and vitamins (Van Ert and Staley, 1971). After incubation for 27 d, material from the plate, containing colonies of planctomycetes, is restreaked on PYG medium (0.025% peptone, 0.025% yeast extract, and 0.025% glucose with vitamins and mineral salts; see genus *Ancalomicrobium* description, this volume). A small, chalky white colony containing gas-vacuolated, rod-shaped cells appears after one month. This is streaked to purity on a medium containing 0.1% glucose, 0.1% Difco Vitamin Free Casamino acids, mineral salts, and vitamins.

Maintenance Procedures

The organism has been maintained by lyophilization for 30 years.

Differentiation of the genus *Enhydrobacter* from other genera

Table BXII.γ.134 shows the differences between *Enhydrobacter* and *Aeromonas*. Although the genera resemble one another in morphology, the type strain and species of *Enhydrobacter* is gas vacuolate. *Enhydrobacter aerosaccus* does not grow on many of the typical media used for cultivation of *Aeromonas* spp., and the time for growth in biochemical tests is 30–60 d.

List of species of the genus Enhydrobacter

1. **Enhydrobacter aerosaccus** Staley, Irgens and Brenner 1987, 290.
aer' o.sac.cus. Gr. n. *aer* air; Gr. n. *sakkos* sack; N.L. *aerosaccus* gas vacuolate.

Nonmotile, gas-vacuolated, nonflagellated rods. Gas vacuoles are not produced when growing on sugars, but are produced when cells are grown on certain organic acids, such as acetate, pyruvate, and succinate. Facultatively aerobic, but best growth aerobically is under microaerophilic conditions. No growth at 7 or 43°C; growth occurs at 20–41°C, with optimum growth at 37–39°C. Grows at pH 5.0–9.5. Nitrate is reduced to nitrite. Folic acid and biotin are required for growth. Lysine, ornithine, and arginine are decarboxylated after 5 weeks at room temperature. The following carbon sources are utilized after incubation at 30°C for 60 d: L-arabinose, D-xylose, L-fucose, L-rhamnose, D-ribose, D-glucose, D-fructose, D-mannose, L-sorbose, D-galactose, D-xylose, sucrose, maltose, acetate, citrate, formate, fumarate, glycerol, succinate, inulin, ethanol, pyruvate, lactate, *meso*-malate, oxaloacetate, and *meso*-tartrate. Colonies, which adhere to the agar, are colorless with an entire margin and convex elevation. The type strain was isolated from the oxygen-depleted zone of a eutrophic lake.

The mol% G + C of the DNA is: 66 (Bd).

Type strain: ATCC 27094, DSM 8914, LMG 81277.

GenBank accession number (16S rRNA): AJ550856.

Order X. **Alteromonadales** *ord. nov.*

JOHN P. BOWMAN AND THOMAS A. MCMEEKIN

Al.ter.o.mon.a.da' les. M.L. fem. n. *Alteromonas* the type genus of the order; L. suff. *-ales* ending which denotes an order; M.L. fem. n. *Alteromonadales* the *Alteromonas* order.

Gram negative, straight or curved rods. Motile by means of a **single polar flagellum**. Do not form endospores or cysts. **Chemoheterotrophs** which are **either facultative anaerobes or strictly aerobic**. If able to grow anaerobically, growth occurs by respiration and, less commonly, by fermentation. Oxygen is used universally as an electron acceptor. **Most strains are catalase and oxidase positive.** Possess psychrophilic, psychrotolerant, and mesophilic growth regimes. Most species **require Na^+ ions** for growth and most species grow optimally on seawater-based media. Most species are able to utilize ammonia as a nitrogen source. Some species have a requirement for amino acids. **Primarily marine inhabitants** found in a wide range of oceanic ecosystems ranging from surface waters and sea ice to abyssal sediments. Usually nonpathogenic. The major coenzyme Q type is ubiquinone-8.

The mol% G + C of the DNA is: 36–54 (T_m, Bd).

Type genus: **Alteromonas** Baumann, Baumann, Mandel and Allen 1972, 418 emend. Gauthier, Gauthier and Christen 1995a, 760

FURTHER DESCRIPTIVE INFORMATION

The order *Alteromonadales* and family *Alteromonadaceae* are created here to accommodate an assemblage of marine Gram-negative bacteria that form a phylogenetic clade in the *Gammaproteobacteria*, positioned between the families *Pseudomonadaceae* and *Enterobacteriaceae*. Members of this group include the genera *Colwellia*, *Moritella* (*Vibrio marinus*), *Shewanella*, *Ferrimonas*, *Alteromonas*, and *Pseudoalteromonas*. These genera are characteristically rod-like in morphology, motile by a single polar flagellum, oxidase positive, require or stimulated by sodium ions, and possess DNA base compositions ranging from 36 to 54 mol% G + C. Cells generally lack inclusions such as poly-β-hydroxybutyrate, resting stages such as spores and microcysts, and cellular extensions such as prostheca, buds, and spinae. The metabolism of the members of the order *Alteromonadales* is quite varied. Some members are facultative anaerobes able to grow anaerobically by fermentation and respiration (*Colwellia*, *Moritella*, and some *Shewanella* species) or by respiration alone (*Ferrimonas* and most *Shewanella* species). Still others are strictly aerobic (*Alteromonas* and *Pseudoalteromonas*).

Overall, there are few if any common properties (except those stated) which the genera in the order *Alteromonadales* have in common. Based on the molecular clock theory (Ochman and Wilson, 1987), the divergence in 16S rRNA gene sequences suggests that members of the order *Alteromonadales* have been evolving in the oceans for at least 500–600 million years (assuming a 1% sequence difference equals ~50 million years). During that time, a multiplicity of marine (and some terrestrial) habitats have been colonized, with the development of a wide range of ecophysiological specialization and versatility. For example, the order *Alteromonadales* is noteworthy for containing all known psychrophilic bacteria belonging to the *Gammaproteobacteria*, the majority of barophilic species, and most bacterial species capable of forming omega-3 polyunsaturated fatty acids.

TAXONOMIC COMMENTS

Before phylogenetic analysis became commonplace, members of the order *Alteromonadales* were grouped either within the family *Vibrionaceae* (e.g., *Shewanella*; MacDonell and Colwell, 1985; Farmer, 1992) or were simply ungrouped (e.g., *Alteromonas*, Baumann et al., 1984d; Gauthier and Breittmayer, 1992). The advent of 16S rRNA-based phylogenetic analysis has resulted in considerable reorganization of the species in this group. This includes major reassignment of species of *Alteromonas* to *Shewanella* (MacDonell and Colwell, 1985; Coyne et al., 1989), *Pseudoalteromonas* (Gauthier et al., 1995a), and *Marinomonas* (van Landschoot and De Ley, 1983). *Colwellia* (Deming et al., 1988a) was created to accommodate a psychrophilic *Vibrio* species (D'Aoust and Kushner, 1972) which, on the basis of 5S and 16S rRNA gene sequence analysis, was clearly distinct from other *Vibrio* species. *Vibrio marinus* (Baumann et al., 1984b) also groups phylogenetically within the family *Alteromonadaceae* and has been recently transferred to a new genus, *Moritella*, as *Moritella marina* (Urakawa et al., 1998). *Ferrimonas*, a genus containing iron-reducing species, is similar in many respects to *Shewanella* and is represented by only a single strain (Rosselló-Mora et al., 1995a).

Family I. **Alteromonadaceae** Ivanova and Mikhailov 2001b, 1229[VP] (Effective publication: Ivanova and Mikhailov 2001a, 15.)

JOHN P. BOWMAN AND THOMAS A. MCMEEKIN

Al.ter.o.mo.na.da' ce.ae. M.L. fem. n. *Alteromonas* the type genus of the family; L. suff. *-aceae* which denotes a family; M.L. fem. n. *Alteromonadaceae* the *Alteromonas* family.

The description is the same as for the order *Alteromonadales*. See Table BXII.γ.135 for characteristics differentiating some genera of the family *Alteromonadaceae*.*

Type genus: **Alteromonas** Baumann, Baumann, Mandel and Allen 1972, 418 emend. Gauthier, Gauthier and Christen 1995a, 760.

**Editorial Note:* Only the genera *Alteromonas*, *Colwellia*, *Idiomarina*, and *Pseudoalteromonas* were included in the family by Ivanova and Mikhailov (2001a). The genera *Alishewanella*, *Ferrimonas*, *Glaciecola*, *Marinobacter*, *Marinobacterium*, *Microbulbifer*, *Moritella*, *Psychromonas*, *Shewanella*, and *Thalassomonas* have been added to this family based on 16S rDNA sequence analysis.

Key to Some Genera of the Family Alteromonadaceae

I. Straight to curved rod-shaped cells, motile, that require or are stimulated by NaCl and are oxidase positive. Strictly aerobic; no anaerobic growth with nitrate as the electron acceptor.
 A. Utilizes D-turanose, salicin, D-glucuronate, and/or DL-glycerate.
  Genus *Alteromonas*
 B. Does not utilize D-turanose, salicin, D-galacturonate, and/or DL-glycerate.
  Genus *Pseudoalteromonas*

II. Straight to curved rod-shaped cells, motile, that require or are stimulated by NaCl and are oxidase positive. Anaerobic growth using nitrate as an electron acceptor.
 A. Gelatinase positive.
  1. Dissimilatory iron-reduction positive and/or form eicosapentaenoic acid (EPA); most species amylase negative.
   Genus *Shewanella*
  2. Dissimilatory iron-reduction negative; form docosahexaenoic acid (DHA).
   a. Amylase positive.
    Genus *Colwellia*
   b. Amylase negative.
    Moritella (*Vibrio marinus*)
 B. Gelatinase negative.
  Genus *Ferrimonas*

Genus I. **Alteromonas** *Baumann, Baumann, Mandel and Allen 1972, 418, emend. Gauthier, Gauthier and Christen 1995a, 760*

JOHN P. BOWMAN AND THOMAS A. MCMEEKIN

Al.te.ro.mo' nas. L. adj. *alter* another; Gr. n. *monas* a unit, monad; M.L. fem. n. *Alteromonas* another monad.

Straight rods, approximately 1 × 2-3 µm, occurring singly or in pairs. Do not form spores or cysts. Do not accumulate poly-β-hydroxybutyrate. **Gram negative. Motile**, propelled by a single polar unsheathed flagellum. Colonies are nonpigmented. **Chemoheterotrophic**. **Aerobic, having a strictly respiratory type of metabolism** with oxygen as the terminal electron acceptor. Catalase and oxidase positive. **Nitrate is not reduced, nor can it be used as an alternative electron acceptor.** Do not grow by hydrogen autotrophy. A constitutive arginine dihydrolase system is absent. A range of carbon substrates can be used, including carbohydrates, alcohols, organic acids, and amino acids. Ammonia serves as a nitrogen source. Growth factors are not required. **Require Na^+ ions for growth.** Growth occurs between 10 and 40°C; **no growth at 4°C** or 45°C. Major quinone is ubiquinone-8 (Q-8). Major fatty acids are $C_{16:0}$, $C_{16:1\ \omega7c}$, $C_{17:1\ \omega8c}$, and $C_{18:1\ \omega7c}$. Isolated from seawater. Member of the order *Alteromonadales*, family *Alteromonadaceae*, class *Gammaproteobacteria*.

The mol% G + C of the DNA is: 44–48 (T_m).

Type species: **Alteromonas macleodii** Baumann, Baumann, Mandel and Allen 1972, 418.

Further descriptive information

Alteromonas macleodii is the only validly published species included in the genus at present.

When growing on various complex or defined seawater or NaCl-containing media such as Difco marine 2216 agar (ZoBell, 1941), basal medium agar[1] (BMA), or yeast extract agar[2] (YEA) (Baumann et al., 1972), the colonies possess an off-white color, smooth texture, circular convex shape, entire edge, and creamy consistency.

All strains grow best on media containing a seawater salts base and fail to grow if Na^+ ions are absent or if Na^+ ions are completely replaced by K^+ ions. *A. macleodii* is relatively halotolerant and able to grow fairly well on media containing 10% NaCl (Ortigosa et al., 1994). Strains are also characteristically mesophilic, growing between 10 and 40°C, with an optimal temperature of 30–35°C. *A. macleodii* and the closely related *"Alteromonas infernus"* are chemoheterotrophs able to utilize a wide range of carbohydrates for growth (Baumann et al., 1984a; Raguénès et al., 1997b). In addition, *A. macleodii* can utilize a range of organic acids, alcohols, and amino acids, but is unable to grow on aromatic compounds (Table BXII.γ.136). *A. macleodii* produces several extracellular enzymes and is able to hydrolyze gelatin, lipids, and starch. A few strains can also attack alginate, but are unable to degrade agar, chitin, or cellulose.

A. macleodii possesses an inducible Entner–Doudoroff pathway (Baumann and Baumann, 1973), which is used for catabolism of D-fructose and D-glucose. Activity for aspartokinase, which is involved in the initial stages of the synthesis of the aspartate family of amino acids, is absent (Baumann and Baumann, 1974).

A. macleodii is not susceptible to predation by *Bdellovibrio* (strains of which were initially isolated by using *Vibrio* species as hosts) (Taylor et al., 1974). *Alteromonas*-like strains have been found to form proteinaceous substances, referred to as marinostatins, which are potent inhibitors of a range of proteases, including subtilisin, papain, ficin, and α-chymotrypsin (Imada et al., 1985a, b, 1986). Several *Alteromonas* strains have been reported to form antibiotic-like substances; however, it is likely that these strains actually belong to the genus *Pseudoalteromonas* (see section on the genus *Pseudoalteromonas*).

The mol% G + C values for the DNA of *A. macleodii* range from 44.9–46.4 (T_m). The mol% G + C contents of "*A. macleodii* subsp. *fijiensis*" (Raguénès et al., 1996) and *"A. infernus"* (Raguénès et al., 1997b) have slightly higher values, of 47–48 (T_m).

Ubiquinone-8 (Q-8) is the major quinone (97% of total), with traces of Q-9 (2%) and Q-10 (1%) present (Akagawa-Matsushita et al., 1992b). The major whole-cell fatty acids of *A. macleodii* (determined only for strain ATCC 27126) include $C_{15:0}$ (3%), $C_{15:1\ \omega 8c}$ (2%), $C_{16:1\ \omega 7c}$ (37%), $C_{16:0}$ (24%), $C_{17:1\ \omega 8c}$ (7%), $C_{17:0}$ (5%), and $C_{18:1\ \omega 7}$ (9%) (Svetashev et al., 1995). Analysis using neural networks is not able to distinguish the fatty acid pattern of *A. macleodii* from those of some other members of the genus *Pseudoalteromonas* (Bertone et al., 1996). Hydroxy fatty acids comprise only a small amount (~1%) of the whole cell fatty acids. The major polyamines in *A. macleodii* include putrescine, 2-hydroxyputrescine, cadaverine, 5-hydroxyspermidine, and spermidine (Hamana, 1997). *Alteromonas* species form acidic polysaccharides. For example, "*A. macleodii* subsp. *fijiensis*" produces a uronic acid-rich polysaccharide with a viscosity similar to that of xanthan gum (Raguénès et al., 1996). *"A. infernus"* secretes two unusual polysaccharides, the first of which is a water-soluble exopolymer made up of monomers of glucose, galactose, galacturonate, and glucuronate and an insoluble gel-forming exopolymer (Raguénès et al., 1997b). Several other *Alteromonas* strains produce a range of novel acidic exopolysaccharides (Ivanova et al., 1994; Vincent et al., 1994; Nazarenko et al., 1993; Samain et al., 1997).

Little is known about the specific ecology of *Alteromonas*. Stud-

Mol% G + C of DNA (T_m)	45–46	46

[a]Symbols: +, positive for 90% or more strains; (+), positive for 75–89% of strains; d, positive for 26–74% of strains; (−), positive for 11–25% of strains; −, positive for 0–10% of strains.

[b]The following substrates are not utilized: D-ribose, D-arabinose, L-arabinose, D-fucose, L-rhamnose, D-mannose, inulin, *i*-erythritol, D-sorbitol, *meso*-inositol, adonitol, ethane-1,2-diol, butane-2,3-diol, methanol, isopropanol, isobutanol, saccharate, mucate, D-glucuronate, formate, oxalate, malonate, succinate, adipate, pimelate, suberate, azelate, sebacate, DL-malate, D(−)-tartrate, L(+)-tartrate, *meso*-tartrate, 2-oxoglutarate, fumarate, citrate, aconitate, maleate, levulinate, citraconate, itaconate, mesaconate, D-mandelate, L-mandelate, benzoyl formate, benzoate, *o*-hydroxybenzoate, *m*-hydroxybenzoate, *p*-hydroxybenzoate, phenylacetate, quinate, D-alanine, β-alanine, L-citrulline, L-histidine, L-lysine, L-norleucine, L-ornithine, L-phenylalanine, L-proline, L-threonine, D-tryptophan, L-tryptophan, DL-kynurenine, kynurenate, anthranilate, *m*-aminobenzoate, *p*-aminobenzoate, γ-aminobutyrate, δ-aminovalerate, hippurate, methylamine, ethanolamine, benzylamine, putrescine, spermine, histamine, tryptamine, butylamine, 2-amylamine, pentylamine, betaine, sarcosine, creatine, pantothenate, acetamide, nicotinate, nicotinamide, trigollenine, allantoin, adenine, guanine, cytosine, thymine, uracil, and *n*-hexadecane.

1. BMA consists of (per liter): Tris-HCl, 6.1 g (to give a pH of 7.5); NH_4Cl, 1.0 g; $K_2HPO_4 \cdot 3H_2O$, 0.075 g; $FeSO_4 \cdot 7H_2O$, 0.028 g; artificial seawater (ASW), 500 ml; distilled water, 500 ml; and agar, 20 g. ASW (MacLeod, 1968) consists of (g/l distilled water): NaCl, 23.4; $MgSO_4 \cdot 7H_2O$, 24.6; KCl, 1.5; and $CaCl_2 \cdot H_2O$, 2.9.

2. YEA medium consists of BMA supplemented with 0.5% (w/v) yeast extract.

ies suggest the species is a common inhabitant of waters of the Mediterranean Sea (Ortigosa et al., 1994) and is probably common in subtropical and tropical waters, owing to its mesophilic temperature requirement. Many *Alteromonas* strains have been isolated from tropical oceanic regions. The type strain of *A. macleodii* was isolated from seawater in the Hawaiian archipelago area (Baumann et al., 1972). "*A. infernus*" and "*A. macleodii* subsp. *fijiensis*" were isolated from a field of hydrothermal vents populated by dense stands of the tubeworm *Rifta pachyptila* where the water temperature was 9–18°C (Raguénès et al., 1996, 1997b).

Enrichment and Isolation Procedures

Alteromonas macleodii strains can be isolated directly from seawater. After filtering seawater samples through membrane filters having a pore diameter of 0.22 or 0.45 μm, the filter is placed on BMA agar containing 0.2% (w/v) lactose. After several days of incubation at approximately 25°C, colonies are transferred and purified on the same medium (Gauthier and Breittmayer, 1992). *"Alteromonas infernus"* can be isolated from hydrothermal vent fluid by enrichment in marine 2216 broth buffered with 50 mM MOPS buffer at pH 7.5, with incubation at 25°C for 2 d. Isolation from the enrichment broths then proceeds by serially diluting the enrichment broth onto marine 2216 agar (Raguénès et al., 1997b).

Maintenance Procedures

Alteromonas strains can be maintained at approximately 15°C on marine agar slants and transferred on a monthly basis. Storage at 15°C is preferred, because survival at 4°C seems to be poor. Cryopreservation and storage in liquid nitrogen using glycerol as a cryoprotectant or lyophilization is effective for long-term storage.

Differentiation of the genus *Alteromonas* from other genera

Differentiation of the *Alteromonas* species from other marine genera appears to be problematic. The most phenotypically similar genus, *Pseudoalteromonas*, is chemotaxomically and metabolically very similar. Both genera possess similar fatty acid profiles (Svetashev et al., 1995), quinones (Akagawa-Matsushita et al., 1992b), and polyamine profiles, although *Pseudoalteromonas* species lack 2-hydroxyputrescine and 5-hydroxyspermidine (Hamana, 1997). The major traits distinguishing these genera are growth at 4°C and utilization of a variety of carbon compounds (see Key to Some Genera of the Family *Alteromonadaceae* and Table BXII.γ.135 of the chapter describing the family). Beyond these limited phenotypic criteria, only 16S rRNA sequencing can provide a definitive identification. *Alteromonas* differs from the marine genera *Marinobacterium*, *Microbulbifer*, *Marinobacter*, and *Halomonas* primarily by possessing lower mol% G + C values for the DNA. In addition, *Alteromonas* can be distinguished from the genera *Oceanospirillum* and *Marinomonas* based on cellular morphology.

Taxonomic Comments

In the last decade or so, following rRNA–DNA hybridization and 5S and 16S rRNA sequence analyses, the genus *Alteromonas* has undergone a reclassification of most of its species and has been reduced to a single validly described species, *A. macleodii.* A 1983 study using rRNA–DNA hybridization was the first to indicate that *A. macleodii* should be classified separately from other species that were originally placed in *Alteromonas* (van Landschoot and De Ley, 1983). The 23S rRNA–DNA hybridization values range from 68.5–71.5 $T_{m(e)}$°C, which indicate *A. macleodii* is genotypically distinct at the genus level. Subsequent phylogenetic analysis of 16S rRNA sequences has also demonstrated that *A. macleodii* is distinct from the other *Alteromonas* species (Kita-Tsukamoto et al., 1993; Gauthier et al., 1995a). This resulted in nomenclatural restructuring of the genus *Alteromonas*, with *Alteromonas macleodii* being retained as the sole species of the genus because it was the type species of the genus (as stipulated by rule 39b of the Nomenclatural Code (Lapage et al., 1992). Former *Alteromonas* species having a predominantly straight rod morphology, including pigmented and nonpigmented strains, have been classified in the genus *Pseudoalteromonas* (Gauthier et al., 1995a). The bioluminescent species *Alteromonas hanedai* (Jensen et al., 1980) and the oyster species *Alteromonas colwelliana* (Weiner et al., 1988) were renamed *Shewanella hanedai* (MacDonell and Colwell, 1985) and *Shewanella colwelliana* (Coyne et al., 1989), respectively. *Alteromonas vaga* and *Alteromonas communis* have been found to form a distinct branch in the vicinity of the genus *Pseudomonas* on the basis of rRNA–DNA homology (van Landschoot and De Ley, 1983) and 16S rRNA sequences (Gauthier et al., 1992; Kita-Tsukamoto et al., 1993) and have been renamed *Marinomonas vaga* and *Marinomonas communis* (van Landschoot and De Ley, 1983). Methanol and methylamine-utilizing marine strains initially described as *"Alteromonas thalassomethanica"* (Yamamoto et al., 1980) have been reclassified as *Methylophaga thalassica* (Janvier et al., 1985; Urakami and Komagata, 1987).

Overall, the genus *Alteromonas* is most closely related to the genus *Pseudoalteromonas* and to various pigmented psychrophilic isolates from Antarctic sea ice (Bowman et al., 1997a). DNA–DNA hybridization studies indicate *A. macleodii* shares no significant levels of hybridization with phenotypically similar, nonpigmented species of the genus *Pseudoalteromonas* (Akagawa-Matsushita et al., 1993).

Isolates forming unusual polysaccharides ("*A. macleodii* subsp. *fijiensis*" and *"A. infernus"*) have been shown to be closely related to *A. macleodii* on the basis of 16S rRNA sequences, forming a tight cluster (sequence divergence ~2%) in the *Gammaproteobacteria* (Raguénès et al., 1996, 1997b). A significant level of DNA hybridization (48%) occurs between *"A. infernus"* and the type strain of *A. macleodii* (ATCC 27126), establishing that *"A. infernus"* is a distinct but closely related genospecies (Raguénès et al., 1997b). The names of these organisms have not yet been validated.

List of species of the genus Alteromonas

1. **Alteromonas macleodii** Baumann, Baumann, Mandel and Allen 1972, 418[AL]
mac.leod'i.i. M.L. gen. n. *macleodii* of MacLeod, named after R.A. MacLeod, a Canadian microbiologist.

Cells are straight rods, about 1 × 2-3 μm. Motile by a single polar flagellum.

Colonies on marine agar are off-white, smooth, circular, convex, with an entire edge, and butyrous in consistency.

Physiological and nutritional traits are presented in Table BXII.γ.136.

Isolated from seawater.

The mol% G + C of the DNA is: 45–46 (T_m).BNL-1

Type strain: 107, ATCC 27126, DSM 6062, IAM 12920, NCMB 1963.

GenBank accession number (16S rRNA): X82145.

Species Incertae Sedis

1. **"Alteromonas infernus"** Raguénès, Peres, Ruimy, Pignet, Christen, Loaec, Rougeaux, Barbier and Guezennec 1997b, 428.

in.fer′ nus. Gr. n. *infernus* from infernal regions, deep-sea hydrothermal vents.

Cells are straight rods, 0.6-.8 × 1.4-2.0 µm. Encapsulated and motile by a single polar flagellum. Poly-β-hydroxybutyrate is accumulated. Strictly aerobic chemoheterotroph. Oxidase and catalase positive. Does not denitrify. Grows between 20–35°C, with no growth at 4°C or 45°C. Na^+ ions are required for growth. Does not require growth factors. Hydrolyzes starch, esculin, and gelatin. Positive for β-galactosidase, alkaline phosphatase, C_8 esterase, and leucine arylamidase. Acid phosphatase and C_4 esterase activity is weak.

Utilizes the following carbon substrates: D-xylose, D-fructose, D-galactose, D-gentiobiose, D-glucose, D-turanose, cellobiose, lactose, maltose, melibiose, sucrose, amygdalin, esculin, salicin, D-mannitol, and D-gluconate. The following carbon substrates are not utilized: D-melezitose, trehalose, arbutin, *N*-acetylglucosamine, and glycogen.

Isolated from seawater from a deep-sea hydrothermal field at 2000 m depth in a rift system of the Guaymas basin.

The mol% G + C of the DNA is: 48.1 (T_m).

Deposited strain: GY785, CNCM I-1628.

2. "**Alteromonas macleodii** *subsp.* **fijiensis**" Raguénès, Pignet, Gauthier, Peres, Rougeaux, Christen, Barbier and Guezennec 1996, 72.

Phenotypic characteristics are similar to those for *Alteromonas macleodii* ATCC 27126; however, this subspecies can be distinguished from *Alteromonas macleodii* ATCC 27126 in that it is able to utilize D-ribose, α-methyl-D-glucoside, and raffinose, but not D-xylose, mannitol, *N*-acetylglucosamine or melezitose.

Isolated from seawater from a deep-sea hydrothermal field near Fiji, Pacific Ocean.

The mol% G + C of the DNA is: 47.6 (T_m).

Deposited strain: ST716, CNCM I-1627.

Genus II. **Alishewanella** *Fonnesbech Vogel, Venkateswaran, Christensen, Falsen, Christiansen and Gram 2000, 1140*[VP]

THE EDITORIAL BOARD

A.li.she.wa.nel′ la. L. pron. *alius* the other; M.L. fem. n. *Alishewanella* the other *Shewanella*.

Gram-negative, facultatively anaerobic, nonmotile rods. Electron acceptors are O_2, nitrate, thiosulphate, and TMAO. **Nonfermative.** One polar flagellum. Catalase and oxidase positive. **Requires NaCl.** Hydrolyzes esculin and gelatin. Does not produce arginine dihydrolase, β-galactosidase, urease, indole, or H_2S.

The mol% G + C of the DNA is: 51.

Type species: **Alishewanella fetalis** Fonnesbech Vogel, Venkateswaran, Christensen, Falsen, Christiansen and Gram 2000, 1141.

Further descriptive information

Alishewanella fetalis R2422019 was isolated from a human fetus at autopsy and originally thought to be related to *Shewanella*.

Analysis of 16S rDNA sequences showed that strain R2422019 was related to but distinct from members of the genera *Shewanella*, *Aeromonas*, *Vibrio*, *Photobacterium*, *Erwinia*, *Klebsiella*, and *Shigella*.

Differentiation of the genus *Alishewanella* from other genera

Fonnesbech Vogel et al. (2000) provide tables of characteristics that distinguish *Alishewanella fetalis* R2422019 from *Shewanella putrefaciens* and *S. algae* (potential human pathogens having phenotypes similar to R2422019) as well as from the genera *Shewanella*, *Aeromonas*, *Vibrio*, *Photobacterium*, *Erwinia*, *Klebsiella*, and *Shigella*.

List of species of the genus Alishewanella

1. **Alishewanella fetalis** Fonnesbech Vogel, Venkateswaran, Christensen, Falsen, Christiansen and Gram 2000, 1141[VP]

fe.ta′ lis. L. adj. *fetalis* pertaining to the fetus, from which the organism was isolated.

Description as for the genus with the following additional characteristics. Cells 0.5–1.0 × 2.0 µm. Grows in medium containing up to 8% in NaCl.

The mol% G + C of the DNA is: 51 (HPLC).

Type strain: R2422019, ATCC BAA-284, CCUG 30811, CIP 106648.

GenBank accession number (16S rRNA): AF144407.

Genus III. **Colwellia** *Deming, Somers, Straube, Swartz and MacDonell 1988b, 328*[VP] *(Effective publication: Deming, Somers, Straube, Swartz and MacDonell 1988a, 159)*

JODY W. DEMING AND KAREN JUNGE

Col.wel′ li.a. M.L. ending *-ia;* M.L. fem. n. *Colwellia* of Colwell, named in honor of the American microbiologist Professor Rita R. Colwell.

Curved or straight rods 0.4–1.0 × 1.5–5.0 µm. Generally motile by polar flagella. Gram negative. Asporogenous. Colonies are off-white, convex, and mucoid, except for the type strain, *Colwellia psychrerythraea*, which produces red pigment. **Facultatively anaerobic. Chemoorganotrophic**. Able to grow by fermentation of a suitable carbohydrate as indicated by acid (but no gas) produc-

tion. Generally able to utilize amino acids and organic acids, but not many of the sugars or alcohols. Capable of **nitrate reduction** but not iron or trimethylamine *N*-oxide reduction or indole or H_2S production. Generally **chitinolytic**, able to degrade starch, and positive for oxidase, catalase, and alkaline phosphatase. Stimulated by, but not dependent on, growth factors in yeast extract and vitamin solutions. Require **sea salts**, with no growth occurring below 25% sea-salt concentration. **Psychrophilic**. Able to grow on solid media in the temperature range of 0° to <20°C (optimum usually <15°C), with slightly higher maximal and lower minimal temperatures in liquid media. **Sometimes barophilic**, requiring high hydrostatic pressure for growth. Produce docosahexaenoic acid ($C_{22:6\ \omega3}$ or DHA) and other **polyunsaturated fatty acids** to help maintain homeoviscosity of cellular membranes under low temperature and high pressure. Cultured strains derived from **permanently cold**, and often deep, marine habitats.

The mol% G + C of the DNA is: 35–46.

Type species: **Colwellia psychrerythraea** (ex D'Aoust and Kushner 1972) Deming, Somers, Straube, Swartz and MacDonell 1988b, 328 (Effective publication: Deming, Somers, Straube, Swartz and MacDonell 1988a, 159 (*"Vibrio psychroerythrus"* D'Aoust and Kushner 1972, 342.)

Further descriptive information

Cell morphology varies from spherical to curved to straight rod-shaped cells with occasional short filaments. The fine structure appears typical of asporogenous Gram-negative bacteria, with no obviously unique structural features, even in the obligate barophiles (see electron micrographs in Deming et al., 1988a, and Deming and Baross, 2000). *C. rossensis*, however, is unique among *Colwellia* species for its ability to form gas vesicles (Gosink and Staley, 1995). Potentially unique cell-membrane composition is implied by the documented production of polyunsaturated fatty acids.

The most distinctive features of the genus *Colwellia* derive from its habitation of permanently cold marine environments. All characterized species are cold adapted, if not strictly psychrophilic, as defined by Morita (1975) (T_{opt} for growth of 15°C or less, T_{max} of ≤20°C). *Colwellia* (along with *Moritella*) thus appears to be unusual among all genera for encompassing exclusively cold-adapted organisms. Cardinal growth temperatures of individual species tend to be several degrees higher in liquid media than in solid media, causing at least one of the type species, *C. psychrotropica*, to be considered psychrotolerant (T_{max} of 25°C in liquid) (Bowman et al., 1998a). *C. psychrerythraea* strain 34H grows at −5°C in liquid media (Huston, 2003) and swims at subzero temperatures to −10°C (Junge et al., 2003). Two of the known strains, *C. hadaliensis* (Deming et al., 1988a) and *Colwellia* strain MT41 (DeLong et al., 1997), are not only strictly psychrophilic but also obligately barophilic, derived from the deepest portions of the cold Atlantic and Pacific Oceans, respectively. The production of polyunsaturated fatty acids (PUFAs), a feature common to members of the genus so analyzed, is attributed to the need to maintain membrane fluidity for metabolism and growth at the constantly cold temperatures (<4°C) and often high pressures of their native habitats, e.g., polar waters, sea ice, and hadal depths in the cold ocean. Their common growth requirement for sea salts and preference for full-strength sea salt concentration also reflect their native marine habitats.

The type species, *C. psychrerythraea*, is unique in the genus for its production of red pigment during colony formation. All other species produce chalk-white, off-white, or colorless colonies, typically of convex, circular, raised, and mucoid morphology, when grown on solid media. The obligate barophiles do not grow on standard agar plates at atmospheric pressure, but rather form spherical off-white colonies when grown within a solid medium under high hydrostatic pressure. *C. psychrotropica* produces a diffusible brown pigment during L-tyrosine hydrolysis in liquid media.

All *Colwellia* species are chemoorganotrophic facultative anaerobes able to grow by fermentation of a suitable carbohydrate, as indicated by acid production in Leifson oxidation–fermentation medium. In general, no gas is detected during fermentation. Carbohydrate oxidation and fermentation vary between species, as does the ability to hydrolyze various substrates (Tables BXII.γ.137 and BXII.γ.138). Utilization of amino acids and organic acids is favored over sugars and alcohols. Most species are able to utilize L-glutamate, L-proline, acetate, butyrate, fumarate, pyruvate, succinate, *N*-acetylglucosamine, oxalacetate, DL-lactate, valerate, caproate, and γ-aminobutyrate, but not lactose, maltose, D-melibiose, L-raffinose, sucrose, trehalose, D-xylose, D-adonitol, D-arabitol, *m*-inositol, D-mannitol, D-sorbitol, L-threonine, L-valine, D-gluconate, D-glucuronate, isovalerate, nonanoate, pimelate, saccharate, α-glycerophosphate, or putrescine. Individual species are distinguished by specific metabolic or hydrolytic traits: e.g., only *C. demingiae* utilizes L-serine; only *C. hornerae* produces acid from L-rhamnose; only *C. rossensis* produces acid from D-galactose, L-arabinose, D-fructose, and D-gluconate; and only *C. psychrotropica* degrades uric acid. Some strains produce extracellular hydrolytic enzymes with unique properties; e.g., *Colwellia* sp. strain 34H produces the most cold-adapted extracellular proteases yet discovered (Huston et al., 2000).

Only *C. hornerae* and *C. maris* are susceptible to vibriostatic agent O/129. Antigenic structure and other antibiotic or drug sensitivities, along with mutants and plasmids, remain to be documented or developed, although *Colwellia*-specific phages have been reported (Borriss et al., 2003). None of the *Colwellia* species are believed to be pathogenic, in keeping with their growth requirement for cold temperatures.

In direct phylogenetic analyses of environmental samples, 16S rRNA sequences specific to *Colwellia* have been detected in cold marine samples from the deep sea (e.g., Moyer et al., 1995), in keeping with what is known about cultured species, but also in coastal waters at temperate latitudes (DeLong et al., 1997). Absent any culturing information, however, the temperature adaptations of such organisms remain unknown.

Enrichment and Isolation Procedures

Members of the genus *Colwellia* are isolated from cold marine samples, using liquid enrichment media containing complex carbon sources, such as peptone, and full-strength sea-salt concentration. The most common medium used is 2216 marine broth (Difco). An initial enrichment period of days to weeks in liquid media, before transfer and cultivation on agar plates, appears to favor the recovery of these psychrophilic strains, although *C. maris* was first enriched on agar medium (Takada et al., 1979). Initial colony formation may require up to 2 months of incubation time at cold temperature. Attention to low-temperature (0° to <4°C) storage of the original sample and of subsequent enrichment incubations is important.

Sea-ice samples are first melted in seawater or brine solutions prior to enrichment procedures to avoid hypotonic shock to salt-requiring strains. Deep-sea samples can be recovered at atmo-

[b]Type strain is positive.

spheric pressure, but barophilic *Colwellia* strains are subsequently enriched and isolated under hydrostatic pressures simulating those encountered *in situ*. Methodologies for cultivation of bacteria, in either liquid or solid media, under high hydrostatic pressure are described in detail by Deming (2002).

Maintenance Procedures

Colwellia spp. are routinely maintained by periodic subcultivation on 2216 marine agar or broth (Difco) at low temperatures: <4°C for strict psychrophiles, but also up to 10°C. Obligate barophiles must be subcultivated at low temperatures under high hydrostatic pressure (Deming, 2002). Cryopreservation is the preferred form of long-term storage, freezing pelleted cultures in glycerol (15% glycerol is effective at −20°C to −80°C; 30% glycerol at −80°C) or using lyophilization. Cryopreservation is advised even for short-term storage of the type strain, *C. psychrerythraea*, since it is not recovered reliably from plates, and for obligate barophiles, which have been problematic to store (the availability of recoverable *C. hadaliensis* is currently uncertain). All *Colwellia* cultures should be shipped frozen and packed on ice to maximize recoverability.

Procedures for Testing Special Characters

Special characteristics of *Colwellia* include growth requirements at low temperatures and sometimes at high pressures and the production of PUFA. Standard incubation devices, from refrigerators to water baths, are used to achieve and maintain low temperatures, but special equipment is required for testing growth and other parameters under high pressure, as described by Deming (2002). Many standard tests for physiological and nutritional features have not yet been developed for high-pressure applications, making molecular assessments essential to determining phylogenetic status. Analysis of 16S rRNA sequences proceeds normally for *Colwellia* spp., if attention is paid to low-temperature requirements in first preparing the cultures. Whole-cell fatty acid analyses rely on standard GC and GC-MS procedures (Bowman et al., 1998a).

Differentiation of the Genus *Colwellia* from Other Genera

The genus *Colwellia* is differentiated from other closely related genera by the combination of being cold adapted, facultatively anaerobic, and able to produce chitinase. Nearest neighbors at the genus level, *Idiomarina*, *Alteromonas*, and *Pseudoalteromonas*, are not usually adapted to growth at low temperatures, are strictly aerobic, and do not typically produce chitinase (some species of *Alteromonas* and *Pseudoalteromonas* do produce the enzyme). The production of PUFA also appears to be an important distinguishing trait for *Colwellia*. Use of 16S rRNA sequence data, however, remains the essential means to distinguish *Colwellia* definitively from other genera. The main features for distinguishing one *Colwellia* species from another are provided in Table BXII.γ.138.

Taxonomic Comments

A phylogenetic treatment based on 16S rRNA sequence data from organisms in culture indicates that the closest relatives to members of the genus *Colwellia* are species of the newly described genus *Idiomarina* (Ivanova et al., 2000b), as represented by the deep-sea isolate *I. abyssalis* in Fig. BXII.γ.152. Sequence similarities between *I. abyssalis* and *Colwellia* spp. range from 85.2% (*Colwellia* sp. strain MT41) to 89.6% (type species *C. psychrerythraea*). *Colwellia* also has close phylogenetic affinities, as evidenced by similar degrees of sequence similarity, to members of the genera *Alteromonas* and *Pseudoalteromonas*, as described previously by Bowman et al. (1998a) and depicted in Fig. BXII.γ.152.

Analysis of 16S rRNA sequences for *Colwellia* species in culture (Fig. BXII.γ.152) indicates sequence similarities that range from 92.4% to 98.7%. The low end of the range derives from a comparison of the deep-sea obligate barophile, *Colwellia* sp. strain MT41, with sea-ice isolate *C. demingiae*. Strain MT41 in general has the lowest sequence similarity values to the other described *Colwellia* species (92.4–94.6%), with the exception of *C. maris* (96.3%). Only 5S (not 16S) rRNA sequence data are available for the other obligate barophile, *C. hadaliensis*, precluding comparisons of the two with each other or with other species. A

[a]Symbols: see standard definitions; blank space, no data available; NG, no growth occurred on test medium; tr, trace fatty acid component making up 0.1% or less of total fatty acid content.

[b]Reaction differs among strains; type strain is positive.

[c]No growth occurs without NaCl.

[d]Reaction differs among strains; type strain is negative.

[e]Acid (but no gas) was formed from this substrates in Leifson oxidation/fermentation medium.

possible close relationship between phylogeny and obligate barophily within the genus thus remains elusive (DeLong et al., 1997). The high end of the sequence similarity range for *Colwellia* species (98.7%) derives from comparison of the type strain *C. psychrerythraea* with *Colwellia* sp. strain 34H, suggesting the latter is also *C. psychrerythraea*. Confirmation of this suggestion comes from DNA–DNA hybridization tests (Huston, 2003). The availability of the whole genome sequence for strain 34H from The Institute for Genomic Research* thus well represents the genus *Colwellia* and enables a first-order genetic analysis of psychrophily and other traits specific to *Colwellia* or unique to the type species. Existing DNA–DNA hybridization tests show clear separation at the species level, with homologies of 12–35% among the type species (Table BXII.γ.139).

The list of *Colwellia* type species has expanded from the first two, described in 1988, to seven only in the last few years. This expansion reflects renewed ecological and biotechnological interests in cold-adapted organisms and their enzymes (Bowman et al., 1998a; Deming and Baross, 2000, 2002). Characterizations of numerous additional strains and species can be expected in the near future, including *Colwellia* sp. strain 34H and possibly strain MT41. Current culture collections of psychrophilic bacteria likely contain many undescribed *Colwellia* spp. Recent acquisition of 16S rRNA sequence data from our collection reveals at least three species, awaiting further taxonomic characterization (Junge et al., 2002).

**Editorial Note:* At the time this volume went to press, the website for the Institute for Genomic Research was http://www.tigr.org.

Acknowledgments

We gratefully acknowledge John Bowman for helpful communications and his substantial contributions to the discovery and characterization of *Colwellia* species.

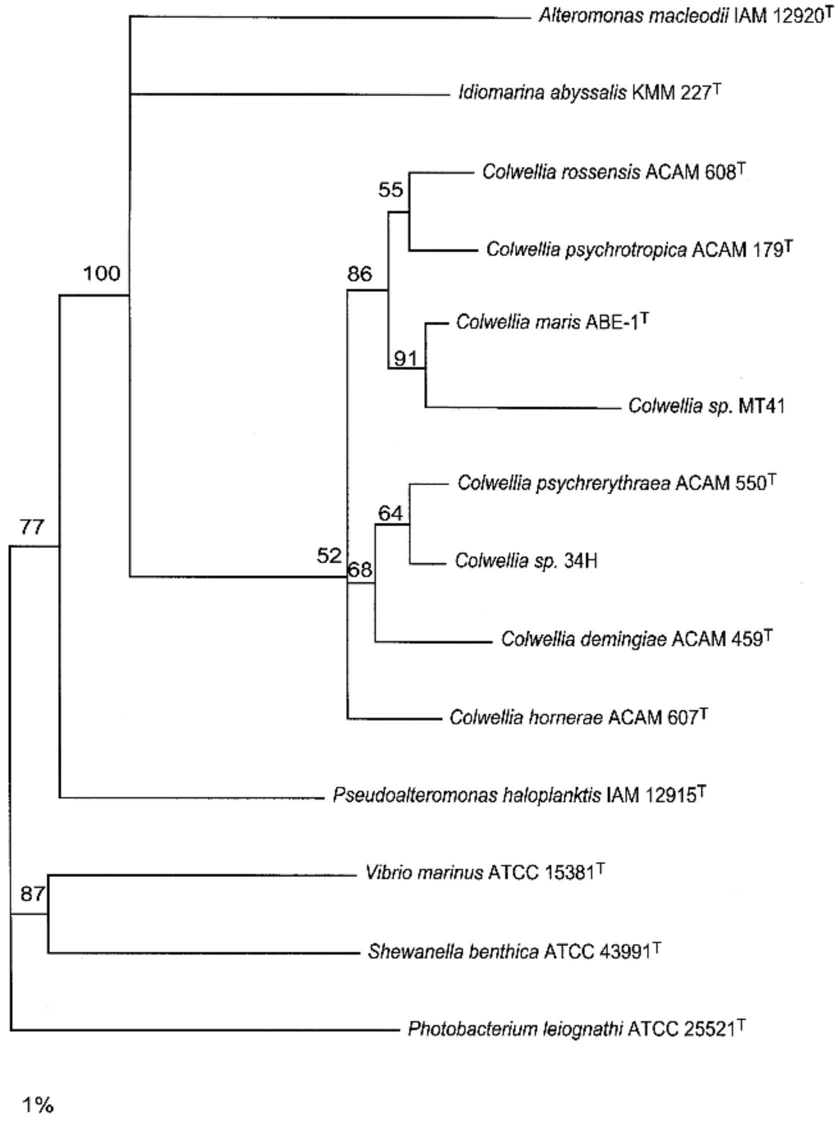

FIGURE BXII.γ.152. Phylogenetic tree based on 16S rRNA sequence comparisons showing the positions of members of the genus *Colwellia* within the *Colwellia* assemblage radiation of the *Gammaproteobacteria*. Phylogenetic analysis was conducted with reference sequences obtained from GenBank. Preliminary alignments were made using the Sequence Align program of the Ribosomal Database Project Web site (RDP) and requesting that common gaps be preserved. Complete sequence alignments were prepared with the sequence alignment editor SeqApp (D.G. Gilbert, 11 July 1994, posting date, Seq-App program, version 1.9a169, http://ftp.bio.indiana.edu/molbio/seqapp) and by manual comparison to secondary structures provided by RDP. For further phylogenetic analysis, aligned sequences corresponding to *E. coli* positions 30–1452 were used. Phylogenetic relationships were inferred using the PAUP program (4.0b8, D.L. Swofford, Smithsonian Institution, 2001). Tree topology was inferred from neighbor-joining analysis determined with the Kimura two-parameter model. *Photobacterium leiognathi* was used as an outgroup. Results from neighbor-joining bootstrap analysis (1000 replicates) are indicated by numbers (as percentages) near each node. Only nodes supported in greater than 50% of the bootstrap replicates are indicated. The scale bar corresponds to 1 fixed mutation per 100 sequence positions. The following 16S rDNA sequences (with their GenBank accession numbers in parentheses) were obtained for the phylogenetic analysis: *Alteromonas macleodii* (X82145), *Colwellia demingiae* (U85845), *Colwellia hornerae* (U85847), *Colwellia maris* (AB002630), *Colwellia psychrerythraea* (AF001375), *Colwellia psychrotropica* (U85846), *Colwellia rossensis* (U14581), *Colwellia* sp. MT41 (U91595), *Colwellia* sp. 34H (AF396670), *Idiomarina abyssalis* (AF05270), *Photobacterium leiognathi* (X74686), *Pseudoalteromonas haloplanktis* (X67024), *Shewanella benthica* (U91594), and *Vibrio marinus* (X82142).

[a]Blank space, not determined.

The characteristics are as described for the genus and as listed in Tables BXII.γ.137 and BXII.γ.138, with the following additional information. Cell length, 2.5–3.5 µm; width, 0.5 µm. Gas vesicles not formed. Motile by means of a single, long polar flagellum. Colonies are white at first appearance (7–8 d) becoming red within 10–12 d, opaque, raised, 3–5 mm in diameter, with entire edge. Psychrophilic. Growth in liquid media occurs at 0–19°C, but not at temperatures higher than 20°C when cell lysis occurs. Requires 2.75% NaCl for growth. Growth factors are not required. Resistant to vibriostatic agent O/129 (100 µg/ml), although growth is slowed by it. Acid (with no gas) is formed fermentatively and oxidatively from glucose and maltose, chitin, and *N*-acetylglucosamine. Casein, gelatin, esculin, chitin, starch, urea, and Tween 80 are hydrolyzed. The following compounds are utilized as sole sources of carbon and energy: D-glucose, glycogen, *N*-acetylglucosamine, 3-hydroxybutyrate, acetate, butyrate, succinate, fumarate, pyruvate, DL-lactate, oxalacetate, L-glutamate, and L-proline. Some strains can also utilize propionate. Isolated from flounder eggs, Norway, and fast sea ice, Antarctica.

The mol% G + C of the DNA is: 35–40 (T_m).

Type strain: ATCC 27364, DSM 8813.

GenBank accession number (16S rRNA): AF001375.

2. **Colwellia demingiae** Bowman, Gosink, McCammon, Lewis, Nichols, Nichols, Skerrat, Staley, and McMeekin 1998a, 1178[VP]

de.ming′ i.ae. L. adj. *demingiae* in honor of Jody W. Deming, an American microbiologist who has expanded the knowledge of deep-sea bacteria.

Individual cells are straight to curved rods, with spherical and short filamentous cells occasionally occurring. Cell length, 1.5–4.5 µm; width, 0.4–0.6 µm. Gas vesicles not formed. Motile. Colonies are off-white, have a mucoid consistency, raised elevation, and convex circular shape with entire to lobate edges. Psychrophilic. In liquid media T_{opt} is about 10–12°C and T_{max} is about 18°C. Requires sea salts for growth. Growth factors are not required. Resistant to vibriostatic agent O/129 (100 µg/ml). Acid (with no gas) is formed fermentatively and oxidatively from chitin and *N*-acetylglucosamine. Casein, esculin, chitin, and starch are hydrolyzed. The following compounds are utilized as sole sources of carbon and energy: *N*-acetylglucosamine, acetate, propionate, butyrate, valerate, caproate, succinate, glutarate, citrate, fumarate, pyruvate, DL-lactate, oxalacetate, L-asparagine, L-glutamate, L-proline, L-serine, and γ-aminobutyrate. Some strains can also utilize glycogen, isobutyrate, heptanoate, caprylate, malonate, azelate, L-alanine, L-aspartate, L-phenylalanine, and hydroxy-L-proline. Isolated from fast sea ice of the Prydz Bay coast, Antarctica.

The mol% G + C of the DNA is: 37 (T_m).

Type strain: ACAM 459.

GenBank accession number (16S rRNA): U85845.

3. **Colwellia hadaliensis** Deming, Somers, Straube, Swartz and MacDonell 1988b, 328[VP] (Effective publication: Deming, Somers, Straube, Swartz and MacDonell 1988a, 159.)

ha′ dal.i.en′ sis. M.L. adj. ending *-iensis;* Eng. adj. *hadal* used in oceanographic terminology; of, or pertaining to, the greatest depths of the ocean; derived from Gr. n. *Hades* god of the underworld.

Individual cells are curved rods. Cell length, 3.0–5.0 µm; width, 0.8 µm. Gas vesicles not formed. Motile by means of polar flagella. Colonies are off-white but form only within solid media under hydrostatic pressure. Psychrophilic. Growth occurs in liquid media at 2–10°C, but not at temperatures of 15°C or higher. Obligately barophilic. Requires hydrostatic pressures of 300–1020 atm for growth at 2°C and 500–1020 atm at 10°C. Cell lysis occurs at <200 atm and 2°C and at <400 atm and 10°C; absolute upper pressure limits for growth and survival unknown. Acid is formed fermentatively and oxidatively from glucose. Chitin is hydrolyzed. Associated with cold (<4°C), hadal (depth of 6000–11,000 m) marine waters and sinking particles.

The mol% G + C of the DNA is: 46 (T_m).

Type strain: BNL-1.

Additional Remarks: The 16S rDNA sequence is not available for *C. hadaliensis*, but see Deming et al. (1988a) for 5S rRNA sequence.

4. **Colwellia hornerae** Bowman, Gosink, McCammon, Lewis, Nichols, Nichols, Skerrat, Staley and McMeekin 1998a, 1178[VP]

horn.ner′ ae. L. adj. *hornerae* in honor of Rita Horner, an American biologist who pioneered studies on sea-ice microbiota.

Individual cells are straight to curved rods, with spherical cells occasionally occurring. Cell length, 1.5–3.0 µm; width, 0.4–0.8 µm. Gas vesicles not formed. Motile. Colonies are off-white, have a mucoid consistency, raised elevation, and convex circular shape with entire to lobate edges. Psychrophilic. In liquid media T_{opt} is about 12°C and T_{max} is about 23°C. Requires sea salts for growth. Growth occurs in the

presence of sea salts at three times normal concentration and is sensitive to vibriostatic agent O/129 (100 μg/ml). Growth factors are not required. Acid (with no gas) is formed fermentatively and oxidatively from L-rhamnose. Acid is formed oxidatively from glycerol. Tween 80, casein, esculin, and starch are hydrolyzed. The following compounds are utilized as sole sources of carbon and energy: glycerol, acetate, propionate, butyrate, valerate, caproate, heptanoate, succinate, glutarate, azelate, citrate, fumarate, pyruvate, DL-lactate, oxaloacetate, L-glutamate, L-proline, hydroxy-L-proline, and γ-aminobutyrate. Isolated from fast sea ice of the Prydz Bay coast, Antarctica.

The mol% G + C of the DNA is: 39 (T_m).

Type strain: ACAM 607, CIP 105821.

GenBank accession number (16S rRNA): U85847.

5. **Colwellia maris** Yumoto, Kawasaki, Iwata, Matsuyama and Okuyama 1998, 1361^{VP}

mar′ is. L. gen. n. *maris* of the sea.

Individual cells are curved rods. Cell length, 2–4 μm; width, 0.6–1.0 μm. Gas vesicles not formed. Motile by means of a single polar flagellum. Colonies are colorless. Catalase and oxidase reactions are positive. Psychrophilic. Growth occurs in liquid media at 0–22°C, with T_{opt} of 15°C. Growth factors not required. Growth occurs in media supplemented with 3% or 4% NaCl, but not in the absence of NaCl or at a salinity higher than 6.5%. Sensitive to vibriostatic agent O/129 (10 and 150 μg/ml). Acids are produced from D-glucose under aerobic, but not anaerobic, conditions. No acids are produced from L-arabinose, D-fructose, maltose, D-mannose, melibiose, and sucrose either aerobically or anaerobically. Gelatin, DNA and Tweens 20, 40, 60, and 80 are hydrolyzed, but not casein, chitin, starch, or alginic acid. D-glucose is utilized as a sole source of carbon and energy. Does not utilize D-mannose, raffinose, D-xylose, L-arabinose, D-fructose, glycerol, lactose, maltose, melibiose, or sucrose. The major isoprenoid quinone is Q-8. The whole-cell fatty acids contain saturated and monounsaturated fatty acids with 10–18 C atoms; saturated and monounsaturated C_{16} fatty acids are predominant in cells grown at 15°C. The strain contains a unique trans-unsaturated fatty acid (9-trans-hexadecanoic acid, $C_{16:1\ \omega 9t}$). Isolated from ice-impacted seawater in the Okhotsuku Sea, Japan.

The mol% G + C of the DNA is: 39 (HPLC).

Type strain: ABE-1, CIP 106458, JCM 10085.

GenBank accession number (16S rRNA): AB002630.

6. **Colwellia psychrotropica** Bowman, Gosink, McCammon, Lewis, Nichols, Nichols, Skerrat, Staley and McMeekin 1998a, 1179^{VP}

psy.chro.tro.pi′ ca. Gr. adj. *psychros* cold; Gr. n. *tropica* circle; M.L. fem. adj. *psychrotropica* having an affinity for cold.

Individual cells are straight to curved rods, with spherical cells occasionally occurring. Cell length, 1.5–3.0 μm; width, 0.4–0.8 μm. Gas vesicles not formed. Motile. Colonies are off-white, have a mucoid consistency, raised elevation, and convex circular shape with entire to lobate edges. Psychrophilic. In liquid media T_{opt} is about 18°C and T_{max} is about 25°C. Requires sea salts for growth. Growth factors not required. Growth occurs in the presence of sea salts at three times normal concentration and is sensitive to vibriostatic agent O/129 (100 μg/ml). Acid (with no gas) is formed fermentatively and oxidatively from chitin and *N*-acetylglucosamine. Urea, uric acid, Tween 80, casein, chitin, and L-tyrosine are hydrolyzed. The following compounds are utilized as sole sources of carbon and energy: *N*-acetylglucosamine, acetate, butyrate, valerate, caproate, succinate, 2-oxoglutarate, 3-hydroxybutyrate, L-malate, fumarate, pyruvate, DL-lactate, oxaloacetate, L-alanine, L-aspartate, L-asparagine, L-glutamate, L-proline, and γ-aminobutyrate. Isolated from the pycnocline of an Antarctic marine-salinity meromictic lake (Burton Lake).

The mol% G + C of the DNA is: 42 (T_m).

Type strain: ACAM 179.

GenBank accession number (16S rRNA): U85846.

7. **Colwellia rossensis** Bowman, Gosink, McCammon, Lewis, Nichols, Nichols, Skerrat, Staley and McMeekin 1998a, 1179^{VP}

ross.en′ sis. M.L. fem. adj. *rossensis* for the Ross Sea, Antarctica.

Individual cells are straight to curved rods, with spherical cells occasionally occurring. Cell length, 1.5–3.0 μm; width, 0.4–0.8 μm. Gas vesicles are formed. Nonmotile. Colonies are chalky-white, have a raised elevation and convex circular shape with entire edges. Psychrophilic. In liquid media T_{opt} is about 10°C and T_{max} is about 15°C. Requires sea salts for growth. Yeast extract required for growth. Resistant to vibriostatic agent O/129 (100 μg/ml). Acid (with no gas) is formed fermentatively and oxidatively from chitin, *N*-acetylglucosamine, and D-glucose. Also produces acid oxidatively from D-galactose and glycerol. Urea, chitin, and starch are hydrolyzed. The following compounds are utilized as sole sources of carbon and energy: glycogen, L-arabinose, *N*-acetylglucosamine, D-fructose, D-glucose, glycerol, acetate, butyrate, valerate, caproate, malonate, succinate, citrate, 3-hydroxybutyrate, L-malate, fumarate, pyruvate, L-alanine, L-aspartate, L-asparagine, L-glutamate, L-proline, and γ-aminobutyrate. Isolated from the sea/ice interface of fast sea ice McMurdo Sound, Antarctica (Gosink and Staley, 1995).

The mol% G + C of the DNA is: 38 (T_m).

Type strain: S51-W(gv)1, ACAM 608.

GenBank accession number (16S rRNA): U14581.

Genus IV. **Ferrimonas** *Rosselló-Mora, Ludwig, Kämpfer, Amann and Schleifer 1996, 362^{VP}* *(Effective publication: Rosselló-Mora, Ludwig, Kämpfer, Amann and Schleifer 1995a, 200)*

Ramon A. Rosselló-Mora

Fer′ ri.mo.nas. L. neut. n. *ferrum* iron; Gr. n. *monas* unit; M.L. fem. n. *Ferrimonas* iron (III)-reducing cell.

Straight rods 0.3–0.5 × 1.2–1.5 μm with rounded ends. Occur singly, occasionally with some pairs or short chains. No resting stages are known. Definite capsules are not evident. Gram negative. **Motile by means of a single polar flagellum.** No intracellular inclusions have been observed. **Chemoorganotroph, having a strictly respiratory metabolism with oxygen, nitrate, Fe(III)-oxy-**

hydroxide, Fe(III)-citrate, and MnO_2 used as electron acceptors. Lactate is oxidized to CO_2 but not to acetate. Sodium dependent; a minimum of 0.5% NaCl is required in the medium. Catalase, oxidase, phenylalanine deaminase, DNAse, and lipase (Tween 80 and Tween 20) positive. Gelatinase, urease, amylase, Simmons citrate, arginine dihydrolase, and lysine decarboxylase negative. Growth at 42°C. Member of the *Gammaproteobacteria*.

The mol% G + C of the DNA is: 54 (T_m).

Type species: **Ferrimonas balearica** Rosselló-Mora, Ludwig, Kämpfer, Amann and Schleifer 1996, 362 (Effective publication: Rosselló-Mora, Ludwig, Kämpfer, Amann and Schleifer 1995a, 200.)

Further descriptive information

Fresh isolates may not form colonies on PYG[1] agar medium, but after several subcultivations in enrichment medium colony-forming units may appear. Colonies on TSI-agar[2] medium produce a black iron precipitate. Aerobic growth on solid medium is often brown and mucous. *Ferrimonas* undergoes autolysis within 5 d under aerobic conditions. Reduction of Fe(III)-oxyhydroxide with lactate as sole electron donor yields magnetite under anaerobic conditions. The range of NaCl tolerance is 0.5–7.5%. *Ferrimonas* does not exhibit growth at 5°C and 44°C but at 42°C. The pH range for growth is 6–9.

Enrichment and Isolation Procedures

Only one strain of *Ferrimonas* has been isolated; it was simultaneously obtained from the same sample by using two different electron donors. Inocula were obtained from the upper few centimeters of a marine sediment of the Palma de Mallorca harbor (Spain). Sediments were inoculated in amorphous Fe(III)-oxyhydroxide medium[3] containing either 0.4% (w/v) sodium acetate or 0.25% (w/v) sodium tartrate as sole electron donors, and in both instances 2% NaCl was added to the medium. The anaerobic atmosphere was composed of 97% N_2 and 3% H_2. Incubations were done at 20°C without shaking and in the dark. Enrichments yielded magnetite after 1 month of incubation. After three subcultivations in enrichment medium the isolation of the organism was carried out by streaking the enrichment culture on Fe(III)-citrate agar. Pure culture was obtained by continuous restreaking under anaerobic incubations for at least 2 weeks.

Maintenance Procedures

Aerobic cultures should be reinoculated often due to the rapid autolysis of this bacterium; it does not survive more than 5 days on either solid or liquid complex medium incubated aerobically. However, anaerobic growth on Fe(III)-oxyhydroxide lactate agar shakes can be maintained for several months. The organism survives for several years frozen at −80°C in nutrient PYG broth containing 15% glycerol. It also survives freeze-drying. However, in cultures maintained by both methods viability may be low due to the tendency of the cells to lyse.

Differentiation of the genus *Ferrimonas* from other genera

Ferrimonas can be distinguished from other strictly respiratory Gram-negative genera of the *Gammaproteobacteria* able to undergo Fe(III) reduction (i.e. *Shewanella putrefaciens*, *S. baltica*, and *S. algae*) as well as from *Alteromonas* species by the following characters: its ability to denitrify, to grow at 42°C and its phenylalanine deaminase activity, its inability to grow in medium containing 0% NaCl, its lack of gelatinase and urease, and its negative Simmons citrate reaction.

An oligonucleotide probe specific for *Ferrimonas* has been designed (5′-ACCCCCCTCTCAAGGACT-3′ complementary to the position 654-672 in *E. coli* 16S rRNA numbering; Brosius et al., 1981). A comparison with 5300 complete or almost complete accessible 16S rRNA sequences present in the RDP database (Maidak et al., 1997) did not reveal any identical complementary sequences other than that of the target organism. T_m, derived from the thermal denaturation curve, is 53.2°C. Optimal stringency conditions for dot blot hybridization with extracted nucleic acids are at 62°C. This probe is also optimized for whole cell *in situ* hybridization. Specificity of the probe is obtained by using 35% formamide with the standard protocol (Manz et al., 1992).

Taxonomic Comments

The genus *Ferrimonas* is phylogenetically affiliated with the *Gammaproteobacteria* as illustrated in Fig. BXII.γ.153. The genus presently consists of a single species, *F. balearica*; to date, no similar strains have been reported.

1. PYG broth: 1% peptone, 0.5% yeast extract, 0.5% glucose, and 0.8% NaCl.

2. TSI-agar: Triple Sugar Iron agar, Difco.

3. Anaerobic basal mineral medium of Lovley and Phillips (1986): (in grams per liter deionized water) $NaHCO_3$, 2.5; $CaCl_2.2H_2O$, 1.0; KCl, 0.1, NH_4Cl, 1.5; NaH_2PO_4, 0.6; NaCl, 20.0; $MgCl_2.6H_2O$, 5.3; $MgSO_4.7H_2O$, 0.1; $MnCl_2.4H_2O$, 0.005; $NaMoO_4.2H_2O$, 0.001; and yeast extract, 0.05. Media is adjusted to pH 7. Electron acceptors were used at 250 mmol/l Fe(III)-oxyhydroxide (for preparation see Lovley and Phillips, 1986) or 20 mmol/l Fe(III)-citrate.

List of species of the genus Ferrimonas

1. **Ferrimonas balearica** Rosselló-Mora, Ludwig, Kämpfer, Amann and Schleifer 1996, 362[VP] (Effective publication: Rosselló-Mora, Ludwig, Kämpfer, Amann and Schleifer 1995a, 200.)
ba.le.a′ri.ca. L. fem. adj. *balearica* of the Balearaic Islands where the organism was isolated.
The description is the same as that given for the genus.
The mol% G + C of the DNA is: 54 (T_m).
Type strain: PAT, DSM 9799.
GenBank accession number (16S rRNA): X93021.

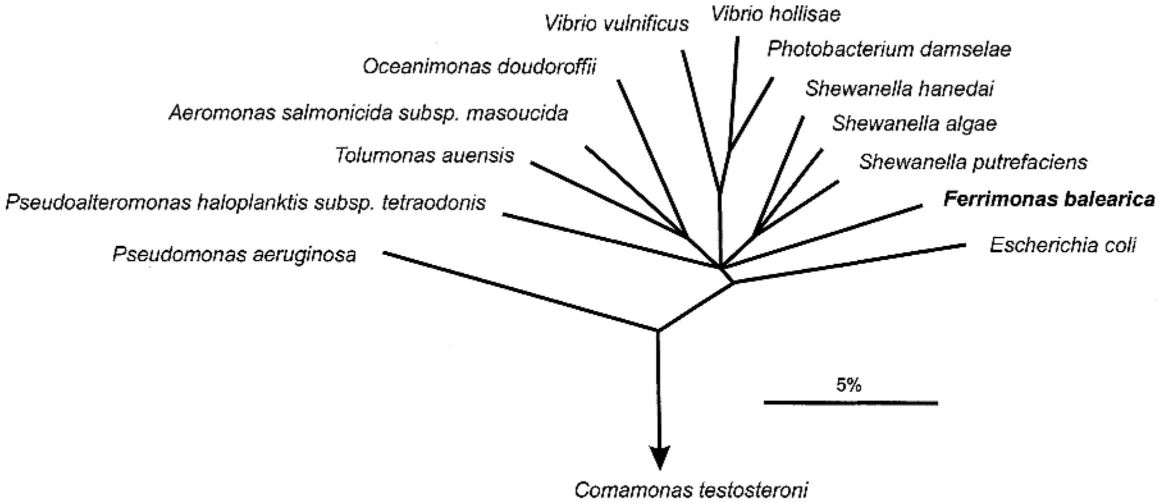

FIGURE BXII.γ.153. 16S rRNA based tree reflecting the phylogenetic affiliation of *Ferrimonas balearica* and a selection of *Proteobacteria.* The tree is based on the results of a distance matrix analysis including only sequence positions that share at least 50% of all available complete or almost complete 16S rRNA sequences from bacteria of this class. Tree topology was evaluated and corrected according to the results of distance matrix, maximum parsimony, and maximum likelihood analyses of various data sets. Accession numbers of shown sequences in the tree are the following: AB021371, M11224, M34133, X74680, X74700, X74707, X76333, X80725, X81623, X82132, X82139, X92889, X93021, and Z95486. Multifurcations indicate topologies that could not be unambiguously resolved. The bar indicates 5% estimated sequence divergence.

Genus V. **Glaciecola** *Bowman, McCammon, Brown and McMeekin 1998b, 1220*VP

JOHN P. BOWMAN

Gla.ci.e'co.la. L. fem. n. *glacies* ice; L. gen. n. *incola* an inhabitant; M.L. fem. n. *Glaciecola* inhabitant of ice.

Slender rod-shaped cells, 0.2–0.4 × 1.0–5.0 μm. May be slightly curved, curved, or spiral. Gram negative. **Motile.** Nonsporeforming. **Aerobic,** having a strictly respiratory type of metabolism with oxygen as the only known terminal electron acceptor. Chemoheterotrophic. **Psychrophilic,** growing best at temperatures well below room temperature. In liquid media, the maximal growth temperature for most strains is at about 25–26°C; on agar media, no growth occurs above 20°C. **Seawater is required for growth. Oxidase and catalase positive.** Major fatty acids are hexadecaenoic acid ($C_{16:1\ \omega7c}$), hexadecanoic acid ($C_{16:0}$), and octadecaenoic acid ($C_{18:1\ \omega7c}$). Belongs to the *Gammaproteobacteria.* Habitat: Antarctic sea-ice diatom assemblages.

The mol% G + C of the DNA is: 40–46.

Type species: **Glaciecola punicea** Bowman, McCammon, Brown and McMeekin 1998b, 1220.

FURTHER DESCRIPTIVE INFORMATION

Glaciecola cells have a generally rod-shaped morphology (0.2–0.4 × 1.0–5.0 μm) and are motile. At the optimal growth temperature, ~15°C, cells are very slender and appear spiral or curved. At supraoptimal (>20°C) and suboptimal (<10°C) temperatures, the cells appear as straight rods. Short filaments also occur, especially in stationary growth cultures. All strains are motile, although information on the type and position of flagella present is still lacking.

The colonies of *G. punicea* are circular and convex in shape, with lobate edges and a butyrous consistency. After 14 d incubation, colony diameter is about 3–5 mm. *G. pallidula* strains form even-edged colonies that have a mucoid consistency and are 3–5 mm after 14 d incubation. Various *Glaciecola* strains are pigmented with unknown compounds that are not extractable with either polar or nonpolar solvents. In the presence of a strong base (20% KOH), the pigment is bleached white. Pigmentation is most obvious in strains of *G. punicea*, which appear musk pink to magenta in color. By comparison, *G. pallidula* colonies have a pale pink coloration.

Strains grow well on marine media, such as Marine 2216 agar (Difco Laboratories). All strains require seawater salts for optimal growth. No growth occurs if NaCl is added alone to the medium; Mg^{2+} and Ca^{2+} ions are also required for growth. Strains of *G. pallidula* are nutritionally non-exacting and will grow in a defined mineral salts medium, such as that used for testing carbon and energy sources of *Shewanella*, *Alteromonas*, and *Pseudoalteromonas* (Baumann et al., 1984a). Most strains of *G. punicea* require yeast extract for growth, and growth of this species can be achieved in a defined mineral salts medium supplemented with 0.02% yeast extract. In any case, growth in minimal media by most *Glaciecola* strains is relatively slow and scant, but it can be boosted somewhat by the addition of a vitamin solution, such as that formulated by Balch et al. (1979).

All strains are psychrophilic. In liquid media, the optimal growth temperature is about 15°C and the maximal growth temperature for most strains is about 25–26°C. Strains will grow at −2°C in liquid marine 2216 media. On agar media, cardinal growth temperature points are reduced by up to 5°C, with no growth occurring at temperatures above 20°C. A detailed study of the salt and temperature optima of *Glaciecola punicea* ACAM 611[T] has been performed by Nichols et al. (1999).

All *Glaciecola* strains are strictly aerobic chemoheterotrophs and strongly produce catalase and cytochrome *c* oxidase. None of the strains grows anaerobically by either fermentation or by anaerobic respiration. Oxidative acid production from carbohydrates is weak and slow on Leifson's oxidation–fermentation medium (Leifson, 1963) and is restricted to a small range of carbohydrates (Table BXII.γ.140). Up to 10 d incubation at 15°C is required before acid production is detectable. The hydrolytic capacity of *Glaciecola* strains is relatively limited. Some strains of *G. punicea* can degrade uric acid (slowly) and esculin, whereas most strains of *G. pallidula* can degrade Tween 80 and produce an amylase. All strains so far tested are able to form alkaline phosphatase, α-galactosidase and β-galactosidase. *G. punicea* strains also produce a 6-phospho-β-galactosidase. Strains are able to utilize a limited range of organic acids, amino acids, and other compounds as sole carbon sources (Table BXII.γ.140). The metabolic pathways and nutrient transport mechanisms in *Glaciecola* strains have yet to be studied.

TABLE BXII.γ.140. Characteristics differentiating the species of the genus *Glaciecola*[a]

Characteristic[b,c]	1. *G. punicea*	2. *G. pallidula*
Pigmentation	Pink-red	Pale pink
Yeast extract requirement	d	−
β-Galacto(6-phosphate)sidase	+	−
Acid from maltose	−	(+)
Hydrolysis of:		
Urate	d	−
Esculin	d	−
Starch	−	d
Tween 80	d	+
Utilization of:		
α-Glycerophosphate	d	+
Succinate, L-malate, fumarate, L-proline	+	−
Glycerol, glycogen, acetate, pyruvate, DL-lactate, L-glutamate	−	+
L-Tyrosine	d	−
Butyrate	−	d
Mol% G + C of the DNA	44–46	40

[a]Symbols: +, test positive for all strains; d, variable (10–90% of strains) results between strains; −, strains negative for test; (+), the test exhibited a weak and delayed reaction.

[b]All *Glaciecola* strains tested are positive for the following tests: growth on Marine 2216, R2A (Oxoid Pty. Ltd.) + 2.5% NaCl, and ZoBells marine medium (5 g bacteriological peptone, 2 g yeast extract dissolved in 1000 ml seawater); growth at <15°C on agar media; catalase, oxidase, α-galactosidase, β-galactosidase; utilization of oxaloacetate; and acid production (but weak and delayed) from D-glucose, D-galactose, D-melibiose, and glycerol.

[c]All *Glaciecola* strains tested are negative for the following tests: growth at 25°C or higher on agar media; growth with 3× or 4× strength seawater; tolerance to 5% ox-bile salts; nitrate as a nitrogen source; nitrate reduction, denitrification, and nitrogen fixation; hydrolysis of urea, xanthine, egg yolk, casein, gelatin, elastin, chitin, dextran, and DNA; production of L-phenylalanine deaminase, L-tryptophan deaminase, arginine dihydrolase, glutamate decarboxylase, lysine decarboxylase, ornithine decarboxylase, α-glucosidase, β-glucosidase, α-fucosidase, α-arabinosidase, β-glucuronidase, β-*N*-acetylglucosaminidase; production of indole from L-tryptophan; production of hydrogen sulfide from thiosulfate or L-cysteine; acid production from L-arabinose, D-mannose, D-fructose, L-rhamnose, D-xylose, D-mannitol, *N*-acetylglucosamine, sucrose, lactose, cellobiose, trehalose, D-raffinose, dextran, adonitol, L-arabitol, D-sorbitol, and *m*-inositol; utilization of *N*-acetylglucosamine, L-arabinose, cellobiose, and D-xylose

G. punicea strains possess a DNA base composition of 44–46 mol% G + C—significantly higher than that of *G. pallidula* strains, which have an average value of 40 mol% G + C.

Whole cell fatty acid profiles of *Glaciecola* species are very similar to one another. The major fatty acids include hexadecaenoic acid ($C_{16:1\ \omega7c}$; 52–62%), octadecaenoic acid ($C_{18:1\ \omega7c}$; 12–21%), hexadecanoic acid ($C_{16:0}$; 9–12%), and heptadecaenoic acid ($C_{17:1\ \omega8c}$; 4–5%). Strains also contain low levels of saturated iso-branched-chain fatty acids ($C_{13:0\ iso}$, $C_{14:0\ iso}$, $C_{15:0\ iso}$, $C_{16:0\ iso}$, and $C_{17:0\ iso}$; total 2.5–3.3%). Polyunsaturated fatty acids and hydroxylated fatty acids (usually associated with the cell envelope) are either absent or are present only at trace levels. The fatty acids present are similar to those of *Alteromonas macleodii* (Svetashev et al., 1995); however, monounsaturated fatty acids predominate in *Glaciecola* strains, whereas saturated fatty acids are the most significant components in *Alteromonas* strains.

So far, *Glaciecola* strains have only been isolated from sea-ice algal assemblages. None have been isolated from under-ice seawater below the same sea-ice collection points. The genus is present at both poles; strains have been isolated from both Antarctic and Arctic (Barrow, Alaska) sea ice (Staley and Gosink, 1999).

Enrichment and Isolation Procedures

Glaciecola strains have been obtained only from algal assemblages present within coastally attached sea ice (fast sea ice). Algal assemblages in fast ice usually occur perennially as a bottom assemblage. To obtain this bottom assemblage, care must be taken to avoid losing the layer when drilling out the ice core. The ice samples are melted in seawater at 4°C or less to avoid hypotonic shock to the bacteria present. The melted sample is then added to Marine 2216 liquid media for 1–2 d at 2°C before plating onto Marine 2216 agar. This enrichment phase encourages the growth of isolates that will not grow readily when directly plated onto a solid agar surface, such as *Glaciecola* spp. Incubation of marine agar plates proceeds for at least 4 weeks at 2°C. The unusual pigments produced by *Glaciecola* strains, particularly those of *G. punicea*, make them distinctive on primary isolation plates and easy to select for further purification. Some strains (all so far undescribed) that are related to the genera *Psychrobacter* and *Marinobacter* can also appear pale pink and so can be potentially confused with *G. pallidula* strains.

Maintenance Procedures

Glaciecola strains can be stored as active cultures on Marine 2216 agar plates or slants at 2°C for at least 12 months. The medium should contain an antifungal agent (nystatin or cycloheximide) to prevent contamination. Strains can also be cryopreserved. For cryopreservation, a heavy suspension of cells from a fresh culture is made in Marine 2216 liquid media supplemented with 30% glycerol. The suspension is then frozen at −20°C and then stored at −70°C. The frozen suspension is then checked within 2 weeks of preparation and every 6 months thereafter. Multiple small tubes of frozen suspension should be prepared to avoid loss of viability from repeated freezing and thawing.

Differentiation of the genus *Glaciecola* from other genera

The sea-ice habitat, distinctive pigmentation and psychrophilic properties of the genus *Glaciecola* make them readily identifiable. The genera that are most closely related to *Glaciecola* include

Alteromonas and *Pseudoalteromonas*. *Alteromonas* strains have not been isolated from polar environments and seem to be more adapted to tropical and temperate marine waters, such as the Mediterranean Sea or mid-Pacific Ocean. *Pseudoalteromonas* species are common in southern ocean seawater and have also been isolated from sea ice (mostly strains of *P. antarctica*, *P. nigrifaciens*, and *P. prydzensis*) (Bowman, 1998); however these species are easy to distinguish from *Glaciecola* spp. because they are nonpigmented, able to grow at temperatures up to 30–35°C on agar, and nutritionally versatile, with strong saccharolytic activity.

TAXONOMIC COMMENTS

The 16S rDNA sequence analysis of *Glaciecola* strains indicates that they form a lineage within the order *Alteromonadales*, which includes other marine genera, such as *Colwellia*, *Shewanella*, *Moritella*, *Ferrimonas*, *Pseudoalteromonas*, and *Alteromonas*. The genus *Alteromonas* is by far the closest related taxon, with a sequence similarity of 0.90–0.92. *Glaciecola punicea* and *Glaciecola pallidula* strains both form individually distinct branches and share a sequence similarity of about 0.93.

The levels of DNA hybridization between strains of the different species have been examined using spectrophotometric-based renaturation rate kinetics (Huss et al., 1983). The levels are equivalent to background levels of reassociation.

DIFFERENTIATION OF THE SPECIES OF THE GENUS *GLACIECOLA*

Characteristics differentiating *G. punicea* and *G. pallidula* are listed in Table BXII.γ.140.

List of species of the genus Glaciecola

1. **Glaciecola punicea** Bowman, McCammon, Brown and McMeekin 1998b, 1220[VP]
pu.nice′ a. L. fem. adj. *punicea* pink-red, referring to the species pigmentation.

The characteristics are as described for the genus and as listed in Table BXII.γ.140. Other characteristics are as follows. Optimum temperature, 15°C; maximum 20–25°C. Colonies are bright pink-red, circular, and convex, with an entire edge and butyrous consistency. Yeast extract is required by some strains; growth is stimulated by vitamin growth factors. Oxidative acid production from carbohydrates is weak and slow; acid may be formed from D-glucose, D-galactose, D-melibiose, and glycerol. Some strains slowly degrade uric acid, esculin, and L-tyrosine. The following enzymes are produced: α-galactosidase, β-galactosidase, 6-phospho-β-galactosidase, and alkaline phosphatase. The following compounds are used as carbon and energy sources: succinate, L-malate, fumarate, oxaloacetate, and L-proline. Some strains utilize α-glycerophosphate. The major fatty acids are hexadecaenoic acid ($C_{16:1\ \omega7c}$), hexadecanoic acid ($C_{16:0}$), and octadecaenoic acid ($C_{18:1\ \omega7c}$). The type strain was isolated from a sea-ice core from the O'Gorman Rocks area of Prydz Bay, Antarctica.

The mol% G + C of the DNA is: 44–46 (T_m).

Type strain: IC067, ACAM 611.

GenBank accession number (16S rRNA): U85853.

2. **Glaciecola pallidula** Bowman, McCammon, Brown and McMeekin 1998b, 1221[VP]
pal.lid′ u.la. L. adj. *pallidula* pallidula somewhat pale, referring to the weak pigmentation of the species.

The characteristics are as described for the genus and as listed in Table BXII.γ.140. Other characteristics are as follows. Optimum temperature, 10–15°C; maximum, 18–20°C. Colonies are pale pink, circular, and raised convex, with entire edges and a butyrous–mucoid consistency. Growth is stimulated by vitamin growth factors. Oxidative acid production from carbohydrates is weak and slow; acid may be formed from D-glucose, D-galactose, D-melibiose, and glycerol. Tween 80 is hydrolyzed. Produce the following enzymes: α-galactosidase, β-galactosidase, and alkaline phosphatase. Some strains slowly degrade starch. Utilize the following compounds as carbon and energy sources: glycogen, glycerol, α-glycerophosphate, acetate, pyruvate, DL-lactate, oxaloacetate, and L-glutamate. Some strains utilize butyrate. Major fatty acids are hexadecaenoic acid ($C_{16:1\ \omega7c}$), hexadecanoic acid ($C_{16:0}$), and octadecaenoic acid ($C_{18:1\ \omega7c}$). The type strain was isolated from sea-ice cores from Taynaya Bay, Antarctica.

The mol% G + C of the DNA is: 40 (T_m).

Type strain: IC079, ACAM 615.

GenBank accession number (16S rRNA): U85854.

Genus VI. **Idiomarina** *Ivanova, Romanenko, Chun, Matte, Matte, Mikhailov, Svetashev, Huq, Maugel and Colwell 2000b, 906*[VP]

THE EDITORIAL BOARD

I.di.o.ma.ri′ na. Gr. adj. *idios* original, true; L. fem. adj. *marina* of the sea, marine; M.L. fem. n. *Idiomarina* pertaining to the peculiar, true marine nature of microorganisms from the ocean (seawater).

Chemoorganotrophic Gram-negative obligately aerobic rods. Motile; one polar flagellum. **Require Na^+ for growth**; no required vitamins or amino acids. Temperature optimum 20–22°C; pH optimum 7.5–8.0. **Oxidase, catalase, gelatinase, lipase, and DNase positive.** Do not hydrolyze starch or agar. Major cellular fatty acids are branched *iso* forms having odd numbers of carbon atoms.

The mol% G + C of the DNA is: 48.9–50.4.

Type species: **Idiomarina abyssalis** Ivanova, Romanenko, Chun, Matte, Matte, Mikhailov, Svetashev, Huq, Maugel and Colwell 2000b, 906.

Further descriptive information

The type strains of both *Idiomarina* species utilized alaninamide, L-alanine, L-alanyl-glycine, L-arginine, glycyl-L-glutamic acid, α-ketobutyric acid, α-ketovaleric acid, monomethylsuccinate, and L-tyrosine in the Biolog™ test system. Neither utilized D-arabinose, glycerol, lactose, L-lysine, maltose, mannitol, D-mannose, melibiose, L-phenylalanine, D-rhamnose, or sucrose (Ivanova et al., 2000b).

The type strains of both *Idiomarina* species were resistant to ampicillin, benzylpenicilllin, kanamycin, lincomycin, oleandomycin, oxacillin, tetracycline, and vancomycin; both were susceptible to erythromycin (Ivanova et al., 2000b).

Analysis of 16S rDNA sequences of *I. abyssalis* and *I. zobellii* placed them together in a clade in the *Gammaproteobacteria* with *Alteromonas*, *Pseudoalteromonas*, and *Colwellia* species (Ivanova et al., 2000b).

Enrichment and Isolation Procedures

Strains were isolated from seawater that was collected at 4000–5000 m, spread on seawater agar amended as described by Ivanova et al. (2000b), and incubated at atmospheric pressure.

Maintenance Procedures

Strains can be maintained at 4°C on semisolid medium B covered with mineral oil (Ivanova et al., 2000b) or at −80°C suspended in Marine Broth containing 30% (v/v) glycerol (Ivanova et al., 2000b).

Differentiation of the genus *Idiomarina* from other genera

Characteristics that differentiate the genus *Idiomarina* from other members of the family *Alteromonadaceae* (*Alteromonas*, *Pseudoalteromonas*, and *Colwellia*) are given by Ivanova and Mikhailov (2001a); characteristics that differentiate *Idiomarina* from those three genera and from members of the genera *Halomonas*, *Marinomonas*, and *Oceanospirillum* are given by Ivanova et al. (2000b). A comparison of fatty acid profiles of members of the genera *Idiomarina*, *Marinomonas*, *Alteromonas*, *Pseudoalteromonas*, and *Glaciecola* was presented by Ivanova et al. (2000c).

Differentiation of the species of the genus *Idiomarina*

I. abyssalis KMM 227 grows in the presence of NaCl up to 15% at 4°C; *I. zobellii* KMM 231, up to 10%. *I. zobellii* KMM 231 possesses fimbriae and produces chitinase; *I. abyssalis* KMM 227 does not. *I. abyssalis* KMM 227 oxidizes acetic acid, cyclodextrin, dextrin, glucose-6-phosphate, glycerol, glycogen, methylpyruvate, and proline. *I. zobellii* KMM 231 utilizes L-ornithine.

List of species of the genus Idiomarina

1. **Idiomarina abyssalis** Ivanova, Romanenko, Chun, Matte, Matte, Mikhailov, Svetashev, Huq, Maugel and Colwell 2000b, 906^VP^

a.bys.sal′is. L. fem. masc. adj. *abyssalis* deep sea; M.L. fem. adj. *abyssalis* of abssyal depths of the ocean (1000–6000 m) from which the organism was isolated.

Description as for the genus with the following additional characteristics. Grows in the presence of 0.6–15% NaCl. Produces proteinase.

The mol% G + C of the DNA is: 50.4 (T_m).

Type strain: KMM 227, ATCC BAA-312.

GenBank accession number (16S rRNA): AF052740.

2. **Idiomarina zobellii** Ivanova, Romanenko, Chun, Matte, Matte, Mikhailov, Svetashev, Huq, Maugel and Colwell 2000b, 906^VP^

zo.bell′i.i. M.L. fem. adj. *zobelli* of Zobell; named after C.E. Zobell, a pioneer marine microbiologist.

Description as for the genus with the following additional characteristics. Grows in the presence of 1–10% NaCl. Produces chitinase.

The mol% G + C of the DNA is: 48 (T_m).

Type strain: KMM 231, ATCC BAA-313.

GenBank accession number (16S rRNA): AF052741.

Genus VII. **Marinobacter** *Gauthier, Lafay, Christen, Fernandez, Acquaviva, Bonin and Bertrand 1992, 574^VP^*

John P. Bowman and Thomas A. McMeekin

Mar.i′no.bac.ter. L. adj. *marinus* of the sea; Gr. n. *bacterion* rod or staff; M.L. masc. n. *Marinobacter* rod of the sea.

Rod-shaped cells 0.6–0.8 × 1.6–2.0 µm. Form surface blebs when grown on *n*-eicosane and other hydrocarbons. **Motile by a single polar flagellum. Gram negative.** Nonpigmented colonies. Aerobic with a strictly respiratory type of metabolism. Oxidase and catalase positive. **Can grow anaerobically by denitrification** coupled to the oxidation of a suitable donor carbon substrate. Chemoheterotrophic. Constitutive arginine dihydrolase system is absent. **Na^+ is required for growth. Halotolerant**, growing in 0.08–3.5 M NaCl. **Mesophilic** growing at temperatures 10–45°C. Organic acids, alcohols, amino acids, and hydrocarbons are used as carbon and energy sources. **Carbohydrates are not utilized.** Polysaccharides are not degraded. Type species produces a nondialyzable bioemulsifier when grown on hydrocarbons and is resistant to vibriostatic agent O/129. The major polyamine is spermidine. Isolated from oil brine. **Member of the** ***Gammaproteobacteria*.**

The mol% G + C of the DNA is: 53 (T_m).

Type species: **Marinobacter hydrocarbonoclasticus** Gauthier, Lafay, Christen, Fernandez, Acquaviva, Bonin and Bertrand 1992, 574.

Further descriptive information

Marinobacter hydrocarbonoclasticus is represented by a single strain (ATCC 49840). The cells do not accumulate poly-β-hydroxybu-

tyrate (PHB) inclusions or form spores or cysts. When cultivated on synthetic salt (SM) medium[1] containing the C_{20} alkane eicosane as a sole carbon source (SM-alkane medium), cells are covered by bleb-like extensions of the cell wall. Flagellation is lost when the strain is grown at Na^+ concentrations well above and below the optimal level - i.e., >1.0 M and <0.2 M NaCl.

On marine agar and SM-peptone (0.5% w/v) agar young colonies are white, circular, and convex, possessing entire edges and a creamy consistency. Colonies usually reach 2–4 mm after 7 d of incubation at 32°C. Older colonies develop a pinkish pigment probably due to accumulation of cytochromes. Diffusible and fluorescent pigments are not produced. The cells are not bioluminescent.

M. hydrocarbonoclasticus has an absolute requirement for Na^+ ions with an optimal growth level of 0.6 M NaCl. The requirement for Na^+ cannot be reversed by replacement of K^+ and Li^+ ions. The strain also exhibits considerable halotolerance and grows at NaCl levels of 0.08–3.5 M NaCl. When suspended in a solution containing 0.5 M NaCl and in the absence of Mg^{2+} ions, cells undergo severe hypotonic shock with the suspension losing about 60% of its optical density. When suspended or washed in the presence of Mg^{2+}, cell walls are considerably stabilized and show only limited, if any, hypotonic shock even if subsequently suspended in distilled water. Stability appears to be due to linking of Mg^{2+} ions between the anionic groups of membrane components (Rayman and MacLeod, 1975).

The optimal growth temperature is 32°C; range 10–45°C. The optimal pH is 7.0–7.5; range 6.0–9.5. The strain is nutritionally nonexacting and does not require growth factors. Nitrate and ammonia ions serve as nitrogen sources.

Cytochrome *c* oxidase and catalase are readily detectable in cell masses; however, cytochrome *aa3* oxidase and cytochrome P-450 appear to be completely absent. Cells can grow anaerobically with nitrate as electron acceptor and a suitable carbon source/electron donor such as citrate, acetate, or succinate. A variety of organic acids and hydrocarbons, such as eicosane and hexadecane, and a few amino acids can be used as carbon and energy sources. Lipase and lecithinase occur but the cells do not hydrolyze polysaccharides, gelatin, or DNA. A constitutive arginine dihydrolase system is absent.

The cells form a nondialyzable bioemulsifier when grown on hydrocarbons as sole sources of carbon and energy (Fernandez-Linares et al., 1996a). When grown on eicosane at various NaCl concentrations, ectoine is the major compatible solute in cells; however, ectoine is readily replaced by glycine betaine (Fernandez-Linares et al., 1996b). Glycine betaine reduces the growth rate at high Na^+ ion concentrations, possibly by interfering with eicosane metabolism as a consequence of decreased ectoine synthesis (Gauthier et al., 1997). *M. hydrocarbonoclasticus* has been shown to degrade 6,10,14-trimethylpentadecan-2-one, a common isoprenoid ketone found in marine sediment (Rontani et al., 1997).

Spermidine is the predominant polyamine constituent (Hamana, 1997), while the major phospholipids of cells include phosphatidylethanolamine, phosphatidylglycerol, and diphospatidylglycerol (Gerin and Goutx, 1993).

1. SM medium consists of (per liter): 30 g NaCl, 12.3 g Tris, 3.7 g NH_4Cl, 6.2 g $MgSO_4 \cdot 7H_20$, 1.5 g $CaCl_2$, and 0.75 g KCl. The pH of the medium is adjusted with 10 M HCl to 7.5. For solid media, agar (15 g/liter) can be added. SM-alkane medium consists of SM medium supplemented with 0.1% (w/v) alkane (eicosane, hexadecane etc.). SM-peptone medium consists of SM medium supplemented with 0.5% peptone.

Little is known about the broader ecology of the genus. The ability to degrade alkane hydrocarbons and broad halotolerance suggests the organisms are commonly associated with oil brines. A gradient diffusion chamber containing increasing levels of NaCl and *p*-toluate resulted in the enrichment of *M. hydrocarbonoclasticus*-like strains (identified as *Pseudomonas nautica*) (Emerson and Breznak, 1997). *M. aquaeolei* was isolated from the head of an offshore oil/gas platform (Nguyen et al., 1999). Several isolates from sea ice and seawater (Bowman et al., 1997c) have been found to be closely related to *M. hydrocarbonoclasticus* and include a variety of psychrophilic and psychrotrophic strains including a strain possessing gas vesicles (Gosink and Staley, 1995).

Enrichment and Isolation Procedures

M. hydrocarbonoclasticus can be isolated by enriching oil brine, seawater, and oil brine contaminated soil samples with SM-alkane liquid broth, which contains a long-chain alkane such as eicosane or hexadecane as the sole carbon and energy source. Enrichment flasks are shaken for several days at approximately 35°C. Growth from these cultures is serially diluted onto SM-alkane agar or marine agar for further purification. Subsequent testing of the traits presented in Table BXII.γ.141 should follow in order to confirm identity of the isolates.

M. aquaeolei VT8 was obtained from an enrichment culture incubated in a complex medium containing 10% NaCl (Nguyen et al., 1999).

Maintenance Procedures

M. hydrocarbonoclasticus can be maintained at −80°C in Marine 2216 broth containing a cyroprotectant agent such as 20–30% glycerol or dimethylsulfoxide. Strains can also be freeze-dried using 20% skim milk as a cyroprotectant. *M. aquaeolei* can be stored in 25% glycerol, 5% NaCl at –70°C (Nguyen et al., 1999).

Procedures for Testing Special Characters

Denitrification in *M. hydrocarbonoclasticus* can be determined by measuring accumulation of nitrous oxide during anaerobic growth with nitrate. The testing medium is SM supplemented with 0.1% acetate, 0.1% succinate, and 4 mM nitrate, and is prepared anaerobically using 100% nitrogen. Denitrification is halted by the addition of acetylene (10 kPa). Nitrous oxide levels are measured by gas chromatography (Bonin et al., 1987).

Differentiation of the genus *Marinobacter* from other genera

Marinobacter is most likely to be confused with nonfermentative Gram-negative, rod-shaped halophilic marine genera including *Halomonas*, *Marinomonas*, *Marinobacterium*, *Microbulbifer*, *Alteromonas*, *Pseudoalteromonas*, and *Shewanella*. The most useful traits available for differentiation of *Marinobacter* strains from these genera include the inability to utilize carbohydrates, or to degrade polysaccharides or gelatinase, the ability to denitrify, and broad halotolerance. Traits useful for differentiation of the genus from some other Gram-negative marine bacteria are presented in Table BXII.γ.141.

Taxonomic Comments

Only limited chemotaxonomic data are available for *M. hydrocarbonoclasticus*. However, the phenotypic traits of *Marinobacter*

are not particularly distinct and it possesses some similarity to species of several families of the *Gammaproteobacteria* including *Halomonadaceae* and *Alteromonadaceae*.

A phylogenetic analysis of *M. hydrocarbonoclasticus* ATCC 49840 using 16S rDNA sequence data indicated that its closest named relative is *Microbulbifer hydrolyticus*, a polysaccharide-degrading marine species (González et al., 1997). Spröer et al. (1998) later showed that *Pseudomonas nautica* is also very closely related to ATCC 49840 and proposed the transfer of *P. nautica* to *M. hydrocarbonoclasticus* (see below). The 6,10,14-trimethylpentadecan-2-one-degrading strain CAB and an isolate from an oil well (strain VT8) were also very closely related to ATCC 49840; Nguyen et al. (1999) have described strain VT8 as *Marinobacter aquaeolei*. Other strains whose 16S rDNA sequences were closely related to *Marinobacter* include a variety of isolates from Antarctic sea ice and under-ice seawater (Gosink and Staley, 1995; Bowman et al., 1997c) (Fig. BXII.γ.154). These strains share the inability to catabolize carbohydrates with *M. hydrocarbonoclasticus* but have other traits different from the current definition of *Marinobacter*: they are unable to reduce nitrate and are psychrophilic and stenohaline. These differences could be sufficient to support the description of a separate genus, closely related to *Marinobacter*.

16S rDNA sequence data (>99% similarity) provided compelling evidence that the species *Pseudomonas nautica* (Baumann et al., 1983b) is a subjective synonym of *M. hydrocarbonoclasticus*. In addition, Spröer et al. (1998) reported 100.8% hybridization of DNA from the type strains of *P. nautica* and *M. hydrocarbonoclasticus* in DNA–DNA hybridization experiments. Finally, the phenotypic similarities of *P. nautica* and *M. hydrocarbonoclasticus* (Table BXII.γ.142), including the ability to utilize a range of hydrocarbon alkanes (Monpert, 1996; Husain et al., 1997a, b) and active denitrification, provide a strong argument to support the transfer of *P. nautica* to *M. hydrocarbonoclasticus*. One initial discrepancy was a difference in the reported DNA base compositions. Reported values for the mol% G + C of the DNA of *P. nautica* were 57.8–61.1 (determined by buoyant density centrifugation; Baumann et al., 1972); these values were higher than the value of 52.7 reported for *M. hydrocarbonoclasticus* (determined by thermal denaturation; Gauthier et al., 1992). However, Spröer et al. (1998) analyzed DNA from the type strain of each species by HPLC and obtained values of 57.7 mol% G + C for *P. nautica* and 57.3% for *M. hydrocarbonoclasticus*. The mol% G + C of *M. aquaeolei* is 55.7 ± 0.1 (determined by HPLC; Nguyen et al., 1999).

TABLE BXII.γ.141. Phenotypic characterisitics differentiating the genus *Marinobacter* from other marine bacteria

Characteristic	*Marinobacter*	*Marinobacterium*	*Microbulbifer*	*Marinomonas*	*Oceanospirillum*
Morphology	Rod	Rod	Rod	Curved rods	Curved, helical
Na^+ requirement	+[a]	+	+	+	+

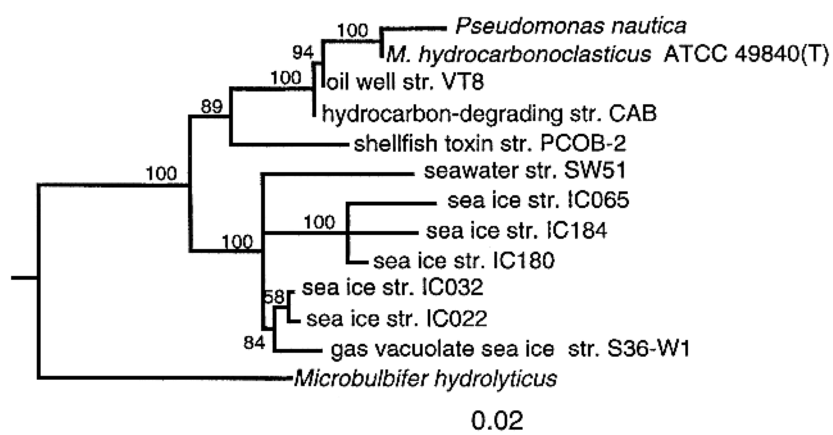

FIGURE BXII.γ.154. Phylogenetic tree of *Marinobacter hydrocarbonoclasticus* ATCC 49840, *Pseudomonas nautica* ATCC 27132, and close relatives based on nearly complete 16S rRNA sequences. The tree was determined using maximum likelihood distances and clustered by neighbor-joining. Strain VT8 has been described as *M. aquaeolei* (Nguyen et al., 1999; GenBank accession no. AJ000726). Various other strains on the tree remain unclassified, including hydrocarbon-degrading strain CAB (Rontani et al., 1997; U61848), shellfish toxin strain PCOB-2 (Maas et al., unpublished; AJ000647); under-ice seawater and sea ice strains SW51, IC065, IC180, IC184, IC032 and IC022 (Bowman et al., 1997c; AF001374, U85863-7); and a gas vacuolate sea ice strain S36-W1 (Gosink and Staley, 1995; U14584). Numbers at branch nodes are bootstrap values (calculated from 250 replicate analyses). Only bootstrap values over 50% are shown. Bar equals a distance of 0.02.

TABLE BXII.γ.142. Phenotypic characteristics of *Marinobacter hydrocarbonoclasticus* and *Pseudomonas nautica*[a,b,c]

Characteristic	*Marinobacter hydrocarbonoclasticus*	*Pseudomonas nautica*
Morphology	Rods	Rods
Flagella	Single polar or none	Single polar or none
Accumulation of poly-β-hydroxybutyrate	−	−
Optimal temperature for growth	32°C	35°C
Growth at 4°C	−	−
Growth at 45°C	+	d
NaCl requirement	+	+
Tolerates 20% NaCl	+	ND
Catalase, oxidase, denitrification	+	+
Hydrogen autotrophy	−	−
Arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase	−	−
Gelatin liquefaction	−	−

Tetradecane, heneicosane, pristane, phenyldecane, phenanthrene	+	ND

[a]Symbols: +, 80–100% of strains are positive; d, 20–80% of strains are positive; −, 0–20% of strains are positive; ND, no data.

[b]Phenotypic data from Gauthier et al. (1992) and Baumann et al. (1983b). *M. hydrocarbonoclasticus* and *P. nautica* do not utilize DL-arabinose, D-ribose, D-fructose, D-glucose, D-mannose, lactose, sucrose, cellobiose, D-mannitol, D-sorbitol, glycerol, D-gluconate, *N*-acetylglucosamine, glycolate, 2-oxoglutarate, *m*-hydroxybenzoate, *o*-hydroxybenzoate, DL-mandelate, propionate, L-arginine, L-asparagine, L-aspartate, glycine, L-lysine, L-methionine, L-ornithine, L-serine, DL-tryptophan, and sarcosine.

[c]In addition most strains of *P. nautica* (<20% positive) do not utilize D-xylose, D-fucose, L-rhamnose, D-galactose, trehalose, maltose, melibiose, saccharate, mucate, D-galacturonate, D-glucuronate, salicin, inulin, cellulose, agar, adonitol, *i*-erythritol, *m*-inositol, ethyleneglycol, methanol, isopropanol, geraniol, formate, oxalate, glutarate, pimelate, suberate, azelate, L(+)-tartrate, D(−)-tartrate, meso-tartrate, glycerate, aconitate, maleate, levulinate, citraconate, itaconate, mesaconate, benzoyl formate, phenylacetate, phenylethanediol, naphthalene, quinate, β-alanine, L-citrulline, L-isoleucine, L-leucine, L-norleucine, L-phenylalanine, L-threonine, L-tyrosine, L-valine, kynurenate, kynurenine, trigollenine, anthranilate, *m*-aminobenzoate, *p*-aminobenzoate, α-aminobutyrate, γ-aminobutyrate, δ-aminovalerate, methylamine, ethanolamine, benzylamine, tryptamine, butylamine, 1-amylamine, 2-amylamine, putrescine, spermine, betaine, creatine, histamine, hippurate, acetamide, pantothenate, nicotinate, nicotinamide.

List of species of the genus Marinobacter

1. **Marinobacter hydrocarbonoclasticus** Gauthier, Lafay, Christen, Fernandez, Acquaviva, Bonin and Bertrand 1992, 574[VP]
hy' dro.car.bo.no.clas.ti.cus. M.L. part. adj. *hydrocarbonoclasticus* hydrocarbonoclastic, hydrocarbon dismantler.

Phenotypic characteristics are described in the text and presented in Tables BXII.γ.141 and BXII.γ.142. Isolated from seawater of the Mediterranean Sea, near a petroleum refinery outlet, Gulf of Fos, France.

The mol% G + C of the DNA is: 53 (T_m); 57.3 (HPLC).

Type strain: SP.17, ATCC 49840, DSM 8798.

GenBank accession number (16S rRNA): X67022 (ATCC 49840).

2. **Marinobacter aquaeolei** Nguyen, Denner, Dang, Wanner and Stan-Lotter 1999, 373[VP]
a.quae.o' le.i. L. n. *aqua* water; L. n. *oleum* oil; M.L. gen. n. *aquaeolei* from water of oil, isolated from an oil-field brine.

Gram-negative motile rods (0.4–0.5 × 1.4–1.6 μm). Single polar flagellum. Nonsporeforming. Growth at 13–50°C, optimum 30°C; pH 5–10, optimum 7.3; and NaCl concentrations 0–20%; optimum 5%. Catalase and oxidase positive. Grows aerobically. Also grows anaerobically on acetate, citrate, and succinate when nitrate is present. Carbon and energy sources include acetate, L-alanine, butyrate, citrate, fumarate, L-glutamate, L-glutamine, L-isoleucine, DL-lactate, L-leucine, L-proline, and succinate. Degrades *n*-hexadecane, pristine, and some compounds in crude oil. Isolated from the head of an offshore oil/gas platform in southern Vietnam.

The mol% G + C of the DNA is: 55.7 ± 0.1 (HPLC).

Type strain: VT8, ATCC 700491, DSM 11845.

GenBank accession number (16S rRNA): AJ000726.

[a]For symbols, see standard definitions; nd, not determined.
[b]The species considered is *A. macleodii*.
[c]The species considered are *P. haloplanktis*, *P. espejiana*, *P. undina*, *P. rubra*, *P. luteoviolacea*, *P. citrea*, *P. aurantia*, *P. nigrifaciens*, and *P. denitrificans*, all of which were previously included in the genus *Alteromonas*.
[d]The species considered are *S. hanedai* and *S. colwelliana*, which were previously included in the genus *Alteromonas*.
[e]The species considered are *H. aquamarina*, *H. cupida*, *H. halophila*, *H. pacifica*, and *H. venusta*, all of which were previously included in the genus *Deleya*.
[f]The species considered are *M. communis* and *M. vaga*, which were formerly assigned to the genus *Alteromonas*.
[g] *Methylomicrobium pelagicum* was previously included in the genera *Methylomonas* and *Methylobacter*.
[h]The two species considered here are straight rods. All other species of *Oceanospirillum* are helical.
[i]Marine pseudomonads differ from terrestrial species by requiring over 75 mM NaCl for optimum growth rate and cell yield.
[j]Refers to strains previously classified as *P. perfectomarina* but shown to belong to *P. stutzeri* by DNA hybridization experiments.
[k]Coccoid cells occur in old cultures.
[l]Only one species, *P. undina*, is a curved rod. Long, filamentous helices, often exceeding 20 μm, occur when *S. colwelliana* grows on surfaces, in nutrient-poor media, or during late growth phases.
[m]*M. communis* is curved; *M. vaga* is straight.
[n]Some cells of *P. stutzeri* (*P. perfectomarina*) may be slightly curved.
[o]*S. colwelliana* utilizes α-ketoglutarate.
[p]*S. hanedai*, *S. colwelliana*, and some strains of *P. haloplanktis* are positive. *P. denitrificans* carries out denitrification with gas formation.
[q]*S. colwelliana* and some strains of *S. hanedai* are unable to use D-glucose.

Genus VIII. **Marinobacterium** *González, Mayer, Moran, Hodson and Whitman 1997, 375*[VP]

JOSÉ M. GONZÁLEZ

Ma.ri.no.bac.te′ri.um. L. adj. *marinus* of the sea; Gr. n. *bakterion* a small rod; M.L. neut. n. *Marinobacterium* small marine rod.

Rod-shaped cells, 0.5–0.7 × 1.6–2.3 µm. Motile by means of a single polar flagellum. Gram negative. Nonsporeforming and noncystforming. **Have a strictly aerobic type of metabolism with O_2 as the terminal electron acceptor.** Denitrification does not occur. Nonpigmented. **Oxidase and catalase positive. Sea salt-based medium is required for growth.** Chemoorganotrophic, growing on various sugars, fatty acids, aromatic compounds, and amino acids. C_1 compounds are utilized, such as methanol or formate. Vitamins, in the form of 0.005% yeast extract or a complex vitamin solution, are required for optimal growth.

The mol% G + C of the DNA is: 54.9.

Type species: **Marinobacterium georgiense** González, Mayer, Moran, Hodson and Whitman 1997, 375.

Further descriptive information

When the type strain is observed by electron microscopy and negative staining, the cells exhibit numerous blebs and vesicles on their surface, and an S layer composed of repeating units covers the surfaces of the blebs and vesicles. Poly-β-hydroxybutyrate is not accumulated.

Temperature range for growth, 4–41°C; optimum, 37°C. The NaCl range for growth is 0.01–2 M; optimum, 0.1–0.5 M.

The type strain contains the following major fatty acids: $C_{16:0}$, $C_{10:0\ 3OH}$, $C_{10:0}$, $C_{12:0}$, $C_{18:0}$, $C_{18:1\ \omega7c}$, $C_{18:1\ \omega9t}$, $C_{18:1\ \omega12t}$, $C_{16:1\ \omega7c}$, and $C_{15\ iso\ 2OH}$.

Enrichment and Isolation Procedures

The type strain was isolated from a marine enrichment community growing on the high molecular weight fraction of a black liquor sample from pulp mill effluent, which is rich in lignin, lignin byproducts, and other plant polymers in a smaller proportion (González et al., 1997). The original inoculum was from a salt marsh on the coast of Georgia, U.S.A. The enrichment medium consists of filter-sterilized seawater containing 5 µM NH_4NO_3, 1 µM KH_2PO_4, and the liquor fraction at a concentration of 20 mg/l. This medium is inoculated with cloudy, brown-green seawater from the salt marsh. Flasks are incubated aerobically with shaking. After enrichment, the organism is isolated on YTSS[1] agar plates incubated at room temperature.

Maintenance Procedures

The type strain is maintained in YTSS broth with 15% glycerol and 15% DMSO at −70°C. Lyophilized cultures are also used.

Differentiation of the genus *Marinobacterium* from other genera

Table BXII.γ.143 (see previous page) lists characteristics differentiating *Marinobacterium* from other aerobic marine bacteria. The NaCl requirement for growth excludes *Marinobacterium* from the family *Halomonadaceae* and the genus *Marinobacter*. The mol% G + C is different from values of members of the genera *Alcaligenes*, *Oceanospirillum*, *Marinomonas*, and *Microbulbifer*.

Taxonomic Comments

Based on 16S rRNA sequence analysis, *Marinobacterium* is related to *Pseudomonas*, *Oceanospirillum*, *Marinomonas*, *Microbulbifer*, *Halomonas*, and *Marinobacter*. However, the percent similarity with any of these genera is less than 90%, indicating that *Marinobacterium* is a distinct genus.

1. YTSS agar (g/l distilled water): yeast extract (Difco Laboratories, Detroit, MI, USA), 4.0; tryptone (Difco), 2.5; sea salts (Sigma Chemical Co., St. Louis, MO), 20; and agar, 18. YTSS broth is the same except that agar is omitted.

List of species of the genus Marinobacterium

1. **Marinobacterium georgiense** González, Mayer, Moran, Hodson and Whitman 1997, 375[VP]
geor.gi.en′se. L. adj. *georgiense* from Georgia, U.S.A., referring to the place where it was first isolated.

The description is as given for the genus and as given in Table BXII.γ.143. In addition, fimbriae are present and small capsules are produced.

Colonies on Marine Agar 2216 (Difco Laboratories, Detroit, Mich.) are translucent.

Growth occurs between pH 5.5 and 9.5; optimum, 7.5. The NaCl range for growth is 0.01–2.0 M, optimum, 0.1–0.5 M.

Growth occurs on the C_1 compounds methanol and formate, organic acids, monosaccharides, disaccharides, amino acids, and aromatic compounds. Included among the aromatic compounds are lignin-related compounds, such as *p*-coumarate, cinnamate, ferulate, and vanillate. Phenol, *p*-hydroxybenzoate, and benzoate are also metabolized.

Cellulose, chitin, gelatin, starch, agar, and xylan are not hydrolyzed.

The mol% G + C of the DNA is: 54.9 (HPLC).

Type strain: KW-40, ATCC 700074, CIP 105236, DSM 11526.

GenBank accession number (16S rRNA): U58339.

Genus IX. **Microbulbifer** *González, Mayer, Moran, Hodson and Whitman 1997, 375*[VP]

JOSÉ M. GONZÁLEZ

Mi.cro.bul′bi.fer. Gr. adj. *micro* small; L. masc. n. *bulbus* bulb; suff. *-fer* carrying, bearing; L. masc. n. *Microbulbifer* small bearer of bulbs.

Rod-shaped cells, 0.3–0.5 × 1.1–1.7 µm. Gram negative. Capsules are produced. Nonsporeforming and noncystforming. **Nonmotile.** Poly-β-hydroxybutyrate is not produced. Colonies are nonpigmented. **Possess a strictly aerobic type of metabolism with oxygen as the terminal electron acceptor.** Denitrification does not occur. **Oxidase and catalase positive. A sea salt-based medium**

is required for growth. Chemoorganotrophic, growing on sugars, fatty acids, aromatic compounds, and amino acids. Cellulose, xylan, chitin, gelatin, starch, and Tween 80 are hydrolyzed. Related to but outside the group of true *Pseudomonas* in the *Gammaproteobacteria*.

The mol% G + C of the DNA is: 57.6.

Type species: **Microbulbifer hydrolyticus** González, Mayer, Moran, Hodson and Whitman 1997, 375.

Further descriptive information

The cell envelope has numerous surface vesicles derived from the outer membrane.

Microbulbifer contains the following major fatty acids: $C_{15:0\ iso}$, $C_{17:1\ iso\ \omega 9c}$, $C_{11:0\ iso\ 3OH}$, $C_{11:0\ iso}$, $C_{17:0\ iso}$, $C_{15:0}$, $C_{17:1\ \omega 8c}$, $C_{17:0}$, $C_{18:1\ \omega 7c}$, $C_{18:1\ \omega 9t}$, $C_{18:1\ \omega 12t}$, $C_{16:1\ \omega 7c}$, and $C_{15\ iso\ 2OH}$.

Enrichment and Isolation Procedures

The type strain was isolated from a marine enrichment community growing on the high-molecular-weight fraction of a black liquor sample from pulp mill effluent, which is rich in lignin, lignin byproducts, and other plant polymers in a smaller proportion (González et al., 1997). The original inoculum was from a salt marsh on the coast of Georgia. The enrichment medium consists of filter-sterilized seawater containing 5 μM NH_4NO_3, 1 μM KH_2PO_4, and the liquor fraction at a concentration of 20 mg/l. This medium is inoculated with cloudy, brown-green sea water from the salt marsh. Flasks are incubated aerobically with shaking. After enrichment, the organism is isolated on YTSS[1] agar plates incubated at room temperature.

Maintenance Procedures

The type strain is maintained in YTSS broth with 15% glycerol and 15% DMSO at −70°C. Lyophilized cultures are also used.

Differentiation of the genus *Microbulbifer* from other genera

The NaCl requirement for growth excludes *Microbulbifer* from the family *Halomonadaceae* and the genus *Marinobacter*. The mol% G + C content of the DNA is different from that of members of the genera *Oceanospirillum*, *Marinomonas*, and *Marinobacter*. *Microbulbifer* is able to use a limited range of carbohydrates, in contrast to most *Pseudomonas* species. The fatty acid profile also differs from those of other bacteria. Among other characteristics, the fatty analysis reveals a low resemblance with *Marinobacterium*. Although the characteristics of *Microbulbifer* are very similar to those of *Alteromonas*, the mol% G + C is outside the range of this genus.

Taxonomic Comments

Based on its 16S rRNA sequence, besides *Pseudomonas*, other closely related bacteria are the marine genera *Oceanospirillum*, *Marinomonas*, *Marinobacterium*, *Halomonas*, and *Marinobacter*.

1. YTSS agar (g/l distilled water): yeast extract (Difco Laboratories, Detroit, MI, USA), 4.0; tryptone (Difco), 2.5; sea salts (Sigma Chemical Co., St. Louis, MO), 20; and agar, 18. YTSS broth is the same except that agar is omitted.

List of species of the genus Microbulbifer

1. **Microbulbifer hydrolyticus** González, Mayer, Moran, Hodson and Whitman 1997, 375[VP]

hy.dro.ly′ ti.cus. Gr. n. *hydor* water; Gr. adj. *lyticus* dissolving, splitting; M.L. adj. *hydrolyticus* splitting with water, referring to the hydrolytic activity of the bacterium.

Cells are rod shaped, 0.3–0.5 × 1.1–1.7 μm. Cells appear as single cells or short chains. In medium with xylan or viscous medium, they form long chains. They do not possess flagella. An S layer is present. Capsules are produced in liquid media. Polyhydroxybutyrate is not produced.

Colonies on marine agar 2216 are circular, convex with entire margins, and cream colored.

Growth occurs between pH 6.5 and 8.5; optimum, 7.5. The temperature range for growth is 10–41°C; optimum, 37°C. Sea salt-based medium is required for growth. The NaCl range for growth is 0.1–1.0 M; optimum, 0.1–0.5 M. Vitamins are required for optimal growth.

Growth occurs on organic acids, amino acids, and a few monosaccharides, disaccharides, and aromatic compounds (glucose, xylose, *N*-acetyl-D-glucosamine, cellobiose, vanillate, and ferulate). Cellulose, xylan, chitin, gelatin, starch, and Tween 80 are hydrolyzed. This species has been found by oligonucleotide probes to be numerically dominant in a pulp mill effluent enrichment community containing only bacteria.

The mol% G + C of the DNA is: 57.6 (HPLC).

Type strain: IRE-31, ATCC 700072; CIP 105235, DSM 11525.

GenBank accession number (16S rRNA): U58338.

Genus X. **Moritella** *Urakawa, Kita-Tsukamoto, Steven, Ohwada and Colwell 1999b, 341*[VP] *(Effective publication: Urakawa, Kita-Tsukamoto, Steven, Ohwada and Colwell 1998, 376)*

The Editorial Board

Mo.ri.tel′ la. M.L. dim. *-ella* ending; M.L. fem. n. *Moritella* named after Richard Y. Morita to honor his work in marine microbiology.

Gram-negative, chemoorganotrophic, facultatively anaerobic motile rods. Polar flagella. **Halophilic.** Catalase and oxidase positive. Voges–Proskauer negative. Negative for production of indole and H_2S. Do not produce arginine dihydrolase or ornithine decarboxylase. Produce acid from D-glucose. Utilize *N*-acetyl glucosamine.

The mol% G + C of the DNA is: 40–45.

Type species: **Moritella marina** (Baumann, Furniss and Lee 1984c) Urakawa, Kita-Tsukamoto, Steven, Ohwada and Colwell

1999b, 341 (Effective publication: Urakawa, Kita-Tsukamoto, Steven, Ohwada and Colwell 1998, 376) (*Vibrio marinus* Baumann, Furniss and Lee 1984c, 356.)

Further descriptive information

The genus *Moritella* includes four species; all inhabitants of marine environments. *M. marina* was isolated from fish skin, seawater, and marine sediment (Colwell and Morita, 1964; Urakawa et al., 1998). *Moritella japonica*, which is barotolerant, was obtained from sediments from the Japan Trench at a depth of 6,356 m (Nogi et al., 1998a). *M. yayanosii*, which requires pressures of 50 MPa or greater, was obtained from sediments from the Mariana Trench at a depth of 10,898 m (Nogi and Kato, 1999a).

M. viscosa is an etiologic agent of the disease "winter ulcer" in Atlantic salmon (*Salmo salar*) and may cause skin disease in other species of fish (Lunder et al., 2000).

Analysis of 16S rDNA sequences placed the genus *Moritella* in the *Gammaproteobacteria* (Urakawa et al., 1998).

Enrichment and Isolation Procedures

Sampling and isolation procedures for *Vibrio marinus* (*Moritella marina*) from seawater are described by Colwell and Morita (1964).

Moritella japonica and *Moritella yayanosii* were isolated by diluting bottom mud sediments in Marine Broth 2216™ (Difco) and incubating at 4–15°C either at atmospheric pressure or in a pressurized vessel (Kato et al., 1995; Nogi et al., 1998a; Nogi and Kato, 1999a).

Moritella viscosa can be isolated from tissue samples on blood agar made 0.5–2.0% in NaCl as described by Lunder et al. (1995).

Maintenance Procedures

Media and conditions for maintenance of *Vibrio marinus* (*Moritella marina*) are described by Colwell and Morita (1964).

Moritella japonica and *Moritella yayanosii* can be maintained on Marine Agar 2216™ (Difco) with incubation at 4–15°C either at atmospheric pressure or in a pressurized vessel as appropriate (Kato et al., 1995; Nogi et al., 1998a; Nogi and Kato, 1999a).

Moritella viscosa strains can be maintained at 4°C on Difco brain–heart infusion agar made 2% in NaCl or on Difco Marine Agar 2216™; long-term storage can be achieved at –80°C in brain–heart infusion broth made 2% in NaCl and 30% in glycerol or in Marine Agar 2216™ made 10% in glycerol (Benediktsdøttir et al., 2000; Lunder et al., 2000).

Differentiation of the genus *Moritella* from other genera

Tables of phenotypic characteristics that differentiate *Moritella* from species of the genera *Shewanella* and *Vibrio* are available (Nogi et al., 1998a; Nogi and Kato, 1999a; Lunder et al., 2000).

Differentiation of the species of the genus *Moritella*

Nogi et al. (1998a), Nogi and Kato (1999a), and Lunder et al. (2000), provide tables of phenotypic characteristics that differentiate *Moritella* species from each other.

List of species of the genus Moritella

1. **Moritella marina** (Baumann, Furniss and Lee 1984c) Urakawa, Kita-Tsukamoto, Steven, Ohwada and Colwell 1999b, 341^{VP} (Effective publication: Urakawa, Kita-Tsukamoto, Steven, Ohwada and Colwell 1998, 376) (*Vibrio marinus* Baumann, Furniss and Lee 1984c, 356)
ma.ri′ na. L. fem. adj. *marina* marine, of the sea.

Description as for the genus with the following additional characteristics. Nitrate reduced to nitrite. Optimum growth temperature 18°C. Major fatty acids $C_{14:0}$, $C_{16:0}$, $C_{16:1}$, $C_{22.6}$.
The mol% G + C of the DNA is: 42.2 (T_m).
Type strain: ATCC 15381, CIP 102861, NCCB 79030, NCIMB 1144.
GenBank accession number (16S rRNA): AB038033, X82142.

2. **Moritella japonica** Nogi, Kato and Horikoshi 1999, 341^{VP} (Effective publication: Nogi, Kato and Horikoshi 1998a, 294.)
ja.pon.i′ ca. L. gen. n. *japonica* named after the Japan Trench, where this strain originated.

Description as for the genus with the following additional characteristics. Psychrophilic (growth optimum 10–15°C) and halophilic (growth optimum 3% NaCl). Able to grow both at atmospheric pressure and at pressures up to 70 MPa. Nitrate reduced to nitrite. Lysine decarboxylase produced. Acid produced from glycerol. Major fatty acids $C_{14:0}$, $C_{16:0}$, $C_{16:1}$, $C_{22:6}$.
The mol% G + C of the DNA is: 45 (HPLC).
Type strain: DSK1, CIP 106291, JCM 10249.
GenBank accession number (16S rRNA): D21224.

3. **Moritella viscosa** (Lunder, Sørum, Holstad, Steigerwalt, Mowinckel and Brenner 2000) Benediktsdøttir, Verdonck, Sproer, Helgasön and Swings 2000, 487^{VP} (*Vibrio viscosus* Lunder, Sørum, Holstad, Steigerwalt, Mowinckel and Brenner 2000, 447.)
vis.co′ sa. L. fem. adj. *viscosa* viscous, because of its thread-forming, adherent colonies.

Description as for the genus with the following additional characteristics. Requires 1–4% NaCl. Lysine decarboxylase produced. Hydrolysis of casein, DNA, gelatin, lecithin, starch (19 of 20 strains), Tween 80, and urea. Acid produced from D-galactose.
The mol% G + C of the DNA is: 42.5 (T_m).
Type strain: NVI 88/478, ATCC BAA-105, NCIMB 13584.
GenBank accession number (16S rRNA): Y17574.

4. **Moritella yayanosii** Nogi and Kato 1999b, 1325^{VP} (Effective publication: Nogi and Kato 1999a, 76.)
ya.ya.nos.i′ i. M.L. gen. n. *yayanosii* in honor of American deep-sea biologist Aristides Yayanos.

Description as for the genus with the following additional characteristics. Cannot grow at pressures less than 50 MPa; able to grow at pressures up to 100 MPa. Requires NaCl. No reduction of nitrate or nitrite. Major fatty acids $C_{14:0}$, $C_{16:0}$, $C_{16:1}$, $C_{22.6}$.
The mol% G + C of the DNA is: 44.6 (HPLC).
Type strain: DB21MT-5, JCM 10263.
GenBank accession number (16S rRNA): AB008797.

Genus XI. **Pseudoalteromonas** *Gauthier, Gauthier and Christen 1995a, 759^VP*

JOHN P. BOWMAN AND THOMAS A. MCMEEKIN

Pseu.do.al.te.ro.mo'nas. Gr. adj. *pseudes* false; M.L. n. *Alteromonas* the genus *Alteromonas*; M.L. n. *Pseudoalteromonas* false *Alteromonas*.

Straight rods, approximately 1 × 2–3 μm, occurring singly or in pairs. Do not form spores or cysts. Do not accumulate poly-β-hydroxybutyrate. Nonbioluminescent. **Gram negative**. **Motile by means of a single polar flagellum**, either unsheathed or sheathed. Colonies are nonpigmented or pigmented. **Chemoheterotrophic. Aerobic, possessing a strictly respiratory type of metabolism** with oxygen as the terminal electron acceptor. No growth occurs anaerobically. A constitutive arginine dihydrolase system is usually absent. One species (*P. denitrificans*) is able to denitrify. Utilize a range of carbon substrates, including carbohydrates, alcohols, organic acids, and amino acids. Form gelatinase and lipase. Ammonia serves as a nitrogen source. Amino acids may be required by some strains for growth. **Requires Na^+ ions for growth.** Mostly psychrotolerant, with growth occurring between 0 and 40°C. Several species produce autotoxic antibiotic compounds. Isolated from seawater, sediment, sea ice, surfaces of stones, marine algae, marine invertebrates, and salted foods. The major quinone is ubiquinone-8 (Q-8). Major fatty acids are $C_{16:0}$, $C_{16:1\ \omega7c}$, $C_{17:1\ \omega8c}$, and $C_{18:1\ \omega7c}$. Member of the order *Alteromonadales*, family *Alteromonadaceae*, in the *Gammaproteobacteria*.

The mol% G + C of the DNA is: 38–48 (T_m).

Type species: **Pseudoalteromonas haloplanktis** (Zobell and Upham 1944) Gauthier, Gauthier and Christen 1995a, 759 (*Alteromonas haloplanktis* (Zobell and Upham 1944) Reichelt and Baumann 1973a, 438; *"Vibrio haloplanktis"* Zobell and Upham 1944, 261.)

FURTHER DESCRIPTIVE INFORMATION

Motility Sheathed flagella occur on cells of *P. denitrificans* (Enger et al., 1987), *P. luteoviolacea* (Novick and Tyler, 1985), and *P. piscicida* (Hansen et al., 1963, 1965). Cells occasionally form three or more polar flagella. Older cultures often exhibit significantly reduced levels of motile cells, and filamentous cells and involution bodies often occur.

Cultural characteristics Colonies on Difco Marine 2216 agar are typically circular and convex, possessing an entire edge and a creamy or mucoid consistency. Colonies are nonpigmented or pigmented with noncarotenoid type pigments. When growing on tyrosine-containing media, some species form black-brown, melanin-like pigments (Table BXII.γ.144). In some instances, such as in the type strain of *P. nigrifaciens* (ATCC 27126), melanin production occurs constitutively on complex media. *P. citrea, P. aurantia*, and *P. piscicida* form yellow or orange pigments. Spectral and preliminary chemical analyses of the pigments of *P. piscicida* suggest the pigments are pteridine derivatives (Weeks et al., 1962). Both *P. rubra* and *P. denitrificans* form bright red prodigiosin-type pigments. When *P. denitrificans* is grown on protamine or L-glutamine, the color of cultures changes from red to bright purple or blue (Enger et al. 1987). Strains of *P. luteoviolacea* form violet colonies owing to accumulation of violacein and can simultaneously form yellow pigments, giving colonies an unusual and characteristic appearance (Gauthier, 1982).

Pseudoalteromonas are either psychrotrophic or mesophilic. No psychrophilic strains, however, have been isolated, even from the cold-water and sea-ice environments of the Antarctic (Bozal et al., 1997; Bowman, 1998).

Antibiotic production Most pigmented and a few nonpigmented *Pseudoalteromonas* strains have the ability to form antibiotic substances. The red pigment of *P. denitrificans*, identified as cycloprodigiosin hydrochloride, has been shown to suppress T-cell proliferation and has been proposed as a immunosuppressant therapeutic agent. Cycloprodigiosin hydrochloride apparently selectively uncouples proton translocation from the ATPase reaction (Kawauchi et al., 1997). Strains of *P. citrea, P. aurantia, P. rubra*, and *P. luteoviolacea* form autotoxic, high-molecular-weight polyanionic substances (70–100 kDa in size), which can inhibit Gram-negative and Gram-positive bacteria (Gauthier, 1976b; Gauthier and Flatau, 1976; Ballester et al., 1977). Analysis of the agent produced by *P. rubra* indicates it is an outer membrane glycoprotein of complex composition (Ballester et al., 1977). *P. citrea* produces two different proteinaceous components, as determined by electrophoretic profiles (Gauthier, 1977). The mode of action of these agents involves inducing an increase in the rate of oxygen consumption in susceptible bacteria, leading to lethal cell damage due to accumulation of oxygen free radicals (Gauthier, 1976b). In addition to this, *P. luteoviolacea* can form a variety of low-molecular-weight brominated compounds, including pentabromopseudilin, which are bacteriolytic (Gauthier and Flatau, 1976; Sakata et al., 1982, 1986; Hanefeld et al., 1994). *P. haloplanktis* forms an unusually bioactive iron siderophore, bisucaberin, which is able to block DNA synthesis in tumor cells and induce macrophage-mediated cytolysis (Kameyama et al., 1987; Takahashi et al., 1987). Siderophore production by *Pseudoalteromonas* strains is thought to give an advantage in the marine environment, where iron often is very scarce (Reid and Butler, 1991; Reid et al., 1993). The ability of *Pseudoalteromonas* to produce antibiotics may have some unexpected advantages; for example, some strains of *P. haloplanktis* produce a heat-labile, proteinaceous compound able to inhibit various pathogenic *Vibrio* species, which has been proposed as a probiotic agent to protect reared scallops and oyster larvae (Riquelme et al., 1996).

The exact scope, ecological role, mechanisms, and ecological impact of antibiotic production by *Pseudoalteromonas* are under increasing investigation. Obviously, antibiotic production would help *Pseudoalteromonas* species effectively compete for potentially scarce nutrients by inhibiting other marine bacteria. Another possible role is that they act as chemical barriers to predation; for example, various marine biota have been observed to possess coats of pigmented, aerobic, rod-shaped bacteria, which produce bioactive substances (Fenical, 1993). *Pseudoalteromonas* strains, however, also have an aggressive role in the marine food chain and are able to kill various types of toxic "red-tide" dinoflagellates and raphidiophytes (such as *Gymnodinium* and *Chatonella* species) using uncharacterized, proteinaceous, secreted substances (Imai et al., 1995; Lovejoy et al., 1998). *P. piscicida* has been claimed to produce a neuromuscular toxin, which is able to kill a variety of fish and crab species (Bein, 1954; Meyers et al., 1959; Hansen et al., 1965). In addition, *P. haloplanktis* subsp. *tetraodonis* can apparently form tetrodotoxin, an exceptionally potent neurotoxin that has been isolated from the puffer fish (*Fugu poecilonotus*), from which this subspecies was first described (Yasumoto

[a]For symbols see standard definitions; nd, not determined.

et al., 1986; Simidu et al., 1987, 1990; Gallacher and Birkbeck, 1993). *Pseudoalteromonas* spp. are generally not pathogenic; however, *P. haloplanktis* may cause disease in oysters (Colwell and Sparks, 1967) and the red-spot disease of the seaweed *Laminaria japonica* (Ezura et al., 1988a, b; Sawabe et al., unpublished).

Sodium ion requirement All *Pseudoalteromonas* species require Na^+ ions for growth; the minimal levels vary somewhat, but are usually in the range of 20 mM. Studies have shown that the Na^+ requirement cannot be replaced by supplying K^+ ions but can be partially reduced in some strains by supplying seawater levels of Ca^{2+}, Na^{2+}, and Mg^{2+} (Thompson et al., 1970; Thompson and MacLeod, 1973). Na^+ is necessary for the activity of cellular uptake systems in *Pseudoalteromonas*, including the transport of amino acids, tricarboxylic acid intermediates, galactose, orthophosphate, and K^+ (MacLeod, 1968; Fein and MacLeod, 1975; Droniuk et al., 1987; MacLeod and MacLeod, 1992). Na^+ ions are also necessary for maintaining the integrity of the cell wall (Forsberg et al., 1970). Most nonpigmented *Pseudoaltero-*

monas species demonstrate some degree of halotolerance and can grow at NaCl concentrations of 9–12%. Strains of *P. prydzensis* can even tolerate NaCl levels of 15–20% (Bowman, 1998). Pigmented species appear to be more stenohaline in nature, with the exception of *P. piscicida*.

Metabolism *Pseudoalteromonas* species are strictly aerobic chemoheterotrophs using a respiratory metabolism with oxygen as the electron acceptor. *P. denitrificans* is able to grow microaerobically by denitrification (Enger et al., 1987), while some strains of *P. haloplanktis* and *P. atlantica* can reduce nitrate to nitrite. A constitutive arginine dihydrolase system is generally absent. Glucose and fructose are assimilated by an inducible Entner–Doudoroff pathway (Sawyer et al., 1977a). All strains possess cytochrome *c* oxidase activity. Catalase activity is usually present, though it may be weakly expressed or absent in certain pigmented species. *P. luteoviolacea* and *P. rubra* possess peroxidase (H_2O_2 oxidoreductase) instead of catalase (Gauthier, 1976a, 1982). The following tests have been found to be negative for all tested species: lysine decarboxylase, ornithine decarboxylase, tryptophan deaminase, phenylalanine deaminase, indole production from tryptophan, fermentation of D-glucose, methyl red test, anaerobic growth with nitrate as the electron acceptor, and sensitivity to vibriostat agent O/129.

Nutrition *Pseudoalteromonas* strains grow well on marine 2216 agar and similar seawater media. Though most strains can use ammonia as a sole nitrogen source, some species, in particular the pigmented species, require amino acids for growth. For these strains, growth in defined media can be achieved by the addition of individual amino acids (Baumann et al., 1984a, c) or by addition of low levels of yeast extract or casein hydrolysate (0.1–0.5% w/v). Media useful for growing *Pseudoalteromonas* species are given in the section on the genus *Alteromonas*.

Pseudoalteromonas species can utilize a range of organic compounds as sole carbon and energy sources, including carbohydrates, alcohols, and amino acids. Pigmented species in general tend to be less nutritionally versatile than the nonpigmented species. *Pseudoalteromonas* species also have the ability to degrade a range of macromolecules. Most species can degrade gelatin, casein, starch, and DNA, and can form a lipase. Several species possess chitinolytic and alginolytic activity. *P. atlantica* possesses a type I β-agarase, the gene for which has been cloned, sequenced, and overexpressed in *Escherichia coli* (Belas, 1989). *P. citrea* may also form agarases (Ivanova et al., 1998), and *P. carrageenovora* possesses the unusual ability to degrade κ-carrageenan (Yaphe and Baxter, 1955) by means of a β-1,3-1,4-glucanase-like κ-carrageenase (Barbeyron et al., 1994). The amylase from *P. haloplanktis* strain A23 is cold adapted and thermolabile (Feller et al., 1992). *P. undina* synthesizes an efficient organophosphorus acid anhydrolase (Cheng et al., 1993).

Genetic characteristics The genome structure of *P. haloplanktis* is complex. Analysis by restriction digestion and pulsed-field gel electrophoresis has detected the presence of two genetic units, one with a length of 2.7 Mb and a second replicon with a length of 0.8 Mb (Lanoil et al., 1996).

Lipids, quinones, polyamines The major fatty acids in *Pseudoalteromonas* include $C_{15:0}$ (2–9%), $C_{15:1\ \omega8c}$ (1–7%), $C_{16:0}$ (18–34%), $C_{16:1\ \omega7c}$ (35–50%), $C_{17:1\ \omega8c}$ (1–13%), and $C_{18:1\ \omega7c}$ (1–9%) (Monteoliva-Sanchez and Ramos-Cormenzana, 1987; Matsui et al., 1991; Svetashev et al., 1995; Bozal et al., 1997; Bowman, 1998). So far, fatty acid characterization has been done only for some of the nonpigmented species. In any case, the profiles are so similar to that of *Alteromonas macleodii* that neural network analysis cannot tell the difference (Bertone et al., 1996). The major isoprenoid quinone is ubiquinone-8 (Q-8, 84–100%), with smaller amounts of Q-6 (0–9%), Q-7 (0–6%), and Q-9 (0–15%) present (Akagawa-Matsushita et al., 1992b). The major cellular polyamines in *Pseudoalteromonas* include putrescine, cadaverine, and spermidine (Hamana, 1997). Some species of *Pseudoalteromonas* synthesize unusual acidic exopolysaccharides (Gorshkova et al., 1993, 1997; Bozal et al., 1994).

Ecology Due to the relatively limited scope of individual studies and often inadequate identification of isolates, it is difficult to obtain a precise idea of how widely distributed each *Pseudoalteromonas* species is. However, strong evidence indicates the genus is common and widespread in the marine ecosystem, with strains isolated from coastal and estuarine seawater, organic detritus, deep water, benthic sediments, sea ice, surfaces of marine fauna and flora, aquaculture systems, and salterns (Kakimoto et al., 1980; Gavrilovic et al., 1982; Sakata et al., 1982; Austin, 1982; Kameyama et al., 1987; Lemos et al., 1985; Nair and Simidu, 1987; Nissen, 1987; Oliver, 1987; Ezura et al., 1988a; del Moral et al., 1988; Nair et al., 1988; Noble et al., 1990; Gauthier and Breittmayer, 1992; Bozal et al., 1994, 1997; Ortigosa et al., 1994; Uchida et al., 1997; Yoshikawa et al., 1997; Bowman, 1998). In addition, strains of *Pseudoalteromonas nigrifaciens* have also been isolated from various salted food products, including butter, from which it was originally described (White, 1940). *P. haloplanktis* seems to have a very wide distribution, having been isolated from all major oceans, save for the polar regions (Gauthier and Breittmayer, 1992). *P. antarctica* appears to be very common in the Antarctic marine environment and is one of the most common isolates from seawater and sea ice (Bozal et al., 1997; Bowman et al., 1997a; Bowman, 1998). Pigmented species are often very sensitive to UV irradiation, thus affecting potential isolation sites (Gauthier and Breittmayer, 1992; Enger et al., 1987).

Enrichment and Isolation Procedures

The isolation of specific *Pseudoalteromonas* species is dependent on recognition of certain obvious phenotypic properties, especially pigmentation (Gauthier and Breittmayer, 1992). In most instances, special enrichment or selection conditions for *Pseudoalteromonas* species are not available, and the organisms usually can only be directly isolated from suitable source material onto marine agar or BMA supplemented with 0.1–0.2% concentration of a particular carbon source that is utilized by the species in question. Certain species have been isolated by enrichment, including *P. denitrificans*, which was isolated from a medium containing L-arginine and L-glutamine as sole carbon and nitrogen sources (Enger et al., 1987). Antibiotic production of colonies on isolation plates can be used to screen for antibiotic-producing *Pseudoalteromonas* species by means of the replica plating procedure (Smibert and Krieg, 1994), as described by Gauthier and Breittmayer (1992). For more details on methods useful in isolating *Pseudoalteromonas* species, see Gauthier and Breittmayer (1992).

Maintenance Procedures

Most nonpigmented strains can be stored on marine agar plates or slants at 2–5°C for several months before subculturing is necessary. Pigmented strains, however, often produce autotoxic antibiotic compounds and so need to be transferred at least once

per week. *Pseudoalteromonas* strains can be successfully stored for several years as dilute suspensions in sterile, unsupplemented seawater at 7–8°C (Enger et al., 1987). They can also be preserved by freeze-drying with 20% skim milk as a cryoprotectant or by freezing in liquid nitrogen or in a −80°C freezer with 20–30% glycerol as a cryoprotectant.

Differentiation of the genus *Pseudoalteromonas* from other genera

Characteristics differentiating the genus *Pseudoalteromonas* from other members of the family *Alteromonadaceae* are shown in Table BXII.γ.135 of the chapter describing the family. Nonpigmented *Pseudoalteromonas* species are most likely to be confused with the genus *Alteromonas*, with which they share many phenotypic and chemotaxonomic similarities. In broad terms, *Pseudoalteromonas* species can be distinguished by their ability to grow at 4°C and inability to utilize a number of carbon substrates. These few phenotypic traits seem inadequate, but until a wider knowledge of the phenotypic differences between these genera are available, the only other effective methods for the conclusive identification are 16S rDNA sequencing, DNA–DNA hybridization, and rRNA–DNA hybridization.

Taxonomic Comments

Pseudoalteromonas was created to accommodate most of the former *Alteromonas* species that comprise a phylogenetic clade distinct from *Alteromonas macleodii* (van Landschoot and De Ley, 1983; Kita-Tsukamoto et al., 1993; Gauthier et al., 1995a). *Pseudoalteromonas piscicida*, previously classified as *"Pseudomonas piscicida"* (Buck et al., 1963), was also included in the new genus (Gauthier et al., 1995a).

More specifically, both rRNA–DNA hybridization and 16S rDNA sequencing studies (Kita-Tsukamoto et al., 1993; Gauthier et al., 1995a) indicate *Pseudoalteromonas* species comprise a relatively tight clade adjacent to the genus *Alteromonas*. Fig. BXII.γ.155 shows a phylogenetic tree based on 16S rDNA sequences for *Pseudoalteromonas*. One interesting feature is the high sequence similarity shared by the nonpigmented species; indeed, six species possess sequences that diverge less than 2%—well within the potential estimated range of sequence divergence for a single species (Stackebrandt and Goebel, 1994). *P. prydzensis* is an outlier of this group. The pigmented species show a greater divergence in sequence than do the nonpigmented species, except for *P. citrea* and *P. aurantia*, which are very closely related.

DNA–DNA (Akagawa-Matsushita et al., 1993) and rDNA–DNA hybridization (van Landschoot and De Ley, 1983) results confirm the very close relatedness of the nonpigmented strains. Overall $T_{m(e)}$ values range from 74.0–77.5°C, while DNA–DNA hybridization values range from 30–60%. *P. piscicida* has a $T_{m(e)}$ of 71.5°C, which corresponds with its more distinct phylogenetic position. On the basis of DNA–DNA hybridization data, Ivanova et al. (1998) have indicated that the species *Alteromonas distincta* (Romanenko et al., 1995b) and *Alteromonas elyakovii* (Ivanova et al., 1996b) are closely related to *P. nigrifaciens* (sharing 40–50% DNA hybridization) while *Alteromonas fuliginea* (Romanenko et al., 1994) is a junior subjective synonym of *P. citrea*.

Several strains are novel, yet to be described, species, based on their phylogenetic positions (Fig. BXII.γ.155). Various sea-ice and under-ice seawater strains (strains IC006, IC013, MB6-03, MB6-05, MB8-02, SW08, and SW29) are distributed throughout the nonpigmented *Pseudoalteromonas* clade; however, based on phenotypic data and DNA hybridization, they are closely related to *P. antarctica* (Bowman, 1998; unpublished data).

Several melanin-producing strains isolated from marine fauna from the eastern Russian-Pacific area have been described as *Alteromonas* species. These include *A. fuliginea* (Romanenko et al., 1994), *Alteromonas distincta* (Romanenko et al., 1995b), and *A. elyakovii* (Ivanova et al., 1996b). Subsequent analysis by DNA–DNA hybridization now indicates that these species have a closer allegiance to the genus *Pseudoalteromonas*, with *A. fuliginea* being a junior subjective synonym of the species *P. citrea* (Ivanova et al., 1998). Because these species do not have their generic positions officially established yet, they have been listed as *Species Incertae Sedis*.

Differentiation of the species of the genus *Pseudoalteromonas*

Characteristics distinguishing *Pseudoalteromonas* species are presented in Table BXII.γ.144. Considerable variation in carbon-source utilization patterns is evident within some species. This may be due to differences in testing procedures, because carbon source results sometimes differ significantly among different studies; examples include the results for the type strains of *P. haloplanktis* subsp. *tetraodonis* (Simidu et al., 1990; Akagawa-Matsushita et al., 1992b) and *P. nigrifaciens* (Baumann et al., 1984a; Akagawa-Matsushita et al., 1992b; Ivanova et al., 1996a). The carbon source data shown in Tables BXII.γ.144 and BXII.γ.145 should therefore be treated with some degree of caution.

List of species of the genus Pseudoalteromonas

1. **Pseudoalteromonas haloplanktis** (Zobell and Upham 1944) Gauthier, Gauthier and Christen 1995a, 759[VP] (*Alteromonas haloplanktis* (Zobell and Upham 1944) Reichelt and Baumann 1973a, 438; *Vibrio haloplanktis* Zobell and Upham 1944, 261.)
ha.lo.plank' tis. Gr. n. *halos* sea; Gr. adj. *planktos* wandering; M.L. adj. *haloplanktis* sea-wandering.

Cells are rod-shaped, 0.8–1.2 × 1.8–3.0 μm. Colonies are nonpigmented, smooth, and convex, with an entire edge. Sodium ions are required for growth. Growth factors (amino acids) are usually not required for growth. Grows between 10°C and 35°C, with optimum growth occurring at approximately 30°C. Some strains may grow at 4°C. Other characteristics are shown in the genus description and in Tables BXII.γ.144 and BXII.γ.145. Strains utilize D-mannose, citrate, and aconitate, but do not hydrolyze alginate or utilize L-malate, isovalerate, caproate, or L-lysine.

Isolated from seawater.

The mol% G + C of the DNA is: 41–45 (T_m).

Type strain: 545, ATCC 14393, DSM 6060, NCIMB 2084.

GenBank accession number (16S rRNA): X67024; X82143.

2. **Pseudoalteromonas antarctica** Bozal, Tudela, Rosselló-Mora, Lalucat and Guinea 1997, 350.[VP]
ant.arc' ti.ca. L. adj. *antarcticus* southern (in this instance pertaining to the Antarctic environment, where the organism was isolated).

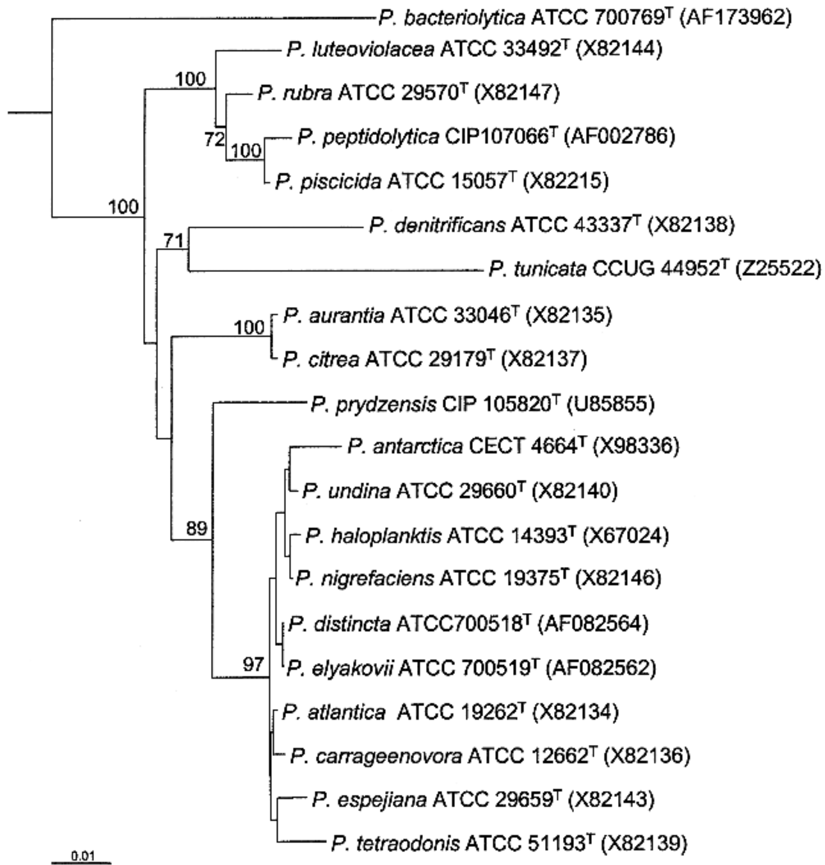

FIGURE BXII.γ.155. Phylogenetic tree of the genus *Pseudoalteromonas* based on nearly complete 16S rRNA sequences, including species validly published as of 2000–2001. The tree was determined using maximum-likelihood distances and clustered by neighbor-joining. Numbers at branch nodes are bootstrap values (calculated from 250 replicate analyses). Only bootstrap values over 50% are shown. *T* denotes a type strain. Bar = distance of 0.01. Numbers in brackets denote GenBank accession codes.

Cells are straight and rod-like, 0.5–0.9 × 0.7–3 μm. Colonies are beige, smooth, convex, and mucoid, with entire edges. Require approximately 17 mM NaCl for growth, but do not require amino acids or other growth factors. Grow between 4 and 30°C; optimum temperature is 25–30°C. Other characteristics are as given in the genus description and in Tables BXII.γ.144 and BXII.γ.145. In addition, strains are lecithinase negative, and acid is formed oxidatively from D-glucose, maltose, starch, D-galactose, and D-mannitol, but not from L-arabinose, D-fructose, rhamnose, sucrose, or D-sorbitol. Acid may be formed from D-mannose or glycerol. Can grow on MacConkey agar, but not on Simmons citrate agar. May grow on cetrimide agar. See Bozal et al. (1994, 1997) for additional characteristics.

Isolated from muddy soils and sediments collected from Antarctic coastal areas.

The mol% G + C of the DNA is: 41–42 (T_m).

Type strain: NF3, CECT 4664.

GenBank accession number (16S rRNA): X98336.

3. **Pseudoalteromonas atlantica** (Akagawa-Matsushita, Matsuo, Koga and Yamasoto 1992b) Gauthier, Gauthier and Christen 1995a, 760[VP] (*Alteromonas atlantica* Akagawa-Matsushita, Matsuo, Koga and Yamasoto 1992b, 624.)

at.lan' ti.ca. L. adj. *atlanticus* from Gr. adj. *Atlantikos* pertaining to the Atlantic Ocean.

Cells are rod-shaped, 0.5–0.8 × 1.5–2.3 μm. Colonies are sunken by agarase activity. Colonies are beige to pale orange, smooth, and convex, with an entire edge. May produce a melanin-like pigment on tyrosine-containing media. Sodium ions are required for growth, but strains do not require amino acids or other growth factors. Grow between 5 and 35°C, with optimum growth at about 30°C. Grows between pH 5.5 and 8.5. Other characteristics are as given in the genus description and in Tables BXII.γ.144 and BXII.γ.145. In addition, strains can reduce methylene blue and coagulate litmus milk; gluconate oxidation, 3-ketolactose production from lactose, and Congo red adsorption tests are negative; strains are unable to degrade carrageenan or xanthine; acid is formed from D-glucose and D-mannitol; and no growth occurs on media containing 0.4% phenethyl alcohol.

Isolated from marine macroalgae and seawater.

The mol% G + C of the DNA is: 40.6–41.7 (T_m).

Type strain: ATCC 19262, IAM 12927, LMG 2138, NCIMB 301.

GenBank accession number (16S rRNA): X82134.

4. **Pseudoalteromonas aurantia** (Gauthier and Breittmayer 1979) Gauthier, Gauthier and Christen 1995a, 760[VP] (*Alteromonas aurantia* Gauthier and Breittmayer 1979, 371.)

[a]For symbols see standard definitions; nd, not determined.

[b]No information is available concerning ascorbate, oxaloacetate, hydroxy-L-proline, L-asparagine, L-glutamine, protamine, 2-deoxyribose, deoxycholate, galacitol, D-galactosamine, α-glycerophosphate, urate, and glycylglycine.

au.ran′ti.a. M.L. n. *aurantium* orange; M.L. fem. adj. *aurantia* orange-colored.

Cells are rod-shaped, 0.5–1.5 × 1.5–4.0 μm. Colonies on agar media are orange, smooth, and convex, with an entire edge. Sodium ions (optimal levels 0.5–0.6 M) and amino acids are required for growth. Grows between 1 and 8% NaCl. Produces a polyanionic, autotoxic antibiotic on complex media. Grows between 4 and 30°C, with optimum growth occuring at about 25°C. Other characteristics are as shown in the genus description and in Tables BXII.γ.144 and BXII.γ.146. In addition, strains can form phospholipase C, collagenase, leucine aminopeptidase, valine aminopeptidase, and phosphoamidase. Strains may also form α-glucosidase, β-glucosaminidase, and α-chymotrypsin and reduce methylene blue. Tryptophanase, α-galactosidase, β-galactosidase, β-glucuronidase, α-mannosidase, α-fucosidase, and C14 lipase are absent. Trimethylamine *N*-oxide is not reduced. See Gauthier and Breittmayer (1979) for additional characteristics.

Isolated from surface seawater.

The mol% G + C of the DNA is: 38.8–42.5 (T_m).

Type strain: 208, ATCC 33046, DSM 6057, NCIMB 2052.

GenBank accession number (16S rRNA): X82135.

5. **Pseudoalteromonas bacteriolytica** Sawabe, Makino, Tatsumi, Nakano, Tajima, Iqbal, Yumoto, Ezura and Christen 1998a, 773[VP]

bac.te.ri.o.ly′ti.ca. Gr. n. *baktron* rod or staff; Gr. adj. *lytica* dissolving; M.L. fem. adj. *bacteriolytica* bacteria-dissolving.

Gram negative. Cells are rod-shaped, 1.9–2.5 × 0.6–0.9 μm, occurring singly or in pairs. Motile by polar flagella. Does not accumulate poly-β-hydroxybutyrate. Colonies are red-pigmented or non-pigmented, circular, smooth, and convex with entire edges. Requires NaCl and amino acids for growth. Grows from 15–35°C; no growth at 37°C.

Strictly aerobic chemoheterotroph. Oxidase positive. Catalase activity is weak. Produces acid oxidatively from D-glucose. Produces amylase. Digests casein and Tween 80. Does not produce chitinase, alginase, agarase, or κ-carrageennase. Does not reduce nitrate to nitrite. Utilizes D-glucose, D-mannose, D-fructose, sucrose, D-galactose, D-glucosamine, fumarate, succinate, acetate, and propionate. Does not utilize xylose, lactose, melibiose, D-gluconate, D-glucuronate, *N*-acetylglucosamine, D-sorbitol, erythritol, glycerol, citrate, DL-malate, aconitate, α-ketoglutarate, *m*-hydroxybenzoate, putrescine, δ-aminovalerate, γ-aminobutyrate, or L-proline.

[a]For symbols see standard definitions; nd, not determined.

[b]No information is available concerning the following substrates: caprate, D-gentiobiose, *n*-propanol, *n*-butanol, mesaconate, suberate, sebacate, *meso*-tartrate, itaconate, D-melizitose, citraconate, levulinate, maleate, benzoate, DL-maleate, β-alanine, mucate, methanol, isopropanol, isobutanol, ethyleneglycol, propyleneglycol, butyleneglycol, formate, quinate, benzoylformate, phenylethanediol, phenol, napthalene, kynurenate, methylamine, pentylamine, 2-amylamine, hippurate, pantothenate, nicotinate, nicotinamide, allantoin, adenine, cytosine, guanine, thymine, uracil, dodecane, phthalate, isophthalate, and *tert*-phthalate.

Isolated from, and causative agent of, red spot disease in beds of *Laminaria japonica*.

The mol% G + C of the DNA is: 44–46 (HPLC).

Type strain: IAM 14595.

GenBank accession number (16S rRNA): D89929.

6. **Pseudoalteromonas carrageenovora** (Akagawa-Matsushita, Matsuo, Koga and Yamasoto 1992b) Gauthier, Gauthier and Christen 1995a, 760[VP] (*Alteromonas carrageenovora* Akagawa-Matsushita, Matsuo, Koga and Yamasoto 1992b, 626.)
car.ra.gee.no′vo.ra. M.L. n. *carrageenum* carrageen, another name for carrageenan; L. v. *vorare,* to devour; M.L. fem. adj. *carrageenovora* carrageenan decomposing.

Cells are rod-shaped, 0.7–0.8 × 1.9–2.5 μm. Colonies are beige to pale yellow, smooth, and convex, with an entire edge. Produces diffusible melanin-like pigments on tyrosine-containing media. Sodium ions are required for growth, but amino acids and other growth factors are not required. Grow between 5 and 35°C, with optimum growth at about 30°C. Grow between pH 5.5 and 9.0. Other characteristics are as given in the genus description and in Tables BXII.γ.144 and BXII.γ.145. In addition, strains can reduce methylene blue and coagulate litmus milk. Gluconate oxidation, 3-ketolactose production from lactose, and Congo red adsorption tests are negative. Degrade carrageenan, but not xanthine. Acid is formed from D-glucose and D-mannitol. No growth occurs on media containing 0.4% phenethyl alcohol (Akagawa-Matsushita et al., 1992b).

Isolated from a mixture of seawater and marine macroalgae (Yaphe and Baxter, 1955).

The mol% G + C of the DNA is: 39.5 (T_m).

Type strain: ATCC 43555, DSM 6820, IAM 12662, IFO 12985, NCIMB 302.

GenBank accession number (16S rRNA): X82136.

7. **Pseudoalteromonas citrea** (Gauthier 1977) Gauthier, Gauthier and Christen 1995a, 760, emend. Ivanova, Kiprianova, Mikhailov, Levanova, Garagulya, Gorshkova, Vysotskii, Nicolau, Yumoto, Taguchi and Yoshikawa 1998, 255[VP] (*Alteromonas citrea* Gauthier 1977, 354; *Alteromonas fuliginea* Romanenko, Lysenko, Mikhailov and Kurika 1995a, 879.)
ci′tre.a. L. adj. *citreus* lemon-yellow.

Cells are straight rods, 0.5–0.8 × 1.0–1.5 μm. Colonies on agar media are smooth, convex with an entire edge, and either nonpigmented, pigmented yellow-orange, or containing diffusible blue-black or brown, melanin-like pigments. Sodium ions are required for growth; optimal growth occurs with about 2–3% NaCl. May require amino acids for growth. Some strains produce a polyanionic, autotoxic antibiotic on complex media. Grows between 4 and 35°C, with optimal growth at about 30°C. Other characteristics are as shown in the genus description and in Tables BXII.γ.144 and BXII.γ.146. Positive for levan production. Strains may hydrolyze pustulan and laminarin. Strains are resistant to rhistomycin, ampicillin, neomycin, kanamycin, streptomycin, benzylpenicillin, lincomycin, and cephalexin, but are sensitive to rifampicin, gentamicin, oxacillin, polymyxin, erythromycin, and ofloxacin.

Isolated from surface seawater, mussels, ascidians, and sponges.

The mol% G + C of the DNA is: 38.9–44.7 (T_m).

Type strain: ATCC 29719, DSM 6058, NCIMB 1889.

GenBank accession number (16S rRNA): X82137.

8. **Pseudoalteromonas denitrificans** (Enger, Nygaard, Solberg, Schei, Nielsen and Dundas 1987) Gauthier, Gauthier and Christen 1995a, 760[VP] (*Alteromonas denitrificans* Enger, Nygaard, Solberg, Schei, Nielsen and Dundas 1987, 421.)
de.ni.tri′fi.cans. M.L. v. *denitrifico* to denitrify; M.L. part. adj. *denitrificans* denitrifying.

Cells are rod-shaped, 0.5–0.7 × 2–4 μm. Motile by a single, sheathed, polar flagellum; rarely, up to 3 polar flagella may be observed. Cells produce a number of prodi-

giosin-type pigments, with a red pigment predominant and identified as cycloprodigiosin. Colonies on agar are initially pink, becoming more intensely red with age, and are smooth and convex with an entire edge. Produce bright blue, purple, or red pigments in liquid media. Produce a polyanionic, autotoxic antibiotic on complex media. Sodium ions are required for growth; the optimal level is about 2.5% NaCl; no growth occurs in the presence of 6% NaCl. Require amino acids for growth. Grow between 2 and 30°C, with optimum growth at about 25°C. Other characteristics are as given in the genus description and in Tables BXII.γ.144 and BXII.γ.146. Strains are also resistant to tetracycline and penicillin, but are susceptible to chloramphenicol. Strains possess a high sensitivity to ultraviolet radiation.

Isolated from seawater collected from fjords of western Norway.

The mol% G + C of the DNA is: 36.5–37.1 (T_m).

Type strain: Nygaard 1977, ATCC 43337, DSM 6059, IAM 14445, NCIMB 13179.

GenBank accession number (16S rRNA): X82138.

9. **Pseudoalteromonas distincta** (Romanenko, Mikhailov, Lysenko and Stapanenko 1995a) Ivanova, Chun, Romanenko, Matte, Mikhailov, Frolova, Huq and Colwell 2000a, 143[VP] (*Alteromonas distincta* Romanenko, Mikhailov, Lysenko and Stapanenko 1995a, 879.)
di.stinc′ta. M.L. adj. *distincta* distinct.

Cells are rods, about 0.9 × 2.5 μm. Motile by a single polar flagellum, very rarely by 2–4 polar flagella with 5–7 lateral flagella. Cells do not form capsules. Colonies on marine agar are black-brown, smooth, convex, and circular with entire edges. Produce a diffusible, black-brown, melanin-like pigment that is formed most strongly at low incubation temperatures and on tyrosine and arginine-containing media. Sodium ions are required for growth. Growth factors are not required. Grow between 4 and 35°C; no growth occurs at 40°C. Grow between pH 6.0 and 9.0. Strictly aerobic with a respiratory metabolism. Oxidase and catalase positive. Do not denitrify. Produce lipase and gelatinase, but do not hydrolyze starch, chitin, alginate, carrageenan, or agar. Decompose L-tyrosine and L-arginine. Utilize citrate, but not D-arabinose, D-xylose, D-glucose, D-mannose, L-rhamnose, cellobiose, lactose, maltose, sucrose, D-mannitol, or *N*-acetylglucosamine.

Isolated from a marine sponge near the Komandorskiye Islands, Russian Pacific region.

The mol% G + C of the DNA is: 44 (T_m).

Type strain: ATCC 700518, KMM 638.

GenBank accession number (16S rRNA): AF043742, AF082564.

10. **Pseudoalteromonas elyakovii** (Ivanova, Mikhailov, Kiprianova, Levanova, Garagulya, Frolova and Swetashev 1997) Sawabe, Tanaka, Iqbal, Tajima, Ezura, Ivanova and Christen 2000, 270[VP] (*Alteromonas elyakovii* Ivanova, Mikhailov, Kiprianova, Levanova, Garagulya, Frolova and Swetashev 1997, 601.)
el.ya.kov′i.i. M.L. gen. n. *elyakovii* of Ekyakov, named after G.B. Elyakov for his work in microbial biotechnology.

Cells are rods, about 0.5–0.7 × 1.0–1.2 μm. Motile by a single polar flagellum. Cells do not form spores or capsules. Colonies on marine agar are nonpigmented, smooth, convex, and circular, with entire edges. Melanin-like pigments are not formed. Nonbioluminescent. Sodium ions are required for growth. Growth factors are not required. Grow between 4 and 35°C; no growth occurs at 41°C. Grow between pH 7 and 8.5. Strictly aerobic with a respiratory metabolism. Oxidase and catalase positive. Do not denitrify. Produce lipase, amylase, and gelatinase, but do not hydrolyse chitin. Decompose L-tyrosine and L-arginine. Utilize D-ribose, D-xylose, D-fructose, D-galactose, D-glucose, cellobiose, lactose, salicin, adonitol, D-sorbitol, *m*-inositol, ethanol, propionate, butyrate, succinate, lactate, 2-oxoglutarate, glycolate, *p*-hydroxybenzoate, phenylacetate, L-alanine, L-histidine, L-lysine, L-ornithine, L-phenylalanine, and L-threonine, but not arabinose, rhamnose D-mannose, cellobiose, lactose, maltose, sucrose, trehalose, D-gluconate, D-mannitol, acetate, caprylate, valerate, caproate, pelargonate, glutarate, citrate, fumarate, L-malate, pyruvate, glycerate, aconitate, L-asparagine, L-glutamate, or L-proline. Other characteristics as are described by Ivanova et al. (1996b).

Isolated from the coelomic fluid of the mussel *Crenomytilus grayanus*.

The mol% G + C of the DNA is: 39 (T_m).

Type strain: 40MC, ATCC 700519, KMM 162, VKPM B3905.

GenBank accession number (16S rRNA): AF082562.

11. **Pseudoalteromonas espejiana** (Chan, Baumann, Garza and Baumann 1978) Gauthier, Gauthier and Christen 1995a, 760[VP] (*Alteromonas espejiana* Chan, Baumann, Garza and Baumann 1978, 220.)
es.pe.ji.a′na. M.L. fem. adj. *espejiana* of Espejo, a Chilean microbiologist who isolated one of the first lipid-containing bacteriophages.

Cells are rod-shaped, 0.2–1.0 × 2.0–3.5 μm. Colonies are nonpigmented, smooth, and convex, with an entire edge. Sodium ions (0.2–0.3 M concentration optimal) required for growth. Amino acids are required for growth. Grow between 10 and 35°C, with optimal growth at about 30°C. No growth at 4°C. Other characteristics are as shown in the genus description and in Tables BXII.γ.144 and BXII.γ.145.

Isolated from seawater.

The mol% G + C of the DNA is: 43–44 (T_m).

Type strain: 261, ATCC 29659, CCUG 16147, DSM 9414, IAM 12640, LMG 2866, NCIMB 2127.

GenBank accession number (16S rRNA): X82143.

12. **Pseudoalteromonas luteoviolacea** (Gauthier 1982) Gauthier, Gauthier and Christen 1995a, 760[VP] (*Alteromonas luteoviolacea* Gauthier 1982, 85; *Alteromonas luteo-violaceus* [sic] Gauthier 1976c, 147.)
lu.te.o.vi.o.la′ce.a. L. adj. *luteus* yellow; L. adj. *viola* violet; M.L. adj. *luteoviolacea* yellow-violet.

Cells are rod-shaped, 0.8–1.5 × 2–4 μm. Motile by single polar flagellum, which may or may not be sheathed. Colonies on agar are smooth or waxy and circular convex, with a more or less violet pigment (violacein); edges of colonies may be pigmented pale violet or yellow. Some strains form diffusible brown pigments on complex media. Most strains produce a polyanionic, autotoxic antibiotic on complex media. Sodium ions are required for growth; the optimal level

is about 2–3% NaCl; no growth occurs in the presence of 8% NaCl. May require amino acids for growth. Grow between 10 and 30°C, with optimal growth at about 25°C. Other characteristics are as given in the genus description and in Tables BXII.γ.144 and BXII.γ.146. In addition, strains can form lecithinase and produce acid from trehalose and maltose. Acid from glucose varies between strains. Negative for the following tests: cellulose hydrolysis, methylene blue reduction, β-galactosidase, glycine decarboxylase, asparagine decarboxylase, and alanine decarboxylase. Acid is not produced from D-mannose, D-xylose, D-fructose, lactose, sucrose, D-mannitol, or glycerol. Susceptible to polymyxin B, chloramphenicol, and oleandomycin.

Isolated from surface seawater.

The mol% G + C of the DNA is: 40.9–42.2 (T_m).

Type strain: CH130, ATCC 33492, DSM 6061, NCIMB 1893.

GenBank accession number (16S rRNA): X82144.

13. **Pseudoalteromonas nigrifaciens** (Baumann, Baumann, Bowditch and Beaman 1984a) Gauthier, Gauthier and Christen 1995a, 760[VP] emend. Ivanova, Kiprianova, Mikhailov, Levanova, Garagulya, Gorshkova, Yumoto and Yoshikawa 1996b, 227 (*Alteromonas nigrifaciens* Baumann, Baumann, Bowditch and Beaman 1984a, 146.)
ni.gri.fa' ci.ens. L. adj. *niger* black; L. v. *facio* to make; M.L. part. adj. *nigrifaciens* blackening.

Cells are straight rods, 0.8–1.2 × 1.8–2.3 μm. Cells may be encapsulated. Colonies are smooth, circular, convex with an entire edge, and nonpigmented. May form a brown-black, melanin-like pigment constitutively at low temperatures. On tyrosine-containing media, melanin-like pigments are formed by all strains. Sodium ions are required for growth. Most strains do not require growth factors. Grow between 4 and 35°C, with optimal growth at about 30°C. Other characteristics are as given in the genus description and in Tables BXII.γ.144 and BXII.γ.145. See Ivanova et al. (1996a) for additional phenotypic information.

Isolated from seawater, mussels and salted food.

The mol% G + C of the DNA is: 38.5–40.2 (T_m).

Type strain: ATCC 19375, DSM 6063, NCIMB 8614.

GenBank accession number (16S rRNA): X82146.

14. **Pseudoalteromonas peptidolytica** Venkateswaran and Kohmoto 2000, 572[VP]
pep.ti.do.lyt' i.ca. Gr. n. *peptos* a class of organic compounds; Gr. adj. *lytica* dissolving; M.L. fem. adj. *peptidolytica* peptide dissolving.

Gram negative. Cells are rods, 2.0–3.0 × 0.7–0.8 μm. Motile with a polar unsheathed flagellum. Colonies on marine agar are circular, opaque, and yellow-pigmented. Requires Na^+ ions for growth. Grows between 1–10% NaCl. Growth occurs at 15–40°C. Optimum growth temperature is 30°C.

Chemoheterotrophic and strictly aerobic. Catalase and oxidase positive. Produces gelatinase, amylase, lipase (Tween 80), and alginase. Arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, chitinase, and β-galactosidase are not produced. Does not produce H_2S from thiosulfate. Indole and Voges–Proskauer tests are negative. Does not denitrify. Utilizes glucose, maltose, *N*-acetylglucosamine, succinate, and fumarate as sole carbon sources. Does not utilize mannose, fructose, galactose, lactose, sucrose, salicin, mannitol, glycerol, citrate, DL-lactate, γ-aminobutyrate, sarcosine, putrescine, α-ketoglutarate, sorbitol, DL-malate, acetate, *m*-hydroxybenzoate, or methanol.

Isolated from surface seawater, Yamoto Islands, Sea of Japan.

The mol% G + C of the DNA is: 41–42 (HPLC).

Type strain: F12–50–A1, MBICC F1250A1.

GenBank accession number (16S rRNA): AF007286.

15. **Pseudoalteromonas piscicida** (ex Bein 1954) Gauthier, Gauthier and Christen 1995a, 760 (*"Pseudomonas piscicida"* (Bein 1954) Buck, Meyers and Leifson 1963, 1125; *"Flavobacterium piscicida"* Bein 1954, 115.)
pi.sci.ci' da. L. n. *piscis* fish; L. suff. *-cida* from L. v. *caedo* to cut or kill; M.L. n. *piscicida* fish killer.

Cells are straight rods, 0.2–0.6 × 1.2–2.0 μm. Fimbriae are present on cells. Possess single, sheathed, polar flagella. Colonies are yellow-orange, translucent, smooth, circular, and convex, with an entire edge and a butyrous consistency. Liquid cultures possess even, moderate turbidity, with a pigmented pellicle.

Cell cultures and filtrates produce an antibiotic active against yeasts. Filtrates and cells also induce neuromuscular toxicity syndromes in a variety of fish and crab species, including minnow (*Gambusia* sp.), schoolmaster (*Lutjans apodus*), sandperch (*Eucinostomus pseudosula*), killifish (*Fundulus similis*), mollie (*Mollieresia latipinna*), and fiddler crabs (*Uca pugnas* and *Uca pugilator*).

Sodium ions required for growth, with cultures growing between 0.5% and 10% NaCl. Use ammonia, but not nitrate as a nitrogen source; require amino acids for growth. Grow between 10 and 37°C; optimal growth is at about 30°C; no growth occurs at 4°C or 40°C. Grow between pH 6.0 and 8.0. Other characteristics are as given in the genus description and in Tables BXII.γ.144 and BXII.γ.146. Strains can also reduce trimethylamine-*N*-oxide to trimethylamine, oxidize gluconate to 2-keto-D-gluconate, coagulate litmus milk, and produce lecithinase. Acid is formed from D-glucose, sucrose, and maltose, but not from lactose, D-xylose, or D-mannitol.

Isolated from an area of dead fish.

The mol% G + C of the DNA is: 43.5–45.5 (Bd).

Type strain: MB-1, ATCC 15057, NCMB1142.

GenBank accession number (16S rRNA): X82215.

16. **Pseudoalteromonas prydzensis** Bowman 1998, 1040[VP]
prydz.en' sis. M.L. fem. adj. *prydzensis* pertaining to Prydz Bay, Antarctica, the site of isolation.

Cells are rod-shaped, 0.5–0.7 × 1–2.5 μm. Colonies on agar are nonpigmented, translucent, smooth, circular, and convex, with an entire or lobate edge; diffusible pigments are not formed on complex or tyrosine-containing media. Sodium ions are required for growth; the optimal level is about 2–3% and cultures grow at NaCl concentrations up to about 15%. Growth factors are not required. Grow between −2 and 30°C, with optimal growth at about 22–25°C. Other characteristics are as shown in the genus description and in Tables BXII.γ.144 and BXII.γ.146. In addition, the strains can produce acid from L-arabinose, D-glucose, D-mannose, maltose, sucrose, trehalose, and *N*-acetylglucosamine. Acid from cellobiose varies between strains. Do not

hydrolyze dextran, urate or xanthine. Acid is not produced from D-xylose, L-rhamnose, D-fructose, D-galactose, lactose, melibiose, D-raffinose, dextran, adonitol, D-mannitol, *meso*-inositol, D-sorbitol, or glycerol. Resistant to ampicillin and bile salts.

Isolated from sea ice.

The mol% G + C of the DNA is: 38–39 (T_m).

Type strain: MB8–11, ACAM 620.

17. **Pseudoalteromonas rubra** (Gauthier 1976a) Gauthier, Gauthier and Christen 1995a, 760[VP] (*Alteromonas rubra* Gauthier 1976a, 464.)
rub′ra. L. fem. adj. *rubra* red.

Cells are rod-shaped, 1.0–1.5 × 2–4 μm. Colonies on agar media are smooth, convex with an entire edge, and pigmented bright red. Sodium ions are required for growth. Require amino acids for growth. Grow between 10 and 35°C; optimum growth occurs at about 30°C, and no growth occurs at ≥40°C. Produce a polyanionic, autotoxic antibiotic on complex media. Other characteristics are shown in the genus description and Tables BXII.γ.144 and BXII.γ.146.

Isolated from surface seawater.

The mol% G + C of the DNA is: 46–48 (T_m).

Type strain: ATCC 29570, DSM 6064.

GenBank accession number (16S rRNA): X82147.

18. **Pseudoalteromonas tetraodonis** (Simidu, Kita-Tsukamoto, Yasumoto and Yotsu 1990) Ivanova, Romanenko, Matté, Matté, Lysenko, Simidu, Kita-Tsukamoto, Sawabe, Vysotskii, Frolova, Mikhailov, Christen and Colwell 2001b, 1077[VP] (*Pseudoalteromonas haloplanktis* subsp. *tetraodonis* Gauthier, Gauthier and Christen 1995a, 760; *Alteromonas tetraodonis* Simidu, Kita-Tsukamoto, Yasumoto and Yotsu 1990, 336.)
tet′ra.o.do.nis. M.L. *tetraodonis* of *Tetraodontidae*, a family of plectognathic fishes.

Cells are rod-shaped, 2.0–3.0 × 1.0 μm. Colonies are non-pigmented, smooth, and convex with an entire edge. Sodium ions are required for growth. Grows between 1–10% NaCl. Growth factors (amino acids) are not required for growth. Grows between 10–35°C, with optimum growth occurring at about 30°C. Optimum pH for growth is 7.5–8.0. Growth occurs between pH 5.5–9.5.

Utilizes glucose, sucrose, maltose, galactose, DL-lactate, valerate, caproate, butyrate, citrate, fumarate, succinate, caprylate, L-glutamate, acetate, pyruvate, ethanol, and L-tyrosine. Does not utilize mannose, fructose, mannitol, L-histidine, L-proline, or DL-malate (Ivanova et al., 2001b). Strains are susceptible to benzylpenicillin, carbenicillin, vancomycin, and tetracycline. Other characteristics are shown in the genus description and in Tables BXII.γ.144 and BXII.γ.145.

The mol% G + C of the DNA is: 41.5 (T_m).

Type strain: GFC, ATCC 51193, DSM 9166, IAM 14160, KMM 458, NCIMB 13177.

GenBank accession number (16S rRNA): X82139; AF214729.

19. **Pseudoalteromonas tunicata** Holström, James, Neilan, White and Kjelleberg 1998, 1210[VP]
tu.ni.ca′ta. L. fem. n. *tunicata* clothed with a tunic

Gram negative. Cells are rods, 2.0–3.4 μm in length. Motile with a polar sheathed flagellum. Colonies on marine agar are circular, opaque, and dark green. Colonies on trypticase soya agar are non-pigmented. Requires Na+ ions for growth with biomass produced optimally with 1–2% NaCl. Growth occurs at 4–30°C; no growth at 37°C. Optimum growth temperature is 25°C. Optimum pH for growth is 7–8; no growth at pH 5 or 11.

Chemoheterotrophic and strictly aerobic. Catalase, oxidase, and gelatinase positive. Utilizes trehalose, glucose, maltose, and Tween 20 as sole carbon sources. Does not utilize galactose, fructose, xylose, sucrose, lactose, raffinose, melibiose, xylitol, erythritol, glycine, threonine, arabinose, L-asparagine, or L-histidine. Susceptible to erythromycin, rifampicin, gentamycin, tetracycline, ampicillin, neomycin, kanamycin, and nalidixic acid at 100 μg/ml. Susceptible to the vibriostatic agent O/129 at 150 μg/ml.

Isolated from an adult of the tunicate species *Ciona intestinalis* collected from the coast of western Sweden.

The mol% G + C of the DNA is: 42.2 (T_m).

Type strain: Strain DS, CUG 26757.

GenBank accession number (16S rRNA): Z25522.

20. **Pseudoalteromonas undina** (Chan, Baumann, Garza and Baumann 1978) Gauthier, Gauthier and Christen 1995a, 760[VP] (*Alteromonas undina* Chan, Baumann, Garza and Baumann 1978, 220.)
un.di′na. L. fem. n. *undina* water nymph.

Cells are rod-shaped, 0.7–0.9 × 1.8–3.0 μm. Colonies are nonpigmented, smooth, and convex with an entire edge. Sodium ions are required for growth. Require amino acids for growth. Grow between 4 and 30°C, with optimum growth occurring at about 25°C. No growth at ≥35°C. Other characteristics are as shown in the genus description and in Tables BXII.γ.144 and BXII.γ.145.

Isolated from seawater.

The mol% G + C of the DNA is: 43–44 (T_m).

Type strain: ATCC 29690, DSM 6065, NCIMB 2128.

GenBank accession number (16S rRNA): X82140.

Genus XII. **Psychromonas** *Mountfort, Rainey, Burghardt, Kaspar and Stackebrandt 1998b, 631[VP] emend. Nogi, Kato and Horikoshi 2002, 1531 (Effective publication: Mountfort, Rainey, Burghardt, Kaspar and Stackebrandt 1998a, 237)*

THE EDITORIAL BOARD

Psy.chro.mo′nas. Gr. adj. *psychros* cold; Gr. fem. n. *monas* a unit; N.L. n. *Psychromonas* a cold monad.

Motile Gram-negative rod-shaped or oval cells; polar flagellum. **Grow at temperatures <22°C.** Catalase and oxidase positive. Major quinone Q-8; major fatty acids are $C_{14:1}$, $C_{16:0}$, and $C_{16:1}$. **Facultative anaerobes;** use carbohydrates for energy for growth. **Found in marine or high salinity environments.**

The mol% G + C of the DNA is: 38.1–43.8.

Type species: **Psychromonas antarctica** Mountfort, Rainey, Burghardt, Kaspar and Stackebrandt 1998b, 631 (Effective publication: Mountfort, Rainey, Burghardt, Kaspar and Stackebrandt 1998a, 237.)

Further descriptive information

The genus *Psychromonas* includes organisms adapted to a variety of conditions in marine or other saline aquatic environments, including an Antarctic saline pond (*Psychromonas antarctica*), seawater (*Psychromonas arctica* and *Psychromonas marina*), and deep sea sediments (*Psychromonas kaikoae* and *Psychromonas profunda*). All species are able to grow at minimum temperatures of 0–4°C and exhibit both fermentative and respiratory metabolism (Mountfort et al., 1998a; Kawasaki et al., 2002; Nogi et al., 2002; Groudieva et al., 2003; Xu et al., 2003). Increased pressure enhances the growth of *Psychromonas profunda* (Xu et al., 2003) and is required for the growth of *Psychromonas kaikoae* (Nogi et al., 2002).

Enrichment and Isolation Procedures

Psychromonas antarctica was isolated under anaerobic conditions and maintained in a basal medium emended with 3% NaCl (w/v) and filtered water from the Antarctic salt pond from which the organism was isolated (5%, v/v) (Mountfort et al., 1998a). *Psychromonas arctica* was enriched and isolated on a complex marine medium (Groudieva et al., 2003) containing starch. High pressure incubation was used for the isolation of *Psychromonas kaikoae* (Nogi et al., 2002). Difco Marine Medium 2216 was used for *Psychromonas kaikoae*, *Psychromonas marina*, and *Psychromonas profunda* (Kawasaki et al., 2002; Nogi et al., 2002; Xu et al., 2003).

Differentiation of the genus *Psychromonas* from other genera

Psychromonas species are facultatively anaerobic, whereas members of the genera *Alteromonas*, *Glaciecola*, *Idiomarina*, *Marinobacterium*, *Microbulbifer*, and *Pseudoalteromonas* are strictly aerobic. *Psychromonas* species exhibit both fermentative and respiratory metabolism, whereas *Ferrimonas balearica* and *Alishewanella* species have a strictly respiratory metabolism; in addition, *Alishewanella* species are nonmotile. *Psychromonas* species utilize carbohydrates as energy sources, whereas *Marinobacter* species do not. *Psychromonas* species can be distinguished from *Shewanella* species by the unusual fatty acid profiles of the latter. *Psychromonas* species are ecologically and phenotypically similar to members of the genera *Colwellia* and *Moritella*.

Differentiation of the species of the genus *Psychromonas*

Differential characteristics of *Psychromonas* species are given in Table BXII.γ.147.

List of species of the genus Psychromonas

1. **Psychromonas antarctica** Mountfort, Rainey, Burghardt, Kaspar and Stackebrandt 1998b, 631[VP] (Effective publication: Mountfort, Rainey, Burghardt, Kaspar and Stackebrandt 1998a, 237.)
ant.arc.ti.ca. M.L. gen. n. *antarctica* of Antarctica.

Rods, 1.3 × 2.5–6.0 µm. Grows at NaCl concentrations 0–4% (w/v); 3% NaCl is optimum and protects against killing by freeze-thaw. Killed quickly by temperatures >50°C or by temperatures >30°C for >20 h. Catalase positive; oxidase positive. Ferments glycogen, starch, *N*-acetyl glucosamine, and hexose monosaccharides and disaccharides with the production of CO_2, formate, acetate, ethanol, lactate, and butyrate. Does not hydrolyze esculin. Does not grow on *N*-acetyl muramic acid, alanine, casamino acids, esculin, formate, fumarate, glycerol, isoleucine, lactate, lactose, malate, mannose, putrescine, rhamnose, sorbitol, valine, yeast extract, xylan, or xylose.

TABLE BXII.γ.147. Differential characteristics of *Psychromonas* species[a,b]

Characteristic	*Psychromonas antarctica*	*Psychromonas arctica*	*Psychromonas kaikoae*	*Psychromonas marina*	*Psychromonas profunda*
Temperature range (optimum) (°C)	2–17 (12)	0–25 (20)	4–15 (10)	0–25 (14–16)	2–13 (3–4)
Growth at atmospheric pressure	+	+	−	+	+

[a]Abbreviations: +, positive; −, negative; nd, not determined; w, weak.

[b]Data from Mountfort et al.(1998a), Kawasaki et al. (2002), Nogi et al. (2002), Groudieva et al. (2003), and Xu et al.(2003).

[c]Extended incubation (up to 4 w) may be required.

Isolated from the anaerobic sediment of a saline pond on the McMurdo Ice Shelf, Antarctica.

The mol% G + C of the DNA is: 42.8 (HPLC).

Type strain: star-1, DSM 10704.

GenBank accession number (16S rRNA): Y14697.

2. **Psychromonas arctica** Groudieva, Grote and Antranikian 2003, 544[VP]

arc' ti.ca. L. fem. adj. *arctica* from the Arctic, referring to the site where the type strain was isolated.

Rods 0.7–1.7 × 1.3–2.6 µm. Aging cultures contain coccoid cells 1.3–1.7 µm in diameter. Forms biofilms by secreting fibrous exopolysaccharides. Optimal NaCl concentration for growth, 2% (w/v); range, 1–7%. Temperature optimum, 20°C; range, 0–25°C. Killed by temperatures >27°C for >4 h. Carbon sources include acetate, alanine, fructose, fumarate, glucose, glycerol, lactose, maltose, mannitol, mannose, pyruvate, succinate, and sucrose. Fermentation products are CO_2, formate, acetate, ethanol, and lactate. No growth on chitin, citrate, gelatin, lactate, malate, propionate, xylan, or xylose. No vitamin requirement.

Isolated from seawater collected off Svalbard, Spitzbergen, Norway.

The mol% G + C of the DNA is: 40.1 (HPLC).

Type strain: Pull 5.3, DSM 14288, KCTC 12111.

GenBank accession number (16S rRNA): AF374385.

3. **Psychromonas kaikoae** Nogi, Kato and Horikoshi 2002, 1531[VP]

kai.ko' ae. N.L. fem. gen. n. *kaikoae* of KAIKO, the unmanned submersible that collected the samples from which the organism was isolated.

Motile rods, 0.8–1.0 × 2.0–4.0 µm; one polar flagellum (unsheathed). NaCl required for growth; optimal concentration 3% (w/v). Catalase and oxidase positive. Optimum growth at 10°C and 50 Mpa; does not grow at atmospheric pressure. Possesses both fermentative and respiratory pathways. Hydrolyzes gelatin. Reduces nitrate to nitrite; nitrite not further reduced. No H_2S, amylase, or indole production. Major quinone Q-8; major fatty acids are $C_{14:0}$, $C_{14:1}$, $C_{16:0}$, and $C_{16:1}$.

Isolated from sediment from the Japan Trench at a depth of 7434 m.

The mol% G + C of the DNA is: 43.8 (method not given).

Type strain: JT7304, ATCC BAA-353, JCM 11054.

GenBank accession number (16S rRNA): AB052160.

4. **Psychromonas marina** Kawasaki, Nogi, Hishinuma, Nodasaka, Matsuyama and Yumoto 2002, 1458[VP]

ma.ri' na. L. adj. *marina* of the sea.

Motile rods, 0.8–1.2 × 1.5–2.0 µm; one polar flagellum. Catalase and oxidase positive. NaCl required for growth; optimum, 3–5% (w/v); maximum, 7%. Temperature range for growth, 0–25°C; no growth at or above 26°C. Ferments D-fructose, D-galactose, D-glucose, D-maltose, D-mannitol, sucrose, and D-xylose with no production of gas; in addition, utilizes *N*-acetyl glucosamine, D-cellobiose, D-galactose, glycerol, and lactose. Does not utilize L-arabinose, *myo*-inositol, D-mannose, melibiose, raffinose, rhamnose, raffinose, sorbitol, or trehalose. No vitamins, amino acids, or organic nitrogen sources required. Reduces nitrate to nitrite; produces H_2S but not indole. Produces β-galactosidase. Hydrolyzes alginic acid, DNA, starch, tributyrin, Tween 20, Tween 40, Tween 60, and Tween 80. Does not hydrolyze gelatin, casein, or chitin. Susceptible to vibriostatic agent O/129. Major fatty acids are $C_{14:1}$, $C_{16:0}$, $C_{16:0\ iso}$, $C_{16:1}$, $C_{18:1}$; also contains $C_{22:6}$.

Isolated from seawater collected in the Okhotsk Sea, Japan.

The mol% G + C of the DNA is: 43.5 (HPLC).

Type strain: 4-22, ATCC BAA-724, JCM 10501, KCTC 12105.

GenBank accession number (16S rRNA): AB023378.

5. **Psychromonas profunda** Xu, Nogi, Kato, Liang, Rüger, Kegel and Glansdorff 2003, 530[VP]

pro.fun' da. L. fem. adj. *profunda* from the deep.

Motile rods, 0.9–1.2 × 2.0–5.5 µm; one polar flagellum (unsheathed). NaCl required for growth. Growth occurs at 2–14°C. Greater than atmospheric pressure enhances growth. Possesses both fermentative and respiratory pathways. Produces acid from both fermentation and oxidation of cellobiose, dulcitol, fructose, galactose, glucose, glycerol, inositol, lactose, maltose, mannitol, mannose, rhamnose, salicin, sucrose, trehalose, and xylose. Hydrolyzes esculin and DNA. Weak hydrolysis of starch; no gelatin hydrolysis. Catalase and oxidase positive. Reduces nitrate to nitrite. Produces indole, H_2S, and β-galactosidase. Susceptible to chloramphenicol, furazolidone, penicillin, polymyxin B, tetracycline, and vibriostatic agent O/129. Major quinone Q-8. Major fatty acids are $C_{14:1}$, $C_{16:0}$, and $C_{16:1}$.

Isolated from Atlantic sediment samples taken at 2770 m depth off the coast of West Africa.

The mol% G + C of the DNA is: 38.1 (HPLC).

Type strain: 2825, JCM 11437.

GenBank accession number (16S rRNA): AJ416756.

Genus XIII. **Shewanella** *MacDonell and Colwell 1986, 355[VP] (Effective publication: MacDonell and Colwell 1985, 180)*

JOHN P. BOWMAN

Shew.a.nel' l.a. M.L. dim. ending *-ella*; *Shewanella* named after James Shewan for his work in fisheries microbiology.

Straight or curved rods, 0.5–0.8 × 0.7–2.0 µm. Endospores and microcysts are not formed. **Motile by a single, unsheathed, polar flagellum.** Gram negative. Colonies are often pale tan to pink-orange, due to cytochrome accumulation. **Oxidase and catalase positive.** Chemoheterotrophic. **Facultatively anaerobic. Oxygen is used as the electron acceptor during aerobic growth. Anaerobic growth is predominantly respiratory**; the oxidation of organic carbon compounds or H_2 is coupled to the reduction of various inorganic and organic electron acceptors, including NO_3^-, NO_2^-, Fe^{3+}, trimethylamine-*N*-oxide, fumarate, various sulfur

compounds, and Mn^{4+}. **May also be fermentative**, producing acid (but usually no gas) from carbohydrates, such as D-glucose and *N*-acetylglucosamine. Constitutive arginine dihydrolase is usually absent. Most strains can form H_2S from thiosulfate. **May require Na^+ ions** for growth. **Most species can grow at 4°C**. Some species are psychrophilic. One species is psychrophilic and barophilic. Major fatty acids are $C_{13:0\ iso}$, $C_{14:0}$, $C_{15:0}$, $C_{15:0\ iso}$, $C_{16:1\ \omega 7c}$, $C_{16:0}$, and $C_{17:1\ \omega 8c}$. Several species can also form significant quantities of the omega-3 fatty acid eicosapentaenoic acid ($C_{20:5\ \omega 3c}$). Isoprenoid quinone components include ubiquinone-8, ubiquinone-7, and menaquinone-7, with smaller amounts of methylmenaquinone-7. Major polyamines are putrescine and cadaverine. Member of the order *Alteromonadales*, family *Alteromonadaceae*, class *Gammaproteobacteria*. Isolated from clinical samples, chilled meats, butter, cutting oils, fresh water, freshwater sediment, estuaries, salt marshes, marine algae, seawater, marine sediment, fish, marine invertebrates, sea ice, marine snow, and abyssal ocean waters.

The mol% G + C of the DNA is: 38–54.

Type species: **Shewanella putrefaciens** (Lee, Gibson and Shewan 1977) MacDonell and Colwell 1986, 355 (Effective publication: MacDonell and Colwell 1985, 180) (*Alteromonas putrefaciens* Lee, Gibson and Shewan 1977, 449.)

Further descriptive information

Morphology Cells are pleomorphic rods, possessing either straight or slightly curved axes. In nutrient media, short filaments and, more rarely, helical forms may develop in older cultures. Cells do not contain poly-β-hydroxybutyrate inclusions or gas vesicles, form endospores or microcysts, or develop cellular appendages, such as prosthecae or spinae. Inclusion bodies of unknown function, possibly consisting of protein, have been found in *S. putrefaciens* (Krause et al., 1996).

Cultural characteristics Colonies on complex nutrient media typically have a pale tan to pink-orange or salmon color, which is due to strong accumulation of cytochrome proteins. This tendency is less pronounced in some species, such as *S. hanedai* and *S. benthica*. *S. colwelliana* and some *S. hanedai* strains form dark brown, melanin-like pigments when growing on complex media or media containing L-tyrosine. Studies on *S. colwelliana* indicate that this pigmentation derives from L-tyrosine, which is catabolized to homogentisate, which in turn is polymerized to form the pigment pyomelanin (Fuqua and Weiner, 1993; Coon et al., 1994; Ruzafa et al., 1994; Kotob et al., 1995).

Several *Shewanella* species require Na^+ for growth, and best growth occurs on seawater media such as marine 2216 agar (Difco Laboratories, Detroit, Michigan). *S. putrefaciens*, *S. baltica*, *S. algae*, and *S. frigidimarina* can grow well on marine agar and most commonly used nutrient media, including nutrient agar (Oxoid Ltd., Basingstoke, UK), plate count agar (Oxoid), triple sugar iron agar (Oxoid), etc. *S. colwelliana* requires amino acids, including L-aspartate and L-glutamate, for growth (Weiner et al., 1988). *S. hanedai* and *S. benthica* strains may also require amino acids and/or vitamins for growth (Baumann et al., 1984d; Bowman et al., 1997b). In defined media, such as basal medium agar (see *Alteromonas*), these requirements can be met by adding yeast extract at concentrations of 0.05–0.1% (w/v). *S. putrefaciens*, *S. baltica*, *S. frigidimarina*, *S. algae*, and *S. gelidimarina* can grow well on defined seawater media containing ammonia as a nitrogen source. The growth requirements for *S. woodyi* are unknown. Some *S. algae* strains and most *S. frigidimarina* strains do not require Na^+ but are stimulated by its presence. Growth occurs between 0.05–1.0 M NaCl, with optimal NaCl concentrations being 0.4–0.5 M. Strains of *S. algae* and *S. frigidimarina* exhibit moderate halotolerance and are able to tolerate Na^+ ion concentrations of up to 1.7–2.0 M.

The physiological diversity of *Shewanella* species is reflected by the wide range of habitats from which they can be isolated. Species may be mesophilic (*S. algae*, *S. colwelliana*, *S. putrefaciens* DNA hybridization group III), psychrotolerant (*S. putrefaciens* group I, *S. baltica*, *S. frigidimarina*, *S. woodyi*), psychrophilic (*S. gelidimarina*, *S. hanedai*), and both psychrophilic and barophilic (*S. benthica*). The majority of *S. algae* strains can grow at 41°C, but no *Shewanella* strains can grow at 45°C or higher.

Energy metabolism *Shewanella* species are chemoheterotrophic facultative anaerobes, with anaerobic growth typically of a respiratory nature; however, some species can also grow fermentatively. These include *S. frigidimarina* and *S. benthica*, both of which can ferment D-glucose, and *S. gelidimarina*, which can ferment *N*-acetylglucosamine and chitin, but not D-glucose (MacDonell and Colwell, 1985; Bowman et al., 1997b). Gas is not produced by these species during fermentation; however, *S. violacea*, a barotolerant species closely related to *S. benthica*, can ferment D-glucose and produce both acid and gas (Nogi et al., 1998b). The end products and relevant biochemistry of this process has not been studied.

Most studies on the diverse modes of anaerobic respiration in *Shewanella* have concentrated on strains of *S. putrefaciens* and *S. algae*; however, all *Shewanella* strains can use nitrate as an electron acceptor for growth (although denitrification is a strain-specific characteristic). Trimethylamine-*N*-oxide (TMAO) is also a common terminal electron acceptor among *Shewanella* species, and its reduction to trimethylamine is usually responsible for the odors associated with *Shewanella* food spoilage (Shewan, 1971). *Shewanella* strains can grow anaerobically by reduction of various sulfur compounds to H_2S, including S^0, thiosulfate, and sulfite (Semple and Westlake, 1987; Perry et al., 1993; Moser and Nealson, 1996), thiosulfate, and sulfite. Anaerobic growth can also occur via reduction of fumarate to succinate, coupled to the oxidation of formate. The fumarate reductase of *S. frigidimarina* NCIMB strain 400 is similar to a fumarate reductase flavoprotein found in *Wolinella succinogenes* (Simon et al., 1998).

Extensive studies have concentrated on the relatively unusual ability of *Shewanella* to facultatively reduce ferric iron, manganese, and other metals. The majority of *Shewanella* strains tested can grow anaerobically by coupling the oxidation of carbon compounds or H_2 (in the presence of a utilizable carbon source) to the reduction of Fe^{3+} to Fe^{2+} (Semple and Westlake, 1987; Lovley and Phillips, 1986; Lovley, 1993) or of Mn^{4+} to insoluble Mn^{3+} (Myers and Nealson, 1988; Caccavo et al., 1996b). Mn^{4+} and Fe^{3+} have redox potentials higher than that of sulfate and are capable of out-competing electron acceptors of lower potential, such as SO_4^{2-} (used for sulfate reduction) and CO_2 (used for methanogenesis) (Nealson and Saffarini, 1994). Dissimilatory metal reduction is believed to be important in terms of metal cycling and mobilization, as well as for its contribution to geomagnetism and sedimentary diagenesis (Nealson and Saffarini, 1994; Lovley, 1997; Pedersen, 1997). Owing to the broad specificity of the *Shewanella* anaerobic reductase enzyme system, *S. putrefaciens* strains can reduce and mobilize toxic and radioactive metallic pollutants, including Co, Cr, Se, Tc, and U (Lovley, 1993; Caccavo et al., 1994, 1996b; Lloyd and McCaskie, 1996; Ganesh

et al., 1997; Gorby et al., 1998). In addition, strains can reductively dehalogenate and transform organic pollutants, such as tetrachloroethane and carbon tetrachloride (Petrovskis et al., 1994; Picardal et al., 1995; Backhus et al., 1997). Studies indicate that the different modes of anaerobic respiration utilize different sets of enzymes. For example, a transposon mutant of *S. putrefaciens* MR-1 lacks fumarate reduction ability, but other reductive pathways are not compromised (Myers and Myers, 1997). Genes for anaerobic respiration by *S. putrefaciens* strain MR-1 appear to be both chromosomal and borne on megaplasmids (Saffarini et al., 1994).

During aerobic and anaerobic growth, *Shewanella* species can utilize a range of organic acids as sole sources of carbon and energy. In general, aromatic and heterocyclic compounds are not utilized, while the degree of utilization of carbohydrates varies considerably among the species, with some strains unable to use any carbohydrates. Glucose is catabolized via the Entner–Doudoroff pathway (Abu et al., 1994; Scott and Nealson, 1994). Most strains can degrade gelatin and form lipases, while certain species form chitinases, but in general do not attack starch, except for *S. colwelliana* and some strains of *S. woodyi* and *S. hanedai*. *S. gelidimarina* appears to be adapted almost specifically to chitin degradation, given its ability to utilize both aerobically and anaerobically only *N*-acetylglucosamine and chitin, out of a wide range of carbohydrates tested.

S. putrefaciens produces a potent iron chelator, putrebactin, that is structurally similar to chelators formed by *Pseudoalteromonas haloplanktis* (bisucaberin) and *Bordetella* spp. (alcaligin) (Ledyard and Butler, 1997). *S. algae* strains have been shown to form 4-epitetrodotoxin, a derivative of tetrodotoxin, which is a potent neurotoxin (Simidu et al., 1987, 1990; Nozue et al., 1992).

Genetic characteristics DNA base composition values for *Shewanella* vary from 38 to 54 mol% (T_m, Bd), and the ranges for individual species are shown in Table BXII.γ.148.

Temperature and pressure-regulated genes have been studied in a number of barotolerant and barophilic *S. benthica* strains (Kato et al., 1997; Chilukuri and Bartlett, 1997) and include a series of cytochrome proteins, including a cytochrome *c* oxidase. A set of PCR-amplified, pressure-regulated gene products have been found to be universal in *S. benthica* strains and have been proposed as a rapid means to identify this particular barophilic species (Li et al., 1998).

S. hanedai and *S. woodyi* have the distinction of being the only known nonfermentative bioluminescent species. Studies of the *luxA* sequence of *S. woodyi* have shown it to have only little homology with the *luxA* nucleotide sequence of *S. hanedai*. Overall, the *S. hanedai luxA* gene shows closer similarity to sequences found in *Vibrio logei* and *Vibrio fischeri* (*Photobacterium fischeri*) (Makemson et al., 1997).

Fatty acid profiles *Shewanella* species have a distinctive fatty acid pattern, as compared with other bacteria of the *Gammaproteobacteria*, in that they are rich in branched and odd-chain-length fatty acids (Wilkinson and Caudwell, 1980; Moule and Wilkinson, 1987; Rosselló-Mora et al., 1995a; Bowman et al., 1997b). Major fatty acids (and their ranges of % composition) include: $C_{13:0\ iso}$ (1–16%), $C_{14:0}$ (1–12%), $C_{15:0\ iso}$ (4–24%), $C_{15:0}$ (1–8%), $C_{16:1\ \omega7c}$ (16–55%), $C_{16:0}$ (5–31%), $C_{17:1\ \omega8c}$ (1–15%), and $C_{18:1\ \omega7c}$ (0–8%). The quantitative proportions of fatty acid components vary considerably among species, but it is difficult to judge with the data available whether these differences would be useful in species differentiation or whether they are merely due to variations in cultivation conditions. *Shewanella* possess both aerobic and anaerobic desaturatase pathways for fatty acid synthesis. *Shewanella* strains grown anaerobically thus form a different fatty acid profile that those grown aerobically (Nichols et al., 1997b; Venkateswaran et al., 1999).

Psychrotolerant and psychrophilic *Shewanella* species have the unusual ability to synthesize eicosapentaenoic acid (EPA, $C_{20:5\ \omega3}$), the levels of which range from 2–22% (Bowman et al., 1997b). Few other bacterial species known to possess EPA, including *Flexibacter polymorphus* (Johns and Perry, 1977) and *Psychroflexus torquis* (Nichols et al., 1997a; Bowman et al. 1998c), which are members of the flavobacteria division. Several studies have detected EPA in unidentified marine bacteria with fatty acid profiles very similar to *Shewanella* (Iwanami et al., 1995, Watanabe et al., 1996; Yazawa, 1996; Jostensen and Landfald, 1997; Yano et al., 1997). Compelling evidence is available that links production of EPA synthesis with cold adaptation. In *S. gelidimarina* ACAM 456, EPA levels decrease markedly when incubation temperatures are above its optimal growth temperature (Nichols et al., 1997b), and there seems to be a correlation between the optimal growth temperatures of *Shewanella* species and their inherent EPA levels (Bowman et al., 1997b). In *S. benthica*, EPA levels increase until the hydrostatic pressure reaches the particular strain's growth pressure optimum (DeLong and Yayanos, 1986). Increased levels of EPA decrease the homeoviscosity of cellular membranes (Nichols et al., 1995), an adaptation important for organisms living in perpetually cold and high-pressure environments. Because omega-3 fatty acid precursors cannot be synthesized *de novo* by most metazoa, it is thought that bacteria and microalgae act as a dietary supply of these lipids (DeLong and Yayanos, 1986). The EPA synthesis gene cluster of *Shewanella* sp. SCRC-2738 has been cloned and sequenced, and weak expression of the genes with EPA production has been conferred to a *Synechococcus* strain (Takeyama et al. 1997). The synthetic pathway of EPA has been partially characterized in the same strain and appears to be derived from an aerobic desaturation pathway (Watanabe et al., 1997). Mesophilic species do not appear to produce EPA, and their fatty acid profiles are similar to those of *Ferrimonas balearica*, another mesophilic, iron-reducing halophilic species isolated from sediment (Rosselló-Mora et al., 1995a). The major polar lipids have been determined in *S. putrefaciens*, *S. baltica*, and *S. algae* and include mostly phosphatidylglycerol and phosphatidylethanolamine, a pattern typical of Gram-negative bacteria (Moule and Wilkinson, 1987).

Lipopolysaccharides (LPS) *S. putrefaciens* possesses R-type lipopolysaccharides, rather than the ladder-type LPS typically found in many other Gram-negative bacteria (Sledjeski and Weiner, 1991). The chemical composition of the LPS varies among various species of *Shewanella* (Moule and Wilkinson, 1989). The lipid fraction of the LPS in *S. putrefaciens* (strains ATCC 8071 and 8073), *S. baltica* (strain ATCC 8072), and *S. algae* (NCIMB 11157) consists of (% range) $C_{13:0\ iso}$ (4–9%), $C_{13:0}$ (6–13%), $C_{10:0\ 3OH}$ (8–13%), $C_{12:0\ 3OH}$ (11–16%), $C_{13:0\ iso\ 3OH}$ (8–14%), $C_{13:0\ 3OH}$ (13–21%), and $C_{14:0\ 3OH}$ (7–9%). In addition, *S. baltica* contains high levels of $C_{12:0\ iso\ 3OH}$ (10%) and $C_{14:0\ iso\ 3OH}$ (8%); these components are much less abundant in the other strains tested (0–2%). The neutral and amino sugar content of the LPS core oligosaccharide of all strains tested contained of galactose and heptose. In addition *S. putrefaciens* ATCC 8071 contains glucose and 3-amino-3,6-dideoxyglucose; both *S. putrefaciens* ATCC 8073 and *S. baltica* contain galactosamine; and *S. algae* contains quinovosamine.

[a]For symbols see standard definitions; S, growth is stimulated by the presence of Na^+ ions.

[b]EPA, eicosapentaenoic acid.

Lipids A number of additional substituted lipids have been found in *S. putrefaciens* ATCC 8071, including two glycolipids, identified as β-D-glucopyranosyldiacylglycerol and β-D-glucopyranuronosyldiacylglycerol, and an ornithine amide lipid (Wilkinson, 1968a, 1972; Wilkinson et al., 1973).

Quinones The quinones found in *S. putrefaciens* (*"Pseudomonas rubescens"*), *S. algae*, *S. baltica*, and *S. frigidimarina* are ubiquinone-7 (11–51%), ubiquinone-8 (31–58%), and menaquinone-7 (5–52%), with small quantities of methylmenaquinone-7 (thermoplasmoquinone-7, 0–6%) also present (Itoh et al., 1985; Moule and Wilkinson, 1987; Akagawa-Matsushita et al., 1992a). This pattern distinguishes *Shewanella* spp. from other related bacteria, such as *Alteromonas* and *Pseudoalteromonas*, which contain mostly Q-8 (Akagawa-Matsushita et al., 1992a). Menaquinones appear to play an important role in anaerobic respiratory activity in *Shewanella* (Myers and Myers, 1993).

Polyamines The major polyamines found in *Shewanella* species are putrescine and cadaverine. This pattern differs from those of *Pseudoalteromonas* and *Alteromonas*, which, in addition to putrescine and cadaverine possess hydroxylated polyamine derivatives. *Moritella marina*, by comparison, possesses only cadaverine (Hamana, 1997).

Exopolysaccharides *S. putrefaciens* strain S29 possesses a phosphorylated exopolysaccharide made up of tetrasaccharide–phosphate repeating units consisting of 2-acetamido-2,6-dideoxyglucose and 4-acetamido-4,6-dideoxyglucose (Shashkov et al., 1997).

Pathogenicity *S. algae* and, less often, *S. putrefaciens* have been implicated occasionally in polymicrobial bacteremia and septicemia (Vogel et al., 1997) and are associated with a wide spectrum of clinical syndromes, such as surface and soft-tissue infections, eye infections, pneumonia, arthritis, peritonitis, and empyema (von Graevenitz and Simon, 1970; Debois et al., 1975; Holmes et al., 1975; Kim et al., 1989; Heller et al., 1990; Chen et al., 1991, 1997; Brink et al., 1995; Butt et al., 1997a; Dominguez et al., 1996; Yohe et al., 1997; Levy and Tessier, 1998). Hemolysin production by *S. algae* is believed to be an important factor contributing to the pathogenicity of this species (Khashe and Janda, 1998), but the exact details are yet to be resolved. *Shewanella*-like isolates have been proposed as a possible cause of lesions on some fish species (Subasinghe and Shariff, 1992; Mashima et al., 1997), although goldfish directly inoculated with a number of *Shewanella* strains have failed to exhibit any infection (Decostere et al., 1996).

Ecology *Shewanella* is a ubiquitous group of bacteria that has been isolated from a wide range of habitats. *S. putrefaciens* and its close relative *S. baltica* are among the major spoilers of chilled foods and are frequently isolated from a wide range of dairy, poultry, beef, and seafood products (Shewan, 1971; Lee et al., 1977; Molin and Ternström, 1982, Stenström and Molin, 1990;

Borch et al., 1996; Gram and Huss, 1996; Leroi et al., 1998). *Shewanella* has also been isolated from cutting and lubricating oils, oil brine, seawater, sediment, soil, ponds and lakes, sewage, and subsurface groundwater (Pivnick, 1955; Iizuka and Komagata, 1964b; Semple and Westlake, 1987; Aznar et al., 1992; DiChristina and DeLong, 1993; Höfle and Brettar, 1996; Pedersen et al., 1996a; Ziemke et al., 1997; Bowman et al., 1997a).

The exact isolation sites of *S. putrefaciens senso stricto* are unclear, owing to the species heterogeneity. The most common sites for isolation include various lightly salted food products, the coastal marine environment, freshwater sediments and overlying waters, and water and soil mixed with crude oil and other petroleum products (Semple and Westlake, 1987). A close relative of *S. putrefaciens*, *S. oneidensis* (Venkateswaran et al., 1998) has been isolated from lake sediment. Another close relative, *S. baltica*, appears to occur frequently in coastal marine environments. Genetic analysis of *S. baltica* (described in the study as *S. putrefaciens*) in Baltic Sea waters indicates the population is stable at the clonal level (Ziemke et al., 1997). Populations spike in correspondence with increased sulfur levels in the Baltic Sea and other locations (Nealson et al., 1991; Brettar and Höfle, 1993). *S. algae* comprises the bulk of strains isolated from clinical specimens (Nozue et al., 1992, Vogel et al., 1997), and this species has also been isolated from various saline habitats, including salt marshes (Rosselló-Mora et al., 1994a), oil brine (Semple and Westlake, 1987), surfaces of macroalgae (Simidu et al., 1990), seawater, and occasionally salted food products (Vogel et al., 1997). Most *Shewanella* species appear to be strictly marine in origin. *S. amazonensis* has so far been isolated only from coastal marine muds off the Brazilian coast. The bioluminescent species *S. woodyi* (Makemson et al., 1997), as well as other novel *Shewanella* strains, has been shown to be associated with the ink and reproductive organs of certain squid (*Loligo* spp.) (Leonardo et al., 1999). *S. woodyi* has also been isolated from seawater and organic detritus collected at depths of 200–300 meters in parts of the Mediterranean Sea. *S. colwelliana* has been isolated from cultured oysters and their vicinity in the Chesapeake Bay, United States (Weiner et al., 1988). Studies suggest that *S. colwelliana* can enter a symbiotic arrangement with a host oyster (Bonar et al., 1986).

A host of cold-adapted *Shewanella* species has been isolated from marine ecosystems. *S. frigidimarina* appears to be ubiquitous in the Antarctic marine environment and has been isolated from seawater, ice, sediments, and cyanobacterial mat communities of the southern ocean and continental, marine-derived lakes (Bowman et al., 1997a, b; Rea et al., unpublished). It has also been isolated from the deep sea (DeLong et al., 1997) and the North Sea (Reid and Gordon, 1999), as indicated by 16S rDNA sequencing of isolates. *S. gelidimarina*, by comparison, has a much more restricted distribution and inhabits diatom-rich communities found in coastal Antarctic sea ice (Bowman et al., 1997a). *S. hanedai* has also been isolated from Antarctic sea ice diatom communities, but was first isolated from sediments of the Arctic and Southern Oceans and from coastal areas of Canada (Jensen et al., 1980). Strains of *S. benthica* as well as *S. violacea* have been isolated from several deep-sea sites, including the Marianas Trench at a depth of nearly 11,000 m (Kato et al., 1995, 1996, 1998). This species has been found in water and sediment samples and organic detritus, but is most frequently associated with decaying deep sea invertebrates, including amphipods and holothurians (Deming et al., 1988a; DeLong et al., 1997).

Enrichment and Isolation Procedures

Most *Shewanella* species can be directly isolated from source material onto marine 2216 (Difco Laboratories) or nutrient agar (Oxoid) without prior enrichment. *Shewanella* colonies are often identifiable by their pale tan or pink-salmon color. *S. putrefaciens* and *S. algae* can be isolated semi-selectively from clinical and environmental samples on a medium containing 1% NaCl, 0.1% ox bile salts, and 1% peptone (Nozue et al., 1992). Nonfermentative, H_2S-producing isolates (which are usually positive for ornithine decarboxylase) can be further selected on deoxycholate–hydrogen sulfide–lactose medium (Eiken Chemical Co., Ltd., Tokyo, Japan). Additional selection for *S. algae* includes incubation at 40°C on nutrient agar containing 6% NaCl. The identification of *S. algae* strains can be confirmed by their α-hemolytic activity on sheep blood agar; strains can also be selected and isolated by plating clinical samples onto *Salmonella*–*Shigella* agar (Nozue et al., 1992). *S. putrefaciens* and *S. algae* strains and several other *Shewanella* species can also be enriched and isolated with iron-, nitrate- or sulfur-reducing media (see Procedures for Testing Special Characters). Alternatively, direct isolation can be performed anaerobically on S^0 reduction agar (Moser and Nealson, 1996) with transfer of growth to nutrient or marine agar.

A brief enrichment of samples in marine 2216 broth at 2°C for 1–2 d is advantageous for the isolation of psychrophilic species such as *S. gelidimarina* (Bowman et al., 1997a). *S. woodyi* and *S. hanedai* produce bioluminescence most effectively on marine agar, rather than on the standard glycerol-containing luminous medium normally used to detect bioluminescent *Vibrio* or *Photobacterium* spp. (Ruby et al., 1980; Hastings and Nealson, 1977).

Isolation of *S. benthica* involves a relatively straightforward method that can also be used to isolate barophilic species belonging to other genera (Sakiyama and Ohwada, 1997); it is similar to methods employed in other studies (DeLong and Yayanos, 1986; DeLong et al., 1997; Kato et al., 1995, 1996, 1998). Small portions of sediment or seawater filters are added to 0.5× marine 2216 broth in small, sterile polyethylene bags (Whirl-Pak, Nasco, USA) and heat sealed. The bags are then incubated at low temperatures (2–4°C) in stainless steel pressure vessels under a hydrostatic pressure equivalent to that at the isolation site. For further details on the use of high-hydrostatic-pressure culture equipment, see Yayanos et al. (1979, 1982). Strains are isolated and purified using marine 2216 broth solidified with 2% SeaPrep low-melting-point agarose (FMW Inc., Maryland, USA) or silica gel (Dietz and Yayanos, 1978) in tubes sealed with silicone rubber double stoppers and pressurized to about 30–70 mPa (300–700 atmospheres). Individual colonies are then cut out of the medium with a scalpel and transferred to fresh marine 2216 broth.

Maintenance Procedures

In general, *Shewanella* species are relatively robust and can be preserved and maintained in various ways in a carbohydrate-free medium in which they grow well, such as nutrient or marine agar. *Shewanella* species can be lyophilized using 20% skim milk as a cryoprotectant. In addition, strains can sustain viability for over 6 months when frozen in liquid nitrogen or cryopreserved at −80°C in broth containing 20–30% glycerol or DMSO. *S. algae* and *S. putrefaciens* strains can be maintained at 15–20°C in semisolid agar medium containing 0.1% Proteose peptone no. 3 (Difco Laboratories), 0.1% yeast extract, 0.05% phytone, 0.02% sodium thiosulfate, 0.005% sodium sulfite, 0.004% ferric citrate, and 0.3% agar dissolved in 3:1 aged seawater (or artificial sea

salts) and water; pH 7.6. (Simidu et al., 1990). *S. frigidimarina* and *S. gelidimarina* can be stored on marine agar slants or as heavy suspensions in sterile seawater at 2°C for 12 months or longer.

Procedures for Testing Special Characters

Dissimilatory iron reduction is a common property of *Shewanella* species and can be used in their isolation. Iron-reducing medium[1] Lovley and Phillips, 1988) supplemented with 0.05% yeast extract to boost growth can be used to test this property and to enrich for iron reducing strains. A variety of iron electron acceptors can be used, including amorphic ferric oxide, ferric citrate, and ferric pyrophosphate (Lovley and Phillips, 1986, 1988). These electron acceptors can be added separately or in combination. Electron donors that are typically utilized include organic acids, such as lactate, citrate, malate, etc. The addition of H_2 to the headspace can substantially stimulate growth (Caccavo et al., 1992). Samples are suspended in phosphate-buffered saline buffer or seawater and then sparged with nitrogen. The diluted sample is then added to the media by syringe or added under a stream of nitrogen, and vials or tubes are crimp sealed. Reduction of Fe^{3+} to Fe^{2+} is indicated by the change of the rust-colored medium to a clear solution that contains white (smectite or vivianite) or black (FeS_2, pyrite) precipitates. A similar approach can be used with other electron acceptors, such as nitrates[2] and MnO_2[3] (Lovley and Phillips, 1988).

Anaerobic sulfur reduction can be tested using a plate assay developed by Moser and Nealson (1996), which contains polysulfide[4]. Colonies within clearing zones on the sulfur plates can then be transferred to nutrient or marine agar for further purification with aerobic incubation.

1. Iron-reducing medium consists (per liter distilled water): $NaHCO_3$, 2.5 g; $CaCl_2·2H_2O$, 0.1g; KCl, 0.1 g; NH_4Cl, 1.5 g; NaH_2PO_4, 0.6 g; carbon source (acetate, lactate, citrate, etc.), 20 mM; trace element solution, 10 ml; and 200 mM amorphic ferric oxide. The medium is prepared with vigorous boiling and gassing with nitrogen to remove oxygen and dispensed into vials or tubes sealed with thick butyl rubber stoppers. Following autoclaving, the medium pH is about 6.7. The trace element solution (Balch et al., 1979) contains (per liter distilled water) nitriloacetate, 1.5 g; $MgSO_4·7H_2O$, 3 g; $MnSO_4·H_2O$, 0.5 g; NaCl, 1 g; $FeSO_4·7H_2O$, 0.1 g; $CoCl_2·6H_2O$, 0.1 g; $CaCl_2·.2H_2O$, 0.1 g; $ZnSO_4·7H_2O$, 0.1 g; $CuSO_4·5H_2O$, 0.01 g; $AlK(SO_4)_2·12H_2O$, 0.01 g; H_3BO_3, 0.01 g; $Na_2MoO_4·2H_2O$, 0.01 g; $NiSO_4·6H_2O$, 0.03 g; Na_2SeO_3, 0.02 g; and $Na_2WO_4·2H_2O$, 0.02 g. The nitriloacetate is dissolved in 500 ml distilled water and the pH is adjusted to 6.5 by KOH. The remaining salts are added one at a time, and the volume is brought up to 1 liter. Samples are added using Hungate techniques or in an anaerobic chamber. N_2/CO_2 (80:20) or $N_2/CO_2/H_2$ (80:10:10) can be used as the headspace atmosphere. For enrichment of marine samples, the medium is supplemented with 27 g/l NaCl and 3.7 g/l $MgCl_2$. Amorphic ferric oxide is prepared by neutralizing a 0.4 M $FeCl_3$ solution to pH 7 with NaOH. Ferric citrate can be used instead of amorphic ferric oxide and is added at 20 mM (with $CaCl_2·2H_2O$ omitted to prevent precipitation).

2. Nitrate-reducing medium: similar to iron-reducing medium, but with amorphic ferric oxide replaced by 20 mM KNO_3 ($CaCl_2·2H_2O$ is omitted to prevent precipitation).

3. Manganese-reducing medium: similar to iron-reducing medium, but with amorphic ferric oxide replaced by 15 mM MnO_2. The latter is prepared by slowly adding 30 mM $MnCl_2$ to 20 mM $KMnO_4$ with constant stirring.

4. For sulfur-reduction plates, the basal medium used is similar to iron-reducing medium, but the amorphic ferric oxide is omitted and the medium is supplemented with 0.5% Casamino acids and 1.5% agar. Immediately before dispensing the medium into plates, 40 mM polysulfide is added from a polysulfide stock (2.25 M total sulfur) prepared by adding 7.2 g sulfur flowers and 24 g $Na_2S·9H_2O$ to 100 ml boiling water and stirring for 15 min. After adding the polysulfide, the medium is left in air overnight to allow for sufficient precipitation of sulfur globules and to shift the pH back to neutrality. The medium is then inoculated and incubated anaerobically.

The ability to ferment carbohydrates is tested most effectively in the oxidation/fermentation medium of Leifson (1963), to which carbohydrates are added at a concentration of 0.5% (w/v). This medium is more sensitive than the usual Hugh and Leifson medium because it contains phenol red instead of bromothymol blue. Other biochemical and nutritional traits can be tested using standard procedures, provided that the incubation-temperature and Na^+-ion requirements are met.

Differentiation of the genus *Shewanella* from other genera

Characteristics that differentiate *Shewanella* from other members of the *Alteromonadaceae* are shown in Table BXII.γ.135 of the chapter describing the family. Due to the diversity of species, there are only a few properties shared by all the members of the genus, thus resulting in a potential for misidentification. Individually, most species possess sufficiently distinct properties (H_2S production, ornithine decarboxylase activity, psychrophily, etc.) to make them relatively easy to identify, assuming enough tests are employed. The generally nonfermentative nature of *Shewanella* species distinguishes them from members of the *Vibrionaceae*. *S. frigidimarina* is an exception; however, it lacks sheathed flagella and possesses a mol% G + C value lower than those of most *Vibrio* species. There is a possibility that *S. algae* can be confused with *Ferrimonas balearica*, but, unlike the latter, it can lyse sheep's blood, degrade gelatin, and tolerate 10% NaCl and is unable to produce phenylalanine deaminase (Rosselló-Mora et al., 1995a). In ambiguous cases, fatty acid analysis and/or partial 16S rRNA sequencing provides direct identification.

Taxonomic Comments

Phylogenetic trees based on 16S rRNA sequences of several *Shewanella* strains are shown in Fig. BXII.γ.156. Overall, two major groups are delineated within the genus, with *S. algae* and *S. amazonensis* (Venkateswaran et al., 1998), forming relatively distinct branches. One large group includes the psychrotolerant, nonhalophilic species *S. putrefaciens*, *S. baltica*, and *S. frigidimarina*. The second group includes the psychrotolerant and psychrophilic Na^+-requiring species *S. benthica*, *S. hanedai*, *S. gelidimarina*, *S. woodyi*, and *S. pealeana* (Leonardo et al., 1999). Overall, *Shewanella* is phylogenetically most closely related to the genera *Pseudoalteromonas*, *Alteromonas*, *Moritella*, *Ferrimonas*, and *Colwellia*, all of which are members of the family *Alteromonadaceae*.

DNA–DNA hybridization (Owen et al., 1978; Semple et al., 1989), ribotyping, and protein electrophoretic pattern analysis (Vogel et al., 1997) have shown the *S. putrefaciens* complex (not including *S. algae*) to be made up of at least three groups. DNA hybridization data for a variety of *S. putrefaciens* and related strains available in major culture collections are shown in Table BXII.γ.149. Other species, such as *S. algae* (Nozue et al., 1992; Vogel et al., 1997), *S. frigidimarina*, *S. gelidimarina*, and *S. hanedai* (Bowman et al., 1997b), each form genotypically distinct groups (Table BXII.γ.149).

S. putrefaciens was first described in 1931 as an *Achromobacter* species (Derby and Hammer, 1931), but was transferred to *Pseudomonas* because of its rod-like morphology, motility, and nonfermentative metabolism (Long and Hammer, 1941). Because its mol% G + C values are considerably lower than those of other pseudomonads (Levin, 1972), the species was reclassified as a species of *Alteromonas* (Lee et al., 1981a). Finally, based on 5S rRNA sequences, the species was renamed *S. putrefaciens* and designated the type species of the genus *Shewanella*. The description

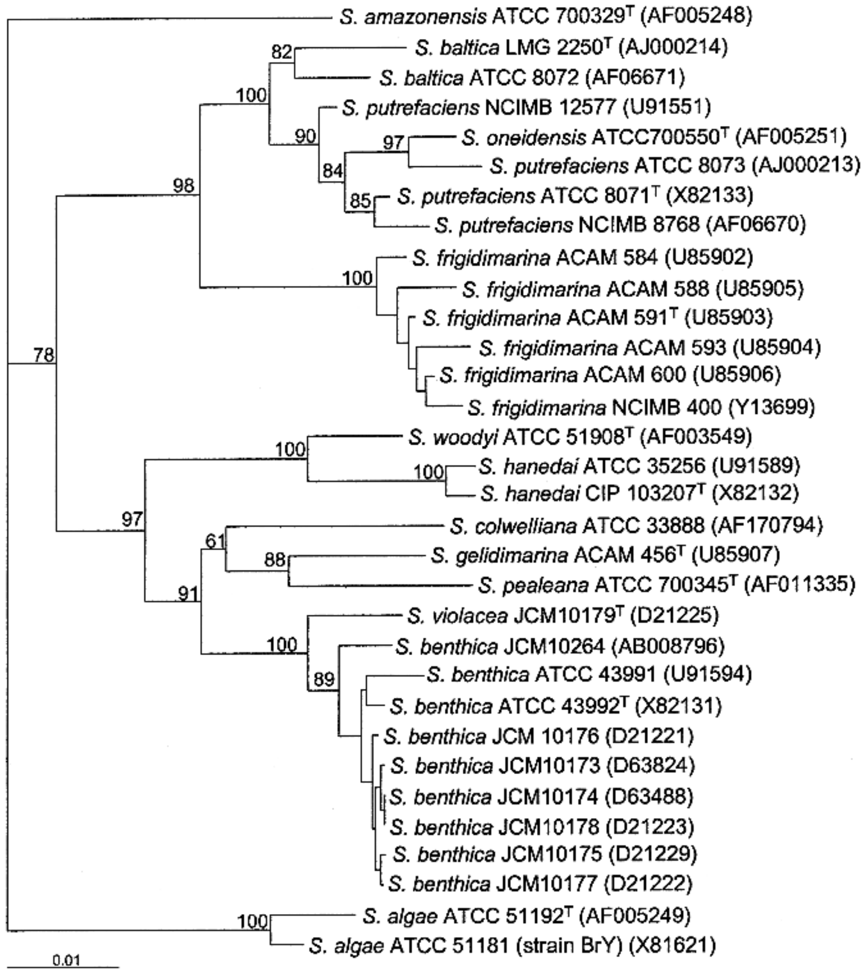

FIGURE BXII.γ.156. Phylogenetic tree of the genus *Shewanella* based on nearly complete 16S rRNA sequences. Species included are those validly published as of 2000. The tree was determined using maximum-likelihood distances and clustered by neighbor-joining. Numbers at branch nodes are bootstrap values (calculated from 250 replicate analyses). Only bootstrap values over 50% are shown. *T* denotes a type strain. Bar = distance of 0.01.

NCTC 10763 (bottled blood)			11		27		

[a]Data from Owen et al. (1978); Semple et al. (1989); Bowman et al. (1997b); Ziemke et al. (1998).

of this genus also included descriptions of *S. hanedai* (previously *Alteromonas hanedai*; Jensen et al., 1980) and *S. benthica* (MacDonell and Colwell, 1985). Although *Shewanella* was initially thought to be a member of the *Vibrionaceae* (MacDonell and Colwell, 1985; Farmer, 1992), 16S rRNA sequences have indicated that *Shewanella* is more closely related to the genus *Alteromonas* and its relatives (Kita-Tsukamoto et al., 1993; Gauthier et al., 1995a). *Shewanella colwelliana* was added to the genus following reassessment of its taxonomy using 5S rRNA sequences (Coyne et al., 1989). *S. algae* was created by Simidu et al. (1990) and has been subsequently emended by Nozue et al. (1992). *S. woodyi* (Makemson et al., 1997), *S. frigidimarina*, *S. gelidimarina* (Bowman et al., 1997b), and *S. baltica* (Ziemke et al., 1998) have only recently been described.

The nomenclature of *S. putrefaciens* is still evolving, but at the time of its renaming as *S. putrefaciens* it was a heterogeneous complex of strains. Owen et al. (1978) have demonstrated that *S. putrefaciens* comprises four DNA hybridization groups. In earlier phenotypic studies of *S. putrefaciens*, at least two groups, or "Gilardi" biovars, were observed. Gilardi biovar 2 includes mostly mesophilic clinical strains, which can grow at 42°C and tolerate 6% NaCl, but cannot utilize glucose or maltose. Gilardi biovars 1 and 3 include mostly food and environmental strains, which are psychrotrophic, saccharolytic, and unable to grow in the presence of 6% NaCl (Gilardi, 1972; Riley et al., 1972; Richard et al., 1985; Khashe and Janda, 1998). Subsequently, Nozue et al. (1992) have determined Gilardi biovar 2 to be comprised mainly of strains of *S. algae*, a species that is equivalent to Owen's DNA hybridization group IV. Additional data in the form of ribotypes and protein electrophoretic patterns indicate that strains belonging to DNA groups I, II, and III can be clearly distinguished from *S. algae* (Vogel et al., 1997). This corresponds well with the distinct phylogeny of *S. algae* and *S. putrefaciens* strains (Fig. BXII.γ.156). However, the resolution among DNA groups I, II, and III using the same procedures is quite poor (Vogel et al., 1997). These methods tend to suggest that *S. putrefaciens* is composed of a continuum of a series of genetically different strains. In their study of fish isolates, Stenström and Molin (1990) have claimed that numerical taxonomic analysis of phenotypic data does not correlate well with the hybridization groups of Owen et al. (1978); however, in the light of more recent data, this conclusion may be biased by their isolation of predominantly group II *S. putrefaciens* strains. Phenotypic analyses of *S. putrefaciens* by Semple and Westlake (1987) and Ziemke et al. (1998) suggest that phenotypic resolution of these groups may be possible, although DNA hybridization results (Semple et al., 1989) suggest that they are not necessarily definitive. For the purpose of completeness, phenotypic data differentiating the various DNA groups of *S. putrefaciens* are presented in Table BXII.γ.150. One limitation is that relatively few strains identified as belonging to group III have been examined. Based on 16S rDNA hybridization and the aforementioned phenotypic properties, group II strains have recently been given species status and named *S. baltica* (Ziemke et al., 1998). Overall, *S. baltica* represents a large proportion of isolates conforming to Gilardi biovars 1 and 3. From phylogenetic studies (Fig. BXII.γ.156), it is evident that heterogeneity remains in the vicinity of the type strain of *S. putrefaciens*, particularly among *S. putrefaciens* DNA group III strains (Venkateswaran et al., 1999).

The taxonomy of the remaining species is more clear-cut. Phenotypic differences can readily distinguish these species (Table BXII.γ.148), although data for *S. woodyi* are somewhat limited. DNA hybridization analysis has also not been performed between *S. hanedai* and *S. woodyi*.

Differentiation of the species of the genus *Shewanella*

Phenotypic characteristics that distinguish the different species and genomospecies of *Shewanella* are presented in Tables BXII.γ.148 and BXII.γ.150.

List of species of the genus Shewanella

1. **Shewanella putrefaciens** (Lee, Gibson and Shewan 1977) MacDonell and Colwell 1986, 355^{VP} (Effective publication: MacDonell and Colwell 1985, 180) (*Alteromonas putrefaciens* Lee, Gibson and Shewan 1977, 449.)
pu.tre.fa′ ci.ens. L. v. *putrefacere* to make rotten; L. part. adj. *putrefaciens* making rotten or putrefying.

Cells are rod-shaped, 0.5–1.0 × 1.5–2.0 μm. Colonies on nutrient agar are light tan to salmon pink, opaque, circular, convex with entire edges, and butyrous in consistency. NaCl is usually not required for growth. Can tolerate up to 6% NaCl. Does not require growth factors.

Mesophilic. Growth occurs between 10 and 40°C; optimum, 30–35°C.

Other characteristics are as given in the genus description and in Tables BXII.γ.148 and BXII.γ.150.

Isolated from fish, poultry, chilled meats, machine cutting oils, and freshwater and marine samples.

The current description of *Shewanella putrefaciens* incorporates at least two distinct genomospecies, including group I (*Shewanella putrefaciens stricto sensu*), group III, and probably other groups. Refer to Table BXII.γ.150 for phenotypic differentiation of groups I and III and to Fig. BXII.γ.156 for phylogeny.

The mol% G + C of the DNA is: 44–47 (T_m, Bd).

Type strain: 95, ATCC 8071, DSM 6067, ICPB 352, LMG 2268, NCIMB 10471.

GenBank accession number (16S rRNA): X82133, X81623.

2. **Shewanella algae** Simidu, Kita-Tsukomoto, Yasumoto and Yotsu 1990, 335^{VP} emend. Nozue, Hayashi, Hashimoto, Ezaki, Hamasaki, Ohwada and Terawaki 1992, 633.
al′ gae. L. gen. n. *algae* of an alga.

Cells are straight rods, about 0.8 × 1.6 μm. On marine agar, colonies are pale tan to salmon, circular, convex with an entire edge, and butyrous in consistency. Growth is stimulated by Na^+ ions, and NaCl concentrations of up to 12% are tolerated. Most strains can grow on *Salmonella–Shigella* agar.

Mesophilic. Growth occurs between 10 and 42°C.

Other characteristics are as given in the genus description and presented in Tables BXII.γ.148 and BXII.γ.150. In addition, strains also produce indophenol oxidase, lecithinase, deoxyribonuclease, and acid from D-ribose. Some

TABLE BXII.γ.150. Characteristics differentiating members of the *Shewanella putrefaciens* species complex, *S. baltica*, *S. algae*, and DNA hybridization Group III[a]

[b]Weak reaction.

strains can produce urease and give a positive Simmons citrate test. Alginate is not hydrolyzed. Acid is not formed from D-arabinose, L-arabinose, D-mannose, D-mannitol, *meso*-inositol, L-rhamnose, D-xylose, sucrose, maltose, or lactose.

Several environmental and clinical strains can produce 4-epi-tetrodotoxin.

Isolated from red algae (*Jainia* spp.), salt marsh surface sediments, and human clinical samples, including blood, pus, sputum, feces, and tissue samples.

The species is equivalent to *Shewanella putrefaciens* DNA hybridization group IV of Owen et al. (1978).

The mol% G + C of the DNA is: 52–54 (T_m).

Type strain: OK-1, ACAM 541, ATCC 51192, IAM14159.

GenBank accession number (16S rRNA): AF005249, U91546.

3. **Shewanella amazonensis** Venkateswaran, Dollhopf, Aller, Stackebrandt, Nealson 1998, 971[VP]
a.ma.zo.nen′sis. M.L. gen. n. *amazonensis* named after the area from the species was isolated.

Cells are rods, 0.4–0.7 × 2–3 μm. Colonies on marine agar are beige to pinkish, circular, convex with entire edges, and butyrous in consistency. No diffusible pigments are formed. NaCl is required for good growth, but cultures grow slowly in the absence of Na^+ ions. For optimal growth, about 1–2% NaCl is required. No growth occurs above 3% NaCl.

Psychrotolerant. Grows between 4 and 40°C; optimum temperature is approximately 37°C.

Other characteristics are as given in the genus description and in Tables BXII.γ.148 and BXII.γ.151. Can couple growth to reduction of S^0 and manganese oxide.

Isolated from oysters.

The mol% G + C of the DNA is: 52 (T_m).

Type strain: SB2B, ATCC 700329.

GenBank accession number (16S rRNA): AF005248.

4. **Shewanella baltica** Ziemke, Höfle, Lalucat and Rosselló-Mora 1998, 184.[VP]
bal′ti.ca. M.L. fem. adj. *baltica* of the Baltic Sea.

Cells are short, straight rods. On nutrient agar, colonies are pale tan, circular, convex with an entire edge, and butyrous in consistency. Do not require NaCl or organic factors for growth.

Psychrotrophic. Growth occurs between 4 and 30°C. No growth at 37°C.

Other characteristics are as given in the genus description and presented in Tables BXII.γ.148 and BXII.γ.150.

Isolated from brackish water, seawater, oil brine, fish and seafood products, and other food products.

The species is equivalent to *Shewanella putrefaciens* DNA hybridization group II of Owen et al. (1978).

The mol% G + C of the DNA is: 44–47 (T_m).

Type strain: CECT 323, DSM 9439, IAM 1477, LMG 2250, NCTC 10735.

GenBank accession number (16S rRNA): AJ000214.

5. **Shewanella benthica** MacDonell and Colwell 1986, 355[VP] (Effective publication: MacDonell and Colwell 1985, 180.)
ben′thi.ca. Gr. n. *benthos* deep sea; L. suff. *-ica* of or pertaining to; M.L. adj. *benthica* pertaining to the deep sea.

[b] *S. frigidimarina*, *S. gelidimarina*, and *S. hanedai* do not utilize DL-arabinose, L-rhamnose, lactose, melibiose, adonitol, *meso*-inositol, D-sorbitol, saccharate, isovalerate, caprylate, adipate, pimelate, azelate, DL-3-hydroxybutyrate, or aconitate. In addition, *S. hanedai* does not utilize D-galacturonate, *i*-erythritol, salicin, ethanol, *n*-propanol, *n*-butanol, propyleneglycol, malonate, glutarate, L-tartrate, benzoate, *m*-hydroxybenzoate, *p*-hydroxybenzoate, phenylacetate, quinate, β-alanine, L-arginine, L-citrulline, L-lysine, L-ornithine, L-valine, DL-δ-aminovalerate, ethanolamine, betaine, hippurate, sarcosine, or trigollenine.

Cells are slightly curved rods, 0.5 × 1.5–3.0 μm. Colonies on marine agar are off-white to pale tan, translucent, circular, convex with an entire edge, and butyrous in consistency. NaCl is required for growth. No growth occurs with 6% NaCl. Barophilic, growing optimally at 400–600 MPa. Grows slowly at atmospheric pressure.

Psychrophilic. Growth occurs at 0–10°C; optimum temperature, ~5°C at atmospheric pressure.

Other characteristics are given in the genus description and in Table BXII.γ.148.

Isolated from abyssal ocean water, sediments, organic detritus, and deep-sea invertebrates.

The mol% G + C of the DNA is: 47 (T_m).

Type strain: W 145, ATCC 43992, DSM 8812.

GenBank accession number (16S rRNA): X82131.

6. **Shewanella colwelliana** (Weiner, Coyne, Brayton, West and Raiken 1988) Coyne, Pillidge, Sledjeski, Hori, Ortiz-Conde, Muir, Weiner and Colwell 1990, 320[VP] (Effective publication: Coyne, Pillidge, Sledjeski, Hori, Ortiz-Conde, Muir, Weiner and Colwell 1989, 278[VP] (*Alteromonas colwelliana* Weiner, Coyne, Brayton, West and Raiken 1988, 242.)

col.well′ i.a.na. L. gen. n. *colwelliana* named after Rita Colwell for her contributions to marine microbiology.

Cells are straight or slightly curved rods, 0.7–1.5 × 1.0–3.0 μm long. Filamentous and helical cells occur in nutrient-poor media. Colonies on marine agar are circular to irregular, convex with undulate edges, and butyrous in consistency. A dark brown, melanin-like, diffusible pigment may be produced on complex growth media by some strains. NaCl is required for growth; optimal NaCl levels for growth are 2–4%. No growth with 6% NaCl. Amino acids are required for growth.

Mesophilic. Grows between 8 and 30°C; optimum temperature, approximately 25°C. Optimal pH for growth is 7.4–7.8.

Other characteristics are as given in the genus description and in Tables BXII.γ.148 and BXII.γ.151. In addition, phosphatase and deoxyribonuclease are produced. Elastin, casein, albumin, L-tyrosine, alginate, and chondroitin are not degraded. No activity detected for lecithinase or sulfatase. Gluconate oxidation, Voges–Proskauer, and chicken-cell agglutination tests are negative. Acid is not produced from carbohydrates.

Isolated from oysters.

The mol% G + C of the DNA is: 46 (T_m).

Type strain: LST-W, ATCC 39565.

Additional Remarks: ATCC 39565 is not currently available; however, a similar strain (ATCC 33888) is available from Dr. R. Weiner, University of Maryland, USA.

7. **Shewanella frigidimarina** Bowman, McCammon, Nichols, Skerratt, Rea, Nichols and McMeekin 1997b, 1045.^{VP}
fri.gid.i.ma.ri′na. L. adj. *frigidus* cold; L. fem. adj. *marina* belonging to the sea; M.L. adj. *frigidimarina* belonging to the cold sea.

Cells are curved or straight rods, 0.5–0.8 × 1.0–2.5 µm. Colonies on marine agar are tan, translucent, circular, convex with entire edges, and butyrous in consistency, but becoming increasingly mucoid with prolonged incubation. NaCl is not required for growth. Can tolerate up to 9% NaCl. Growth factors are not required.

Psychrotrophic. Growth occurs between <0 and 30°C; optimum temperature, ~20–22°C.

Other characteristics are as given in the genus description and in Tables BXII.γ.148 and BXII.γ.151. In addition, strains produce deoxyribonuclease and lecithinase and hydrolyze casein. Strains may degrade L-tyrosine and give a positive Simmons citrate test. Do not hydrolyze alginate, esculin, urea, urate, or xanthine. Acid is produced from cellobiose, maltose, D-mannitol, and sucrose. Strains may produce acid from trehalose, D-galactose, D-mannose, and D-xylose. Acid is not formed from L-arabinose, L-rhamnose, lactose, D-melibiose, D-melezitose, D-raffinose, dextran, *N*-acetylglucosamine, adonitol, *meso*-inositol, D-sorbitol, or glycerol. Resistant to 0.0075% KCN and 5% ox-bile salts.

Isolated from sea ice, seawater, marine sediments, and waters and sediments of saline meromictic lakes.

The mol% G + C of the DNA is: 40–43 (T_m).

Type strain: IC-P1, ACAM 591, DSM 12253.

GenBank accession number (16S rRNA): U85903.

8. **Shewanella gelidimarina** Bowman, McCammon, Nichols, Skerratt, Rea, Nichols and McMeekin 1997b, 1045^{VP}
ge.li.di.ma.ri′na. L. adj. *gelidus* ice-cold; L. fem. adj. *marina* belonging to the sea; M.L. adj. *gelidimarina* belonging to the icy sea.

Cells are curved or straight rods, 0.5–0.8 × 1.0–2.5 µm. Colonies on marine agar are light tan, opaque, circular, convex with entire edges, and butyrous in consistency. NaCl is required for growth. Can tolerate up to 6% NaCl. Growth factors are not required.

Psychrophilic. Growth occurs between <0 and 23°C in liquid media; no growth occurs at 20°C on agar media. Optimal temperature, approximately 15–17°C.

Other characteristics are as given in the genus description and in Tables BXII.γ.148 and BXII.γ.151. In addition, strains produce lecithinase and can hydrolyze casein. Strains may produce deoxyribonuclease. Simmons citrate and urease tests are negative. Unable to hydrolyze alginate, esculin, urate, or xanthine. Acid is produced oxidatively and fermentatively from *N*-acetylglucosamine and chitin, but not from other carbohydrates. Resistant to 0.0075% KCN and 5% ox-bile salts.

Isolated from sea-ice diatom blooms.

The mol% G + C of the DNA is: 40–43 (T_m).

Type strain: IC-P6, ACAM 456.

GenBank accession number (16S rRNA): U85907.

9. **Shewanella hanedai** (Jensen, Tebo, Baumann, Mandel and Nealson 1981) MacDonell and Colwell 1986, 355^{VP} (Effective publication: MacDonell and Colwell 1985, 180) (*Alteromonas hanedai* Jensen, Tebo, Baumann, Mandel and Nealson 1981, 382.)
han.e′dai. M.L. gen. n. *hanedai* of Haneda; named after Y. Haneda, a Japanese biologist who pioneered studies on bioluminescence.

Cells are rod-shaped, 0.5–1.0 × 1.5–2.0 µm. Colonies on marine agar are light tan, translucent, circular, convex with entire edges, and butyrous in consistency. NaCl is required for growth. Can tolerate up to 6% NaCl. Strains may require yeast extract or vitamins for growth.

Psychrophilic. Growth occurs between 0 and 25°C; optimum temperature, approximately 15°C.

Other characteristics are as given in the genus description and in Tables BXII.γ.148 and BXII.γ.151. In addition, alginate is not hydrolyzed.

Isolated from sediments and seawater of the Arctic Ocean, Southern Ocean, and western coast of Canada.

The mol% G + C of the DNA is: 44–47 (T_m).

Type strain: ATCC 33224, CIP 103207, DSM 6066.

GenBank accession number (16S rRNA): X82132, U91590.

10. **Shewanella oneidensis** Venkateswaran, Moser, Dollhopf, Lies, Saffarini, MacGregor, Ringleberg, White, Nishijima, Sano, Burghardt, Stackebrandt and Nealson 1999, 721^{VP}
o.nei.den′sis. M.L. gen. n. *oneidensis* named after Lake Oneida where the species was isolated.

Cells are rods, 0.5–0.6 × 2–3 µm. Colonies on nutrient agar are pinkish beige, circular, smooth, convex with entire edges, and butyrous in consistency. No diffusible pigments are formed. NaCl is not required for growth.

Grows between 4 and 40°C; optimum temperature, ~30°C.

Other characteristics are as given in the genus description and in Table BXII.γ.148. Can couple growth to the reduction of manganese oxide (Nealson and Saffarini, 1994) and S^0 (Moser and Nealson, 1996). Does not form indole, acetoin, alginase, arginine dihydrolase, or lysine decarboxylase. Utilizes D-galactose, but not D-fructose, citrate, D-mannitol, glycerol, D-sorbitol, DL-malate, or DL-lactate. Some strains can utilize lactose, succinate, and citrate.

Isolated from water and sediment of Lake Oneida, New York, USA and from clinical specimens.

The mol% G + C of the DNA is: 45 (T_m).

Type strain: MR-1, ATCC 700550.

GenBank accession number (16S rRNA): AF005251.

11. **Shewanella pealeana** Leonardo, Moser, Barbieri, Branstner, MacGregor, Paster, Stackebrandt and Nealson 1999, 1349^{VP}
peal′le.ana. M.L. adj. *pealeana* from *peale or pealei* the species name of the squid; *Loligo pealei* from which the bacterial species was isolated.

Gram negative. Cells are rods, 2.0–3.0 × 0.4–0.6 µm. Motile with a single polar flagellum. Colonies on marine agar are circular, opaque, and salmon-colored. Requires Na^+ ions for growth with biomass produced optimally at 0.5 M NaCl. Also requires choline chloride as an essential growth factor in minimal media. Grows between 0.125–0.75

M NaCl. Growth occurs at 4–30°C. Optimum growth temperature is 25°C. Grows between pH 6–8. Optimum pH for growth is 7.0.

Chemoheterotrophic facultative anaerobe. Can grow anaerobically using nitrate, fumarate, iron, manganese, TMAO, thiosulfate, and elemental sulfur as alternative electron acceptors with lactate acting as the carbon source. Catalase, oxidase, and lipase positive. Amylase and gelatinase negative. Glucose, galactose, lactate, acetate, pyruvate, citrate, succinate, glutamate, Casamino acids, yeast extract, and peptone are used aerobically as energy sources. Fructose, glycerol, sorbitol, arabinose, formate, and ethanol are not utilized.

Isolated from the accessory nidamental glands of female adults of the squid species *Loligo pealei*.

The mol% G + C of the DNA is: 45.0 (HPLC).

Type strain: ANG-SQ1, ATCC 700345.

GenBank accession number (16S rRNA): AF011335.

12. **Shewanella violacea** Nogi, Kato and Horikoshi 1999, 341[VP] (Effective publication: Nogi, Kato and Horikoshi 1998b, 337.)

vi.o.la' ce.a. L. gen. n. *violacea* of violet.

Cells are straight or slightly curved rods, 0.8–1.0 × 2–4 μm. Colonies on marine agar are circular, smooth, convex with entire edges, and butyrous in consistency. After 2–3 d, colonies are nonpigmented; after more than 7 d, colonies appear violet. NaCl is required for growth; optimal levels for growth are 2–3%. No growth with 6% NaCl.

Psychrophilic. Grows optimally between 4–10°C. Barophilic. Optimal pressure for growth is 30 MPa.

Other characteristics are as given in the genus description and in Table BXII.γ.148. Acid is produced from cellobiose and D-galactose, but not from DL-arabinose, D-fructose, glycerol, inositol, lactose, maltose, D-mannitol, D-mannose, D-raffinose, L-rhamnose, D-sorbitol, sucrose, D-trehalose, or D-xylose.

Isolated from the Ryukyu Trench, northwest Pacific Ocean, at a depth of 5110 m.

The mol% G + C of the DNA is: 47 (T_m).

Type strain: DSS12, JCM 10179.

GenBank accession number (16S rRNA): D21225.

13. **Shewanella woodyi** Makemson, Fulayfil, Landry, Van Ert, Wimpee, Widder and Case 1997, 1039[VP]

wood' y.i. M.L. gen. n. *woodyi* of Woody, in honor of the American biologist J. Woodland Hastings.

Cells are rod-shaped, 0.4–1.0 × 1.4–2.0 μm. Colonies on marine agar are pink-orange due to the accumulation of cytochromes. NaCl is required for growth. Growth factors are not required.

Psychrophilic. Growth occurs between 4 and 25°C; optimum temperature, 20–25°C; no growth at 30°C.

Other characteristics are as given in the genus description and in Tables BXII.γ.148 and BXII.γ.151.

Isolated from squid ink, seawater and marine snow (collected from the Alboran Sea).

The mol% G + C of the DNA is: 39 (by measurement of the relative binding of DNA-binding-fluorescent dyes bisbenzimide and chromomycin A3).

Type strain: MS32, ATCC 51908, DSM 12036.

GenBank accession number (16S rRNA): AF003549.

Order XI. **"Vibrionales"**

Vib.ri.o.na' les. M.L. masc. n. *Vibrio* type genus of the order; *-ales* ending to denote order; M.L. fem. pl. n. *Vibrionales* the order of bacteria whose circumscription is based on the genus *Vibrio*.

Description is the same as for the family *Vibrionaceae*.

Type genus: **Vibrio** Pacini 1854, 411.

Family I. **Vibrionaceae** Véron 1965, 5245[AL]

J.J. Farmer III and J. Michael Janda

Vib.ri.o.na' ce.ae. M.L. masc. n. *Vibrio* type genus of the family; *-aceae* ending to denote family; M.L. fem. pl. n. *Vibrionaceae* the family of bacteria whose circumscription is based on the genus *Vibrio*.

Gram-negative straight or curved rods. Motile by means of polar flagella. Additional lateral flagella may be produced when grown on solid media; these differ in wavelength and antigenicity from the polar flagellum and may number from a few to over 100 flagella/cell. Do not form endospores or microcysts. Chemoorganotrophs. Facultative anaerobes, having both a respiratory and a fermentative metabolism. Oxygen is a universal electron acceptor. Do not denitrify. Most strains: are oxidase positive, reduce nitrate to nitrite, ferment D-glucose and utilize it as a sole or principal source of carbon and energy, grow in minimal media with D-glucose or other compounds as the sole source of carbon and energy and use NH_4^+ as the sole nitrogen source. A few species require vitamins and amino acids. Ferment and utilize a wide variety of simple and complex carbohydrates and utilize a wide variety of other carbon sources. Most species require Na^+ or a seawater base for growth and require 0.5–3% NaCl for optimum growth. Several species are bioluminescent; other species include a few bioluminescent strains. Primarily aquatic. Found in fresh, brackish, and sea water, often in association with aquatic animals and plants. Several species are pathogenic for humans.

M NaCl. Growth occurs at 4–30°C. Optimum growth temperature is 25°C. Grows between pH 6–8. Optimum pH for growth is 7.0.

Chemoheterotrophic facultative anaerobe. Can grow anaerobically using nitrate, fumarate, iron, manganese, TMAO, thiosulfate, and elemental sulfur as alternative electron acceptors with lactate acting as the carbon source. Catalase, oxidase, and lipase positive. Amylase and gelatinase negative. Glucose, galactose, lactate, acetate, pyruvate, citrate, succinate, glutamate, Casamino acids, yeast extract, and peptone are used aerobically as energy sources. Fructose, glycerol, sorbitol, arabinose, formate, and ethanol are not utilized.

Isolated from the accessory nidamental glands of female adults of the squid species *Loligo pealei*.

The mol% G + C of the DNA is: 45.0 (HPLC).

Type strain: ANG-SQ1, ATCC 700345.

GenBank accession number (16S rRNA): AF011335.

12. **Shewanella violacea** Nogi, Kato and Horikoshi 1999, 341[VP] (Effective publication: Nogi, Kato and Horikoshi 1998b, 337.)

vi.o.la′ ce.a. L. gen. n. *violacea* of violet.

Cells are straight or slightly curved rods, 0.8–1.0 × 2–4 µm. Colonies on marine agar are circular, smooth, convex with entire edges, and butyrous in consistency. After 2–3 d, colonies are nonpigmented; after more than 7 d, colonies appear violet. NaCl is required for growth; optimal levels for growth are 2–3%. No growth with 6% NaCl.

Psychrophilic. Grows optimally between 4–10°C. Barophilic. Optimal pressure for growth is 30 MPa.

Other characteristics are as given in the genus description and in Table BXII.γ.148. Acid is produced from cellobiose and D-galactose, but not from DL-arabinose, D-fructose, glycerol, inositol, lactose, maltose, D-mannitol, D-mannose, D-raffinose, L-rhamnose, D-sorbitol, sucrose, D-trehalose, or D-xylose.

Isolated from the Ryukyu Trench, northwest Pacific Ocean, at a depth of 5110 m.

The mol% G + C of the DNA is: 47 (T_m).

Type strain: DSS12, JCM 10179.

GenBank accession number (16S rRNA): D21225.

13. **Shewanella woodyi** Makemson, Fulayfil, Landry, Van Ert, Wimpee, Widder and Case 1997, 1039[VP]

wood′ y.i. M.L. gen. n. *woodyi* of Woody, in honor of the American biologist J. Woodland Hastings.

Cells are rod-shaped, 0.4–1.0 × 1.4–2.0 µm. Colonies on marine agar are pink-orange due to the accumulation of cytochromes. NaCl is required for growth. Growth factors are not required.

Psychrophilic. Growth occurs between 4 and 25°C; optimum temperature, 20–25°C; no growth at 30°C.

Other characteristics are as given in the genus description and in Tables BXII.γ.148 and BXII.γ.151.

Isolated from squid ink, seawater and marine snow (collected from the Alboran Sea).

The mol% G + C of the DNA is: 39 (by measurement of the relative binding of DNA-binding-fluorescent dyes bisbenzimide and chromomycin A3).

Type strain: MS32, ATCC 51908, DSM 12036.

GenBank accession number (16S rRNA): AF003549.

Order XI. **"Vibrionales"**

Vib.ri.o.na′ les. M.L. masc. n. *Vibrio* type genus of the order; *-ales* ending to denote order; M.L. fem. pl. n. *Vibrionales* the order of bacteria whose circumscription is based on the genus *Vibrio*.

Description is the same as for the family *Vibrionaceae*.

Type genus: **Vibrio** Pacini 1854, 411.

Family I. **Vibrionaceae** Véron 1965, 5245[AL]

J.J. Farmer III and J. Michael Janda

Vib.ri.o.na′ ce.ae. M.L. masc. n. *Vibrio* type genus of the family; *-aceae* ending to denote family; M.L. fem. pl. n. *Vibrionaceae* the family of bacteria whose circumscription is based on the genus *Vibrio*.

Gram-negative straight or curved rods. Motile by means of polar flagella. Additional lateral flagella may be produced when grown on solid media; these differ in wavelength and antigenicity from the polar flagellum and may number from a few to over 100 flagella/cell. Do not form endospores or microcysts. Chemoorganotrophs. Facultative anaerobes, having both a respiratory and a fermentative metabolism. Oxygen is a universal electron acceptor. Do not denitrify. Most strains: are oxidase positive, reduce nitrate to nitrite, ferment D-glucose and utilize it as a sole or principal source of carbon and energy, grow in minimal media with D-glucose or other compounds as the sole source of carbon and energy and use NH_4^+ as the sole nitrogen source. A few species require vitamins and amino acids. Ferment and utilize a wide variety of simple and complex carbohydrates and utilize a wide variety of other carbon sources. Primarily aquatic. Found in fresh, brackish, and sea water, often in association with aquatic animals and plants. Several species are pathogenic for humans.

Other species are pathogenic for fish, eels, and other aquatic animals. The mol% G + C of the DNA is 38–51%. The family is classified in the phylum *Proteobacteria* in the class *Gammaproteobacteria*.

Type genus: **Vibrio** Pacini 1854, 411.

Historical overview A history of the family *Vibrionaceae* as it has appeared in *Bergey's Manual* is given in Table BXII.γ.152. Related families include *Enterobacteriaceae*, *Aeromonadaceae*, and *Pasteurellaceae*. The family *Vibrionaceae* has undergone intense study since the first edition of *Bergey's Manual of Systematic Bacteriology* (Krieg and Holt, 1984) was published in 1984. In their chapter on the family *Vibrionaceae* in that edition, Baumann and Schubert (1984) included the genera *Vibrio*, *Photobacterium*, *Aeromonas*, and *Plesiomonas*. These are the same four genera included in the original classification of the family proposed by Véron almost twenty years earlier (Véron, 1965). In this *Manual* *Aeromonas* and *Plesiomonas* are classified in other families (Table BXII.γ.152). For practical identification schemes, it is still useful to consider *Aeromonas* and *Plesiomonas* together with other oxidase positive genera of fermentative bacteria such as *Vibrio* and *Photobacterium* (Table BXII.γ.153). A detailed history of changes in the classification of *Vibrio* and related genera that occurred as new methods were introduced has been given by Farmer (1992). These methods include examinations of the structure, function, and regulation of proteins; comparison of mol% G + C content; DNA–DNA hybridization; rRNA–DNA hybridization; 5S rRNA cataloging and sequence comparisons; and 16S rRNA gene sequence comparisons (Fig. BXII.γ.157).

The family *Vibrionaceae* presently includes three genera:

Genus I. *Vibrio* (the type genus)
Genus II. *Photobacterium*
Genus III. *Salinivibrio*

The type strain of the type and only species of the genus *Allomonas*, *Allomonas enterica*, is very closely related to *Vibrio fluvialis* by DNA–DNA hybridization studies and phenotypic analysis (Kalina et al., 1984). *Allomonas* and *Allomonas enterica* are not described separately in this edition of the *Manual*; the reader is referred to the description of *V. fluvialis*. The two species of the genus *Listonella*, *Listonella anguillarum* (the type species) and *Listonella pelagia*, are included in the genus *Vibrio* in this edition of the *Manual* as *Vibrio anguillarum* and *Vibrio pelagius*.*

Further descriptive information

Habitats The ecological niches of members of the family *Vibrionaceae* have been described by Campbell (1957); Baumann and Baumann (1981a); Sakazaki and Balows (1981); and Simidu and Tsukamoto (1985)). In humans, some vibrios cause diarrhea, wound infections, and occasionally other extraintestinal infections. In aquatic animals, vibrios cause wound and generalized infections. Many vibrios and related organisms are also widely distributed in aquatic environments. Many factors govern the distribution of these organisms, but the most important probably include: particular human, animal or plant hosts; inorganic nutrients and carbon sources available; temperature; salinity; dissolved oxygen; and depth below the surface for the species that are found in the ocean (Simidu and Tsukamoto, 1985). A few species are adapted to particular hosts. For example, *Vibrio cholerae* serogroup O1 is adapted to humans and is the cause of cholera, a life-threatening diarrheal disease. Recent studies have shown that the ecology of this organism is more complex than originally thought. *Photobacterium leiognathi* is usually isolated from fish in shallow tropical water, and *P. phosphoreum* is usually found in the luminous organs of fish that live at depths of 200–1200 meters (Hastings and Nealson, 1981).

Isolation Most members of the *Vibrionaceae* grow well on ordinary complex media. Samples are spread onto solid medium or diluted in an enrichment broth. NaCl concentrations of 0.5–0.85% satisfy the requirements of most species, although a few require greater concentrations of NaCl. Incubation temperatures are also important. A few species grow only at temperatures <25°C; others grow at 25°C but not at 35–37°C. General and selective media for *Vibrionaceae* are described in the chapter on the genus *Vibrio*.

Identification Methods for the isolation and identification of *Vibrio* spp. from clinical specimens and non-clinical samples are discussed in detail in the chapter describing the genus *Vibrio*. Assignment of non-clinical isolates to a species can be problematic because over 50 species of *Vibrio* and *Photobacterium* must be considered and because comparative data for these organisms are sparse relative to data available for clinically important species.

The US Centers for Disease Control and Prevention maintain computer programs and databases for the identification of isolates subjected to a battery of 45–60 phenotypic tests; for details contact the *Vibrio* Laboratory at the CDC.

These alternatives to phenotypic methods are now being used routinely and have proven extremely useful in a research setting. It will be important to evaluate the sensitivity and specificity, and to understand the advantages and disadvantages of these methods. In the United States, the reporting of cultures from human specimens is subject to specific government regulations (the Clinical Laboratory Improvement Amendments of 1988), which has limited the application of these approaches in clinical and public health laboratories.

Acknowledgments

We dedicate this chapter to M. Véron for giving us the name *Vibrionaceae* and for all his contributions to our understanding of the family, its organisms, and their close and distant relatives.

Genus I. **Vibrio** *Pacini 1854, 411*[AL]

J.J. Farmer III, J. Michael Janda, Frances W. Brenner, Daniel N. Cameron and Karen M. Birkhead

Vib' ri.o. L. v. *vibrio* move rapidly back and forth, vibrate; M.L. masc. n. *Vibrio* the vibrating, darting organism.

Small, straight, slightly curved, curved, or comma-shaped rods, 0.5–0.8 × 1.4–2.6 μm. Involution forms often occur in old cultures and are formed under adverse growth conditions. Do not form endospores or microcysts. Gram negative. In liquid media, motile by monotrichous or multitrichous **polar flagella enclosed in a sheath** continuous with the outer membrane of the cell wall. **On solid media, some species synthesize numerous lateral flagella** with a wavelength shorter than that of the sheathed polar flagellum. **Facultative anaerobes** capable of both **fermentative and respiratory metabolism**. Molecular oxygen is a universal electron acceptor. Most do not denitrify or fix molecular nitrogen. All are chemoorganotrophs; most are able to **grow in a mineral medium containing D-glucose as the sole carbon source and NH^+ as the sole nitrogen source**. A few strains have organic growth factor requirements. **$Na_4{}^+$ stimulates growth of all species and is an absolute requirement for most**; the minimal concentration necessary for optimal growth ranges from 5 to 700 mM (0.029–4.1%). Most species grow well in media containing a seawater base. **All ferment D-glucose producing acid but rarely gas; several species produce acetoin and acetyl methyl carbinol (positive Voges–Proskauer test)**. Most ferment and utilize D-fructose, maltose, and glycerol; are **oxidase positive and reduce nitrate to nitrite**. Several grow at 4°C; all grow at 20°C; most grow at 30°C; many grow at 35–37°C. **A few species are bioluminescent**, as are a few strains of normally nonluminescent species. **Primarily aquatic**; species distribution is usually dependent on Na^+ and nutrient content of the water as well as its temperature. Very common in marine and estuarine environments and on the surfaces and in the intestinal contents of marine animals. Species with a low Na^+ requirement are also found in freshwater habitats. Twelve species occur in human clinical specimens; **11 of these are apparently pathogenic for humans, causing diarrhea or extraintestinal infections. Several species cause diseases of other vertebrates and invertebrates**.

The mol% G + C of the DNA is: 38–51.

Type species: **Vibrio cholerae** Pacini 1854, 411.

Further descriptive information

Cell morphology The cell morphology of *Vibrio cholerae* and related organisms has been studied extensively since *V. cholerae* was first depicted by Robert Koch. Examples of cell morphology, including cytoplasmic inclusions and cell surface features such as tubular appendages and "blebs", are shown in the section below describing flagella and in figures accompanying the species descriptions. Vibrios commonly appear as small, straight, slightly curved, curved or comma-shaped rods 0.5–0.8 × 1.4–2.6 μm in size. The amount of curvature is generally more pronounced in early stationary phase in liquid media than during exponential growth (Baumann et al., 1984b). However, considerable pleomorphism can occur. Some marine vibrios naturally have significant morphologic variation when grown in broth, and irregularly shaped bacilli co-exist with "involuted cells" that resemble L-forms (Onarheim et al., 1994). This phenomenon often occurs in stationary phase cultures (Farmer and Hickman-Brenner, 1992). Other halophilic species, including those associated with human disease, may form spherical or thin elongated forms in response to growth conditions containing suboptimal electrolyte (NaCl) concentrations. When vibrios are deprived of nutrients, a series of morphologic changes occurs over 1–7 days. Early events in this morphogenesis include a decreasing cell diameter

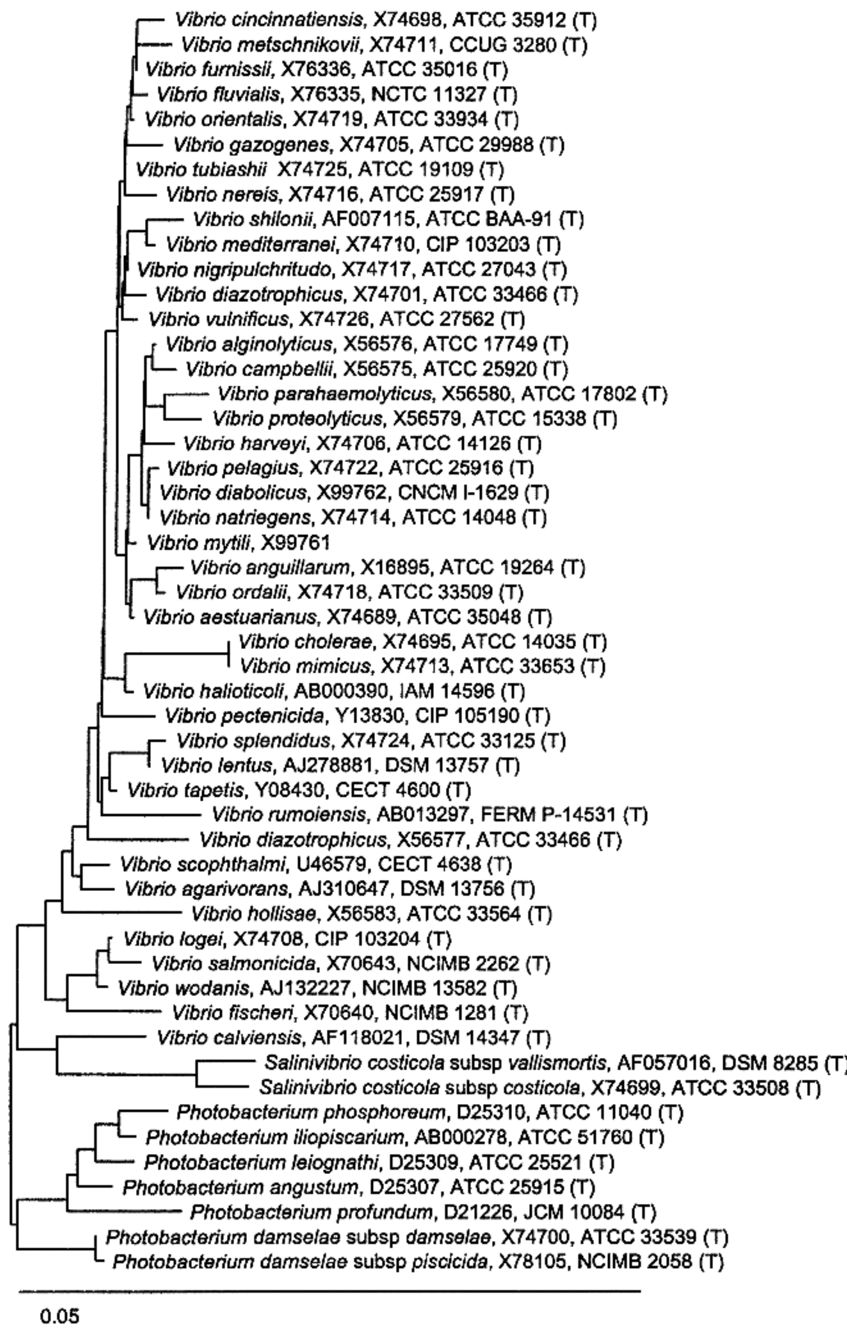

FIGURE BXII.γ.157. Relationship of most of the species of *Vibrio* and relatives based on 16S rRNA gene sequences.* Only the type strain of each species was included. The distances in the tree were calculated using 1101 positions (the least-squares method, Jukes-Cantor model). (Courtesy T. Lilburn of the Ribosomal Database Project.)

**Editorial Note: Photobacterium damselae* subsp. *damselae* is a junior objective synonym of *Vibrio damsela*. *Vibrio pelagius* and *Vibrio anguillarum* are synonyms of *Listonella pelagia* and *Listonella anguillarum*, respectively.

and volume (15–67%) and a conversion of rods into coccal forms called spherical ultramicrocells (Holmquist and Kjelleberg, 1993; Kondo et al., 1994; Nelson et al., 1997). As the length of nutrient starvation increases, cytoplasmic inclusions and granules disappear, cell cultivability decreases, and the nuclear region becomes compressed (Hood et al., 1986). There are also noticeable differences in the integrity of the outer membrane and cell wall. Some changes may be linked to specific nutrient starvation (for example, nitrogen starvation produces long filaments and phosphorus starvation produces swollen large rods), whereas others occur regardless of the type of nutritional stress (Holmquist and Kjelleberg, 1993). "Non-culturable" *V. cholerae* O1 strains produced in response to nutrient deprivation display a number of ultrastructural changes, which include an undulating outer membrane, a surface layer of fine fibers, and a thicker peptidoglycan layer (Kondo et al., 1994).

Poly-β-hydroxybutyrate granules (PHB) can be found in a number of *Vibrio* species, including *V. cholerae* O1 and O139 and *V. harveyi* (Hood et al., 1986; Sun et al., 1994; Finkelstein et al., 1997). In *V. cholerae*, accumulation of PHB appears to be related to colonial opacity and growth on glycerol-containing media (Finkelstein et al., 1997). In *V. harveyi*, PHB accumulation is dependent on cell density and is controlled by the autoinducer, *N*-(3-hydroxybutanoyl) homoserine lactone (Sun et al., 1994). Other kinds of granules can be found in vibrios, including electron dense lipoid particles and electron translucent inclusions of unknown composition (Sun et al., 1994; Finkelstein et al., 1997).

Cell wall composition Vibrios contain the same three lipopolysaccharide (LPS) elements found in other Gram-negative bacteria: lipid A, core polysaccharide, and an O polysaccharide side chain that determines serological specificity. The most extensive work on biochemical characterization of *Vibrio* LPS has been done on *V. cholerae*. The lipid A portion consists of a β(1′-6)-linked glucosamine disaccharide backbone with two phosphoryl groups (Janda, 1998). Pyrophosphorylethanolamine is linked to one of these phosphoryl groups at the C-1 position of the reducing sugar, and a phosphate group ester is bound to the nonreducing glucosamine residue (Manning et al., 1994). Three fatty acids are ester linked at hydroxyl positions to this disaccharide backbone: tetradecanoic acid ($C_{14:0}$), hexadecanoic acid ($C_{16:0}$), and 3-hydroxydodecanoic acid ($C_{12:0\ 3OH}$). A fourth, 3-hydroxytetradecanoic acid ($C_{14:0\ 3OH}$), is connected to the backbone by an amide bond.

The core oligosaccharide region of *V. cholerae* contains KDO (keto-3-deoxy-D-mannose-octulosonic acid), D-glucose, heptose (L-glycero-D-manno-heptose), D-fructose, and ethanolamine phosphate (Manning et al., 1994). KDO, a normal constituent of the core oligosaccharide of enteric LPS, was originally thought to be absent in *Vibrio* species. However, when conventional periodate-thiobarbituric acid tests were replaced by strong acid hydrolysates, KDO was detected in *Vibrio* (Janda, 1998). The KDO molecule of *V. cholerae* differs in several aspects from those of enteric bacteria such as *Escherichia coli* and the genus *Salmonella*: only a single KDO molecule has been detected in the core oligosaccharide of *V. cholerae*, and the KDO moiety is phosphorylated at the C4 position (Kondo et al., 1990; Manning et al., 1994). The C5 position binds to a distal portion of the core region (heptose) similar to the KDO-C5 binding of L-glycero-D-manno-heptose (Janda, 1998). The other sugars form the remaining portion of the core oligosaccharide region and often contain additional sugar substitutions at various positions.

The *O*-polysaccharide side chain of *V. cholerae* O1 is a homopolymer of D-perosamine (4,6-dideoxy-D-mannose) approximately 17–18 units in length (Manning et al., 1994; Knirel et al., 1997). The amino groups of perosamine units are commonly acetylated with 3-deoxy-L-glycero-tetronic acid. Another compound, quinovosamine, is thought to be a "capping sugar" on either the distal or the proximal end of the O antigen (Manning et al., 1994). An unusual sugar, 4-amino-4,6-dideoxy-2-*O*-methylmannose is present only in the LPS of serogroup Ogawa and may have a role in serological specificity (Itoh et al., 1994).

The LPS composition of *V. cholerae* O139—a second serotype capable of causing pandemic cholera—is remarkably similar to that of O1 (Hisatsune et al., 1993; Isshiki et al., 1996). The lipid A moieties of O1 and O139, including fatty acid substitutions, appear to be identical (Hisatsune et al., 1993). The core oligosaccharide region contains two subtle differences: the presence of 2-aminoethyl phosphate, which is the *O*-acetyl group, and the presence of a second fructose molecule (Knirel et al., 1997). The most profound differences between O-groups 1 and 139 occur in the *O*-polysaccharide side chain. Unlike serogroup O1, which has long *O*-polysaccharide side chains, *V. cholerae* O139 has a short chain LPS similar to "SR strains" (Knirel et al., 1997). These truncated side chains migrate with the core oligosaccharide-lipid A fraction in LPS SDS-PAGE gels (Waldor et al., 1994). Classic "ladder-like" profiles of silver stained LPS side chains in SDS-PAGE gels are absent in O139 strains (Hisatsune et al., 1993; Nandy et al., 1995). Perosamine, the main component of the O1 side chain, is also absent in O139 strains (Hisatsune et al., 1993); instead, the unique sugar colitose (3,6-dideoxy-L-galactose)—which is not found in any other *Vibrio* species—is the main side chain subunit in O139 strains (Hisatsune et al., 1993). The abbreviated *O*-polysaccharide side chain of *V. cholerae* O139 appears to be a hexasaccharide containing colitose residues and a cyclic phosphate group (Knirel et al., 1997). The LPS of other *Vibrio* species is similar in many aspects to that of O139. KDO-phosphate has been detected in *V. parahaemolyticus* by gas chromatography-mass spectrometry analysis (Janda, 1998). The O-polysaccharide side chains of *Vibrio* species produce only a single fast-migrating band on silver-stained SDS-PAGE gels (Amaro et al., 1992; Iguchi et al., 1995). This result suggests that the side chains are short; a chain length of ≤10 monosaccharides has been proposed for *V. parahaemolyticus* (Iguchi et al., 1995). Some species however (e.g., *V. vulnificus*) may exhibit ladder-like patterns by immunoblotting with whole cell antisera; this result suggests that the LPS *O*-polysaccharide side chains are acidic. Lambert et al. (1983) studied the cellular fatty acids of most of the *Vibrionaceae* and postulated that differences among the *Vibrio* species might prove useful for identification.

Flagella Two types of flagella are synthesized by vibrios in different environments. In liquid culture, swimmer cells predominate due to production of a single sheathed polar flagellum in most species (Figs. BXII.γ.158 and BXII.γ.159). The sheath is an extension of the outer membrane (Fig. BXII.γ.160). The polar flagella are 24–30 nm in diameter with a central core 14–16 nm in thickness with a wavelength of 1.4–1.8 μm (Baumann et al., 1984b; Janda, 1998). Some *Vibrio* species (e.g., *V. harveyi*, *V. fischeri*, *V. logei*, and *V. salmonicida*) produce tufts (3–12) of polar flagella (Fig. BXII.γ.161) with a wavelength of approximately 3.6 μm (Baumann et al., 1984b; Ishimaru et al., 1996). Polar flagella provide chemotactic motility in liquid media and derive their energy from the sodium membrane potential (McCarter, 1995). In some marine vibrios (e. g., *V. anguillarum*), the polar flagellum appears critical for disease production in estuarine fish (Milton et al., 1996; O' Toole et al., 1996). When vibrios come into contact with solid surfaces, a series of morphogenetic changes are initiated that result in the conversion of swimmer cells into swarmer cells in some marine species such as *V. parahaemolyticus*, *V. alginolyticus*, *V. diabolicus*, and *V. pectenicida* (Raguénès et al., 1997a; Lambert et al., 1998). During this process, cell septation ceases, the cells elongate from 1 to 30 μm, and numerous lateral flagella are formed (Fig. BXII.γ.162) (McCarter and Silverman, 1990). These lateral flagella, 14–15 nm in diameter with a wavelength of 0.9 μm, are distinct from polar flagella. They are unsheathed, have a different protein subunit composition, and are internally driven by the protonmotive force (Baumann et al., 1984b; McCarter, 1995). Formation of lateral flagella permits swarmer

migration across solid surfaces and results in progressive spreading of the bacterial colony (McCarter and Silverman, 1990), a phenomenon called swarming. Swarming in many vibrio species is dependent upon a number of factors including agar concentration, media composition, iron availability, temperature, and relative viscosity (Baumann et al., 1984b; McCarter and Silverman, 1990). The microscopic morphology of vibrio cells removed from different concentric zones of swarming has been studied in some *Vibrio* strains (Sar and Rosenberg, 1989). Innermost zones consist of irregular cells including bent rods that progressively evolve into short rods and then into large rods with bundles of detached flagella (Fig.BXII.γ.163), whereas cells in

the outermost circles of swarming colonies consist of long filamentous forms.

Fimbriae Fimbriae are produced by a number of pathogenic vibrios such as *V. cholerae* O1 and non-O1, *V. parahaemolyticus*, and *V. vulnificus* (Hall et al., 1988; Honda et al., 1988; Gander and LaRocco, 1989; Nakasone and Iwanaga, 1990). Several different morphologic types of fimbriae have been described in *V. cholerae* O1. These include both wavy pili 3 nm in diameter and rigid filaments 5–6 nm wide and 180–800 nm in length (Hall et al., 1988). The most important of these pili is composed of the protein TcpA; these pili are 5–6 nm wide and form bundles of parallel undulating filaments up to 15 μm long (Hall et al., 1988). TcpA formation is coregulated with cholera toxin expression and is a key determinant of *in vivo* colonization. The gene encoding TcpA appears to reside on a pathogenicity island.

Capsules Capsules have been detected surrounding cells of strains of *V. cholerae* O139 and *V. vulnificus* strains with a variety of staining techniques such as uranyl acetate, polycationic ferritin, and ruthenium red (Janda, 1998). The *V. vulnificus* polysaccharide capsule is 60 nm thick and has a low electron density (Amako et al., 1984; Hayat et al., 1993). The carbohydrate composition of the capsule of *V. vulnificus* varies from strain to strain. Sugars detected in different isolates include α-*N*-acetyl quinovosamine, α-*N*-acetyl galactosamine uronic acid, rhamnosamine, and fucosamine (Hayat et al., 1993).

Colonial morphology Most vibrios grow well on a variety of media, including protein-based agars and marine and seawater media, if sufficient Na^+ is present (Baumann et al., 1984b; Farmer and Hickman-Brenner, 1992). On most selective media, vibrios appear as smooth, buff-to-cream-colored colonies 2–5 mm in diameter, with an entire margin after overnight incubation (Baumann et al., 1984b; Janda, 1998). Some species tend to produce grayish colonies, particularly on blood agar. Considerable variation in colonial morphology has been reported for some species, and this is best demonstrated by observing colonies with a dissecting microscope at 10–25 magnification with oblique lighting. *V. cholerae* strains can have several different colonial morphologies (smooth, rough, and rugose forms) in response to different growth conditions. Rugose colonies are often chlorine-resistant. They are usually found in older cultures and are composed of an amorphous intercellular matrix of aggregated bacteria and exopolysaccharide material (Morris et al., 1996). Formation of rugose colonies can be enhanced by growth in enrichment broths such as alkaline peptone water (APW) or by picking the growth that has migrated up the sides of a culture tube. They can largely be avoided by picking a smooth colony and freezing it. In addition to these colony types, several path-

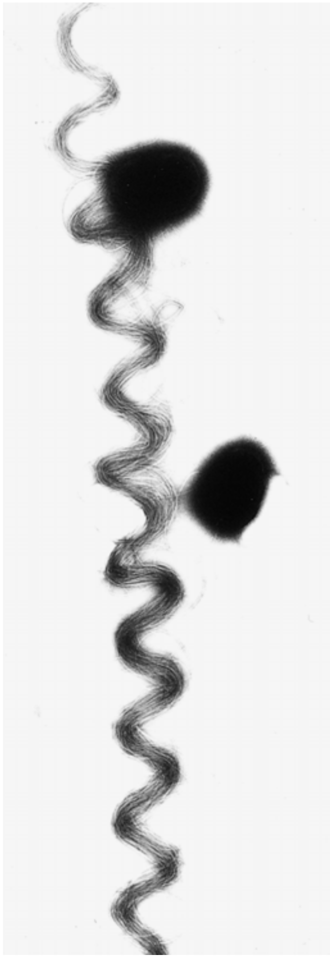

FIGURE BXII.γ.163. Large bundle of flagella in a culture of *Vibrio harveyi*. These bundles are frequently observed in cultures grown on solid medium. Negatively stained preparation. × 13,000. (Courtesy of R.D. Allen.)

ogenic vibrios, including *V. cholerae* and *V. vulnificus*, produce opaque and translucent varieties of smooth colonies on common media such as heart infusion and meat extract agars (Simpson et al., 1987; Finkelstein et al., 1992, 1997). Cells from colonies of these different morphologies differ from each other in a number of characteristics, including encapsulation, cell surface composition, cellular metabolism, and ability to survive under adverse conditions.

Pigmentation Several *Vibrio* species produce pigmented colonies. *V. nigripulchritudo* produces an insoluble blue-black pigment that accumulates in a crystalline form within the colonies (Baumann et al., 1984b). Other *Vibrio* species also produce blue-black crystals under various growth conditions, but typically do not produce the characteristic blue-black colonies of *V. nigripulchritudo*. Similar blue-black colonies are produced by a few strains of *Kluyvera* (Farmer et al., 1981a). Other pigmented species include *V. gazogenes* (red) and *V. fischeri* and *V. logei* (yellow-orange). A few strains of *V. cholerae* produce a brown diffusible melanin-like pigment (Ivins and Holmes, 1980).

Life cycles The marine environment is the natural habitat of vibrios, and the life cycle of these organisms is probably quite complex. A model for the life of *V. cholerae* in Gulf Coast estuaries has been proposed (Hood et al., 1984). Depending on nutrient scarcity and the density/availability of particulate matter, *V. cholerae* can exist in several states. An epibiotic form attached to plankton predominates during periods of relatively high nutrient/particulate matter concentrations; this form changes to a microvibrio form (small rounded cells) during times of nutrient and particulate deprivation (Hood et al., 1984; Janda, 1998). This latter form may be analogous to the "viable but nonculturable state" (Colwell, 1984) that has been described for many *Vibrio* species including *V. cholerae*, *V. parahaemolyticus*, *V. vulnificus*, *V. anguillarum*, *V. campbellii*, *V. harveyi*, and *V. fischeri* during colder seasons of the year (Oliver, 1995). The microvibrio and "nonculturable" stages may be dormant phases for vibrios in winter from which subsequent blooms are triggered in response to increasing temperatures in spring and summer. However, it is still unclear whether any dormant state actually exists and whether blooms are due to the growth of a small number of cultivable cells (present at all times) or the actual resuscitation of dormant cells (Ravel et al., 1995; Bogosian et al., 1998).

Nutrition and growth conditions *Vibrio* species vary in their nutrition and growth requirements. The most important feature is that Na^+ is required for or stimulates growth. Minimum concentrations of Na^+ required for optimal growth (Fig. BXII.γ.164) range from 5–15 mM (0.029–0.087%) for *V. cholerae* and *V. metschnikovii* to 600–700 mM (3.5–4.1%) for *Salinivibrio costicola* (Baumann et al., 1984b). Most species grow well in solid or liquid media containing 0.5–2% NaCl. Some species (*Photobacterium iliopiscarium*) form bacterial aggregates in broth culture containing 2% NaCl (Onarheim et al., 1994).

The "salt requirement" of a strain will often depend on the test conditions. The main variables are temperature, the growth medium used prior to testing, the suspending medium, and the testing medium. All *Vibrio* species except *V. cholerae* and *V. mimicus* have an absolute requirement for Na^+ (Fig. BXII.γ.164). In some instances, this requirement may be partially offset by concentrations of Mg^{2+} or Ca^{2+} similar to those normally present in seawater (Baumann et al., 1984b). However, most species exhibit a specific requirement for Na^+ (Pujalte and Garay, 1986; Borrego et al., 1996). The range and optimum concentrations of NaCl supporting growth of some of the more recently described *Vibrio* species are listed in Table BXII.γ.154. No single medium or NaCl concentration is optimal for the recovery or growth of all *Vibrio* species. Many vibrios will grow in mildly alkaline conditions. Although most species prefer a pH range of 7–8 (Raguénès et al., 1997a), some species, including *V. cholerae* and *V. metschnikovii*, will even grow at a pH of 10 (Baumann et al., 1984b).

Vibrios also vary in their temperature requirements for growth. Almost all *Vibrio* species grow well at 18–22°C. Some will grow at 0–4°C, whereas others can grow at temperatures up to 45°C. The temperature at which vibrios can grow is also dependent upon other factors including the composition of the medium and the NaCl concentration (Onarheim et al., 1994).

Most *Vibrio* species do not require specific organic growth factors such as vitamins or amino acids, although amino acid supplementation may be required to revive some strains stored for prolonged periods (Baumann et al., 1984b). Complex nutrients are required to induce growth of some species (Baumann et al., 1984b; Raguénès et al., 1997a). Such required supplements include yeast extract (for *V. anguillarum*, *Moritella marina*, and *V. logei*) and a seawater base (for *V. diabolicus*).

Vibrios use a variety of compounds as carbon and energy

[b]Nutritional versatility is the number of carbon compounds used as a sole energy source/number of compounds tested.

sources. Some of the newly described environmental species (*V. ichthyoenteri*, *V. scophthalmi*) and related organisms (*Photobacterium iliopiscarium*) can only utilize a small number of substrates (<10 compounds) as sole carbon or energy sources (Table BXII.γ.154), while other species utilize over 40 compounds. The carbohydrates utilized include polysaccharides, monosaccharides, disaccharides, and polyhydroxyl alcohols. Vibrios produce a variety of extracellular enzymes that degrade DNA, RNA, proteins, lipids, lecithin, mucin, chitin, agar, alginic acid, starch, and related compounds. They also produce biologically active molecules such as hemolysins, and other toxins.

Physiology and metabolism Vibrios and photobacteria are chemoorganotrophic, facultatively anaerobic bacteria that produce several different acids during fermentation. Common metabolic end products of D-glucose metabolism include formic, acetic, lactic, succinic, and pyruvic acids (Baumann et al., 1984b). Most vibrios ferment sugars without visible gas production ("anaerogenic" fermentation), although some species such as *V. furnissii*, *V. gazogenes*, *V. mytili*, *Photobacterium iliopiscarium*, and a few strains of *Vibrio damsela* produce CO_2 and H_2 as fermentation products. D-Glucose is transported into cells and phosphorylated to glucose-6-phosphate by the phosphoenolpyruvate:carbohydrate phosphotransferase (PTS) system (Postma et al., 1993). A number of other sugars are transported by the glucose–PTS system in *Vibrio* species including trehalose, D-fructose, D-mannose, and D-mannitol (Postma et al., 1993; Sarker et al., 1994). In *V. parahaemolyticus* the glucose–PTS is constitutive or partially inducible. A second mechanism for glucose transport in *V. parahaemolyticus* has been recently identified (Sarker et al., 1994). This Na^+/glucose symport system is stimulated by Na^+ and to a lesser extent by Li^+. D-Galactose, α-D-fucose, and methyl-α-glucosidase also appear to be transported by this mechanism, whereas D-glucose partially represses this Na^+/glucose symport

system. A number of aromatic compounds are degraded by the *meta*-cleavage of the intermediate protocatechuate by the α-ketoacid pathway (Baumann et al., 1984b). All *Vibrio* species except *V. metschnikovii* and *V. gazogenes* are oxidase positive; possession of this trait is correlated with the presence of cytochrome *c* systems (Baumann et al., 1984b). Cytochromes *b*, *c*, *d*, *o*, and a_1 occur in *V. cholerae*, *V. anguillarum*, *V. natriegens*, and *V. alginolyticus*. A number of different *c*-type cytochromes (*c4*, *c5*) have been shown to be present in some species based upon data from *N*-terminal amino acid sequencing of proteins and spectral analysis (Petushkov and Lee, 1997). *V. metschnikovii*, which is oxidase negative, lacks *c*-type cytochromes (Baumann et al., 1984b). *V. alginolyticus* possesses an ubiquinol oxidase of the cytochrome *bo*-type, which may function as a proton pump in the respiratory chain (Miyoshi-Akiyama et al., 1993).

Vibrios can acquire iron for growth by producing iron chelating molecules termed siderophores. Many *Vibrio* species including *V. cholerae*, *V. anguillarum*, *V. parahaemolyticus*, *V. fluvialis*, and *V. mediterranei* produce catechol-like siderophores called vibriobactins (Amaro et al., 1990; Guerinot, 1994). Less often, some *V. cholerae* non-O1, *V. parahaemolyticus*, and *V. fluvialis* strains produce a second hydroxymate-type siderophore. In *V. mimicus* and *V. hollisae* this hydroxymate-type siderophore has been identified as aerobactin (Okujo and Yamamoto, 1994). In *V. anguillarum*, a siderophore, called anguibactin is produced; anguibactin has both catechol and hydroxymate moieties (Guerinot, 1994). In addition to these iron chelators, vibrios can acquire iron by non-siderophore-dependent mechanisms. Ferric citrate can be actively transported into the cell by some vibrios via a non-inducible energy-dependent system (Mazoy et al., 1997). A number of other compounds can also serve as sole iron sources; these compounds include ferrichrome, hemoglobin, and saturated ferritin and transferrin (Simpson and Oliver, 1987; Fouz et al., 1994; Guerinot, 1994).

Several *Vibrio* species have a constitutive arginine-dihydrolase system. All *Vibrio* species produce a single iron-containing superoxide dismutase (Baumann et al., 1984b). The first cysteine protease in a *Vibrio* species has recently been identified in a luminous strain of *V. harveyi* isolated from a diseased tiger prawn (Liu et al., 1997c).

Bioluminescence A striking property of some *Vibrio* strains is the ability to emit yellow to blue-green light in response to certain environmental triggers. Bioluminescent marine species include *V. fischeri*, *V. harveyi*, *V. logei*, and *V. splendidus*. Light is produced as a consequence of the oxidation of the reduced flavin mononucleotide $FMNH_2$ and long-chain aliphatic aldehydes (Hastings and Nealson, 1977). The enzyme catalyzing this reaction is luciferase, an 80,000 MW heterodimer composed of an α (42,000 MW) and a β (38,000 MW) subunit; the α subunit contains the site of catalytic activity (Baumann et al., 1984b). Considerable *N*-terminal amino acid sequence homology exists (57–71%) between the α and β subunits of different luminescent species. At least 35–40% homology also exists between heterologous subunits; this fact suggests that these sequences originally arose from the duplication of a common ancestral gene (Baumann et al., 1984b).

Bioluminescence in marine *Vibrio* species is dependent upon quorum sensing (Stevens and Greenberg, 1997). Quorum sensing involves the ability of bacterial species to recognize relative population densities in their immediate environment and to induce specific cell functions once certain bacterial concentrations have been achieved (Stevens and Greenberg, 1997). In seawater, the concentrations of *V. fischeri* are $<10^2$ cells/ml and bioluminescence is not induced (Kolibachuk and Greenberg, 1993). However, *V. fischeri* also exists in symbiotic associations with marine animals such as the bobtail sepiolid squid. This symbiotic association may be regulated by ADP-ribosyltransferases halovibrin α and β, which could act as signaling molecules in the symbiosis between *V. fischeri* and the squid (Reich et al., 1997). In the light organ of the squid (Fig. BXII.γ.165), population sizes of *V. fischeri* may reach 10^{10}–10^{11} cells/ml and luminescence is induced (Kolibachuk and Greenberg, 1993; Ruby and Lee, 1998).

In vivo, luminescence is triggered when autoinducers reach critical intracellular levels. *N*-(3-oxohexanoyl) homoserine lactone and *N*-(3-hydroxybutanoyl) homoserine lactone are the autoinducers for *V. fischeri* and *V. harveyi* respectively (Sun et al., 1994). The cells are freely permeable to these compounds. At high cell densities, greater concentrations of autoinducers accumulate intracellularly and trigger the expression of specific luminescence genes (Kolibachuk and Greenberg, 1993). Two genes activated in this process are *luxI* and *luxR* (Stevens and Greenberg, 1997). *luxI* encodes an autoinducer synthetase and *luxR* encodes an autoinducer-dependent activator of luminescence genes (Stevens and Greenberg, 1997). *luxR* activates transcription from the promoter of the *lux* operon, which contains seven genes. LuxR is a 250-amino acid polypeptide containing two separate domains. The N-terminal region of LuxR binds the autoinducer; this binding then allows the C-terminal region to activate transcription of the *lux* operon (Stevens and Greenberg, 1997).

Genetics Recent studies employing pulsed-field gel electrophoresis (PFGE), representational difference analysis, and restriction fragment length polymorphism indicate that there are major differences in genome size and composition between *V. cholerae* El Tor, O1, and O139 (Choudhury et al., 1994; Calia et al., 1998). The estimated genome size of *V. cholerae* O1 (3.0 Mb) is at least 500 Kb larger than that of the El Tor biotype (Choudhury et al., 1994). Recent construction of the physical map of a classical biotype strain, *V. cholerae* 395 (Ogawa), by PFGE of genomic DNA digested with I-*CeuI*, *SfiI*, and *NotI* indicates a substantially larger chromosome (4.0 Mb) than previously estimated for this biotype (Trucksis et al., 1998).

Furthermore, it appears that both the classical and El Tor biotypes of *V. cholerae* O1 contain two unique and circular megareplicons rather than a single chromosome (Trucksis et al., 1998). Generation of novel or emerging pandemic strains of *V. cholerae* may occur *in vivo* by transduction. The chromosomal genes for cholera toxin are located on the pathogenicity island CTXΦ, which actually represents the genome of a transducing filamentous bacteriophage (Waldor and Mekalanos, 1996; Mekalanos et al., 1997). It is postulated that new strains may arise as a result of recombination in the intestinal tract of humans simultaneously coinfected with both toxigenic and nontoxigenic strains of *V. cholerae*. A second bacteriophage, K139, belongs to the kappa family of bacteriophages and can be found in a number of *V. cholerae* isolates, including O139 (Mekalanos et al., 1997; Calia et al., 1998). This bacteriophage carries a *glo* gene that encodes for a G-related protein of unknown function. Other large segments of *V. cholerae* chromosomal DNA may be involved in genetic exchange between strains. The pathogenicity island VPI, which houses the structural gene for the toxin coregulated pilus, may have arisen in *V. cholerae* by horizontal gene transfer

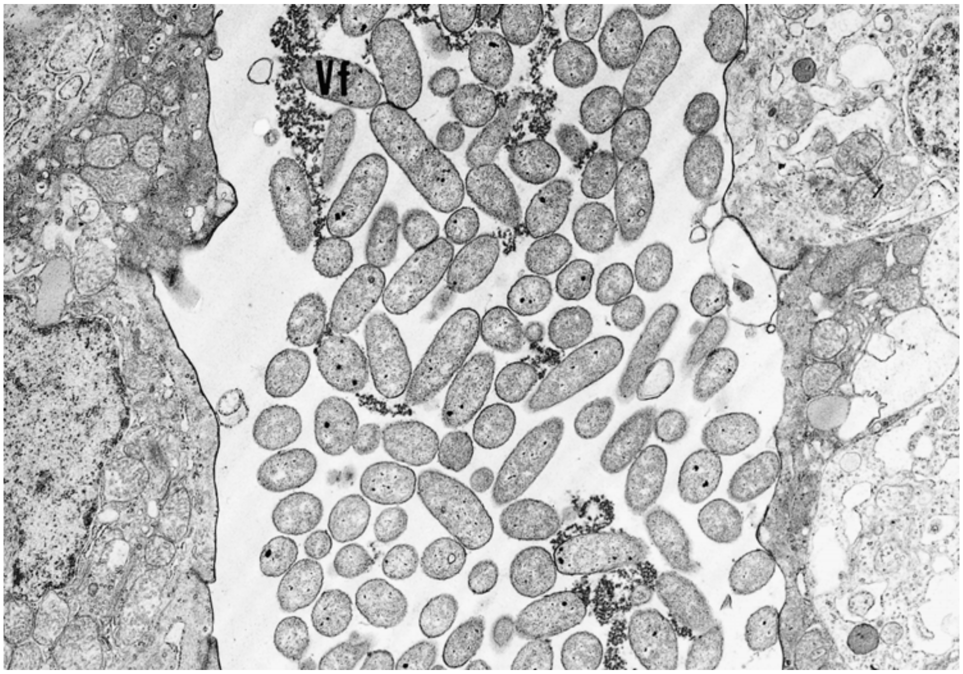

FIGURE BXII.γ.165. Ultrathin section through the luminous organ of *Monocentris japonicus* showing many cells of *Vibrio fischeri*. (× 9000). (Courtesy of K.H. Nealson and B.M. Tebo.)

from a heterologous species and may be transmissible (Mekalanos et al., 1997). A filamentous bacteriophage, designated VPIϕ, carries the VPI pathogenicity island (Karaolis et al., 1999). VPIϕ can be transferred between some *V. cholerae* strains, and the toxin coregulated pilin subunit of the pathogenicity island, TcpA, appears to be a coat protein of VPIϕ. Thus, it appears that the VPIϕ encodes for a protein (toxin coregulated pilus) that serves as a surface receptor for entry of a second phage, CTXΦ, into the bacterial cell. These findings suggest a sequential infection process of the bacterial cells by the two bacteriophages, a scenario which may lead to the emergence of new pathogenic strains of *V. cholerae*.

A 62-Kb chromosomal region, the SXT element, specifies resistance to streptomycin, trimethoprim, and sulfamethoxazole and can be transferred between *V. cholerae* strains by an unknown cell-dependent mechanism (Mekalanos et al., 1997). Transformation of *V. cholerae* strains with plasmids is very inefficient, presumably due to the large amounts of extracellular deoxyribonuclease (DNase) produced. However, transformation of DNase-negative strains using electroporation has been successful (Marcus et al., 1990). Conjugal mating in *V. cholerae*, which is mediated by sex factor P, is another potential mechanism of genetic exchange (Baumann et al., 1984b).

Filamentous phages have been isolated from a number of *V. cholerae* O139 strains (Honma et al., 1997; Shimodori et al., 1997; Jouravleva et al., 1998). These phages contain either single- or double-stranded DNA molecules ranging in size from 6.3 to 9.3 Kb. An open reading frame in one of these filamentous phages codes for a potential protein of 384 amino acid residues that has significant homology to the *zot* gene of *V. cholerae* (Honma et al., 1997). This finding suggests that such filamentous phage might play important roles in the horizontal transmission of genetic information between O1 and O139 strains (Jouravleva et al., 1998).

Current information on the genetics of other *Vibrio* species, although limited, suggests that gene transfer occurs among phylogenetically distant species. The thermostable direct hemolysin of *V. parahaemolyticus* has been detected in a number of vibrios including *V. cholerae* non-O1, *V. mimicus*, and *V. hollisae* (Nishibuchi et al., 1996). In the case of *V. cholerae* and *V. mimicus*, horizontal gene transfer from *V. parahaemolyticus* to these species appears to have occurred recently and to have been mediated by insertion sequence-like elements flanking the *tdh* genes. The *V. hollisae tdh* gene, exhibits significant sequence divergence from *tdh* genes of other *Vibrio* species; this finding suggests an earlier stable transfer of this hemolysin to the former group. Analysis of six *Salinivibrio costicola* strains indicates that the genome size varies from 2.1 to 2.6 Mb and that the DNA is highly methylated (Mellado et al., 1997). DNA methylation in *Salinivibrio costicola* might be affected by salt concentrations present in growth medium.

Mutants Chemical mutagens have been used *in vivo* and *in vitro* to generate mutants of both pathogenic and non-pathogenic *Vibrio* species. Compounds used include *N*-methyl-*N*′-nitro-*N*-nitrosoguanidine, ethylmethane sulfonate, and hydroxylamine (Baumann et al., 1984b; Iida et al., 1995). The Kappa-type lysogenic bacteriophages VcA-1, VcA-2, and VcA-3 have been exploited to generate "random" mutations in the chromosome of *V. cholerae* (Guidolin and Manning, 1987). Insertion of these bacteriophages into bacterial DNA inactivates the genes into which the prophage has been inserted. This process is analogous to that seen with bacteriophage phage Mu. Transposons have been successfully used to construct isogenic mutants in vibrios. The Tn*phoA* system has been used to produce *V. cholerae* mutants in chromosomal iron-regulated genes expressed on the cell surface and gene fusions for important colonization factors such as TcpA (Taylor et al., 1987; Goldberg et al., 1990). However, many strains

of some species such as *V. vulnificus* are refractory to transposon mutagenesis.

Plasmids P plasmids are conjugative extrachromosomal elements in *V. cholerae* that are capable of self-transfer from P^+ to P^- cells (Guidolin and Manning, 1987). Stable integration of P into the host cell DNA does not occur. P plasmids are approximately 68 Kb in size; the exact function of these plasmids is presently unknown. Possession of P plasmids has been linked to attenuated virulence in *V. cholerae* and is associated with decreased TCP pilus production (Bartowsky et al., 1990).

In a study of over 100 *V. cholerae* O1 strains, only 2% were found to contain plasmids (Newland et al., 1984). In contrast, 21–33% of the strains of *Vibrio cholerae* non-O1 examined contained extrachromosomal elements (Newland et al., 1984; Barja et al., 1990; Dalsgaard et al., 1995). Most plasmids are of low molecular weight (2.5 to 22 Kb) (Barja et al., 1990; Dalsgaard et al., 1995). The function of these small plasmids is not known, although some large plasmids (>170 Kb) have been detected which carry genes encoding antibiotic resistance determinants and genes for cytotoxin production (Barja et al., 1990). *V. parahaemolyticus* and *V. vulnificus* infrequently harbor plasmids (Twedt et al., 1981; Davidson and Oliver, 1986). Strains of *Vibrio damsela*, *V. metschnikovii*, and *V. furnissii* commonly contain plasmids (Dalsgaard et al., 1996; 1997; Pedersen et al., 1997). Large plasmids of 190–200 kb have been detected in both *Vibrio damsela* and *V. metschnikovii*, but their function is unknown. Plasmids have also been detected in *V. fischeri*, *V. salmonicida*, *V. ordalii*, and *V. anguillarum* (Giles et al., 1995; Pedersen et al., 1996c). Most strains of *V. anguillarum* serogroup O1 have a 65–67-Kb plasmid named pJM1; this plasmid is a major virulence factor in hemorrhagic septicemia disease in salmonid fish (Litwin and Calderwood, 1993). pJM1 encodes several proteins associated with iron acquisition, including the siderophore anguibactin and an outer membrane receptor protein OM2. Plasmidless derivatives have reduced virulence. A 32-Kb cryptic plasmid is found in most *V. ordalii* strains, although some restriction fragment length polymorphism exists (Pedersen et al., 1996b). A few *Salinivibrio costicola* strains carry multiple plasmids ranging in size from 3–21 Kb up to a megaplasmid of undetermined mass; however, most strains of *S. costicola* do not harbor extrachromosomal elements (Mellado et al., 1997).

Phages and phage typing Temperate bacteriophages active against many *V. cholerae* strains serve as the basis for several phage-typing schemes. Only the scheme of Murkerjee has been used widely to type the classical biovar of *V. cholerae* (Baumann et al., 1984b). A typing system based on lytic phages originally developed by Murkerjee and Basu for *Vibrio cholerae* El Tor has been expanded to provide greater sensitivity (Chattopadhyay et al., 1993); the modified scheme incorporates five new phages as well as modifications of the protocol. Of 1000 *V. cholerae* O1 biogroup El Tor strains tested, >99% could be placed in one of 146 different phage types.

V. cholerae O139 isolates have a capsule and thus they are not usually lysed by choleraphages active against *Vibrio cholerae* O1. Albert et al. (1996) isolated an O139-specific bacteriophage named JA1 that lysed 119 of 122 *V. cholerae* O139 strains. Two Tn*phoA* mutants of *V. cholerae* O139 that lacked the O antigen and capsular polysaccharide were not lysed by phage JA1; this result suggests that the capsule is the receptor for this choleraphage (Albert et al., 1996). A typing scheme for *V. cholerae* O139 strains has been devised based upon the responses of strains to five lytic phages (Chakrabarti et al., 1997); over 60% of the isolates fell into only one of eight phage patterns.

Bacteriocins and bdellovibrios Little recent work has been done on vibriocins. *Enterococcus faecalis*, *Enterococcus faecium*, and *Enterococcus durans* produce substances that are active *in vitro* against *V. cholerae* O1 and non-O1 (Simonetta et al., 1997). The activity is abolished by pre-treatment with proteases, but is resistant to 100°C for 30 min.

A number of *Vibrio* species serve as hosts for predatory marine *Bdellovibrio* strains (Baumann et al., 1984b; see the chapter describing the genus *Bdellovibrio*). The ability of bdellovibrios to lyse *V. parahaemolyticus* strains is temperature dependent; this finding suggests one possible explanation for the seasonal life cycle of this halophile (Joseph et al., 1982).

Antigenic structure As in the *Enterobacteriaceae*, the antigenic structure of *Vibrio* species is defined on the major classes of bacterial antigens: somatic (O), capsular (K), and flagellar (H), which are associated with the bacterial lipopolysaccharide, extracellular layer or capsule, and flagellum respectively (Janda, 1998). Within *V. cholerae* there are over 180 defined O antigens, but serotypes O1 and O139 contain all strains that have caused all large epidemics and pandemics of cholera (Shimada et al., 1994b; Yamai et al., 1997). Strains of *Vibrio cholerae* O1 can be further differentiated into two subtypes designated Ogawa and Inaba, which have antigenic formulas of the AB and AC type, respectively (Table BXII.γ.155; Shimada et al., 1994b). A third, unstable, antigenic type, Hikojima, with serofactors A, B, and C, has also been described (Janda, 1998). The "Hakata" group of *V. cholerae* possesses the C (Inaba) factor but not B (Ogawa) or A (common major O1 antigen) factors and has been designated as serogroup O140 by Shimada et al. (1994b). O serogroups 22 and 155 also share antigenic factors with O139 strains (Shimada et al., 1994b). The flagellar antigens of *V. mimicus* are identical or very similar to those of *V. cholerae*, and most *V. mimicus* strains fall into recognized O-groups of *V. cholerae*.

V. parahaemolyticus strains are differentiated serologically based on O and K (capsular) antigens. At present, 13 O antigens and more than 60 K antigens are recognized (Hisatsune et al., 1993; Janda, 1998). Compositional analysis of the lipopolysaccharide component of *V. parahaemolyticus* serogroups suggests that the side chain consists of no more than 10 monosaccharides (Iguchi et al., 1995). All serogroups produce R-type lipopolysaccharide. Carbohydrate analysis of Sephadex G-50 fractions indicates that glucose, L-glycero-D-manno-heptose, and D-glucuronic acid are common to all 13 serogroups (Iguchi et al., 1995). Serogroup-

TABLE BXII.γ.155. Antigenic serofactors of *Vibrio cholerae* O1: subtypes Ogawa, Inaba, and Hikojima

Serotype O1 subtype	O factors present in culture	Agglutination in absorbed serum:	
		Ogawa[a]	Inaba[a]
Ogawa	A, B	+	−
Inaba	A, C	−	+
Hikojima[b]	A, B, C	+	+

[a]The specific O factor sera are prepared by absorption. For example, an Ogawa antiserum is prepared by injecting an Ogawa culture, and then absorbing the resulting antiserum with an Inaba culture, which removes the antibodies to O serofactor A, leaving antibodies to O serofactor B.

[b]Most authors do not recognize subtype Hikojima and report cultures as either Inaba or Ogawa, based on which serum causes the fastest and strongest agglutination.

related sugars include fucose, arabinose, D-glycero-D-manno-heptose, D-glucosamine, D-galactosamine, 3-amino-3,6-dideoxyglucose, 3-amino-3,6-dideoxygalactose, 2-keto-3-deoxy-D-threo-hexonic acid, and 2-keto-3-deoxyoctonic acid (Iguchi et al., 1995).

Serologic typing schemes have been developed by the National Institutes of Health in Tokyo, Japan for several of the more commonly isolated *Vibrio* species. *V. vulnificus* strains can be subdivided into one of 7 O antigen groups (Shimada and Sakazaki, 1984). Most *V. vulnificus* (90%) were typable by this system, with O groups 1 and 4 predominating. Some strains have a heat-labile masking antigen that inhibits O agglutination reactions (Shimada and Sakazaki, 1984). All O antisera contain R antibody. The flagellar antigens of all *V. vulnificus* strains examined are identical. An international typing scheme composed of 35 serotypes has been developed for *V. fluvialis* and *V. furnissii* (Shimada et al., 1991). Some serotypes are apparently identical to those of *V. cholerae* O6, O39, and O41. Serogroup O19 possesses the C (Inaba) factor of *V. cholerae* O1 but not A or B (Shimada et al., 1987). At least 16 serogroups of *V. anguillarum* are presently recognized; O1 and O2 occur worldwide (Grisez and Ollevier, 1995). All strains of *V. ordalii* belong to O-group 2 of *V. anguillarum*. Flagellins from the polar flagella of many *Vibrio* species share common antigenic determinant(s): these species include *V. cholerae*, *V. mimicus*, *V. metschnikovii*, *V. harveyi*, *V. campbellii*, *V. parahaemolyticus*, *V. alginolyticus*, *V. anguillarum*, *V. fischeri*, *V. splendidus*, *V. nigripulchritudo*, and *Salinivibrio costicola* (Baumann et al., 1984b).

Antibiotic sensitivity There are surprisingly few detailed descriptions of the *in vitro* antibiotic susceptibility of halophilic and nonhalophilic *Vibrio* species. Most recent reports highlight only the susceptibility patterns of clinically significant groups (Morris et al., 1985; Clark, 1992; Farmer and Hickman-Brenner, 1992) although some other species, notably *V. harveyi* (now known to be same as the clinically important species *V. carchariae*), have been studied to some extent (French et al., 1989; Liu et al., 1997b). Most studies indicate that most vibrio isolates, regardless of species designation, are susceptible to tetracyclines, aminoglycosides (gentamicin), chloramphenicol, monobactams, carbapenems, quinolones, and nalidixic acid (Table BXII.γ.156) (Clark, 1992; Farmer and Hickman-Brenner, 1992; Janda, 1998). Widespread resistance to sulfa-containing antimicrobials, trimethoprim, penicillin, carbenicillin, ampicillin, and older cephalosporins has been reported and is often linked to specific species or groups (French et al., 1989; Farmer and Hickman-Brenner, 1992). Resistance to newer cephalosporins such as cefotaxime and ceftazidime is less common (French et al., 1989). Cefotaxime and minocycline show a synergistic activity that inhibits the growth of one clinical isolate of *V. vulnificus in vitro* (Chuang et al., 1997). Discrepancies in the literature regarding the susceptibility of *Vibrio* species to various chemotherapeutic agents may be related to test methodology or geographical variation. In a study of 240 strains representing nine *Vibrio* species, about 60% of all isolates expressed a β-lactamase based upon the nitrocefin test; >95% of all *V. alginolyticus* and *V. splendidus* were β-lactamase-positive, whereas <10% of *V. fluvialis* produced this enzyme (French et al., 1989).

Since the late 1970s, increasing drug resistance in *V. cholerae* has been reported. Outbreaks of disease in Bangladesh and Tanzania caused by multiresistant strains of *V. cholerae* O1 El Tor have been reported (Morris et al., 1985; Janda, 1998). These strains carry R factors encoding resistance to many common antimicrobial agents including ampicillin, chloramphenicol, and tetracycline. Drug resistance in these strains has been linked to possession of an IncC plasmid (Janda, 1998). Many isolates (>30%) of *V. cholerae* O1 from an outbreak of cholera in the western hemisphere were resistant to chloramphenicol, doxycycline, tetracycline, and trimethoprim-sulfamethoxazole. Large conjugative plasmids of the IncC group were detected in these strains. An unusual strain of *V. cholerae* O1 El Tor isolated during the same outbreak was resistant to cefotaxime and could transfer this resistance to *E. coli* by conjugation. After an outbreak of cholera in India in the 1990's due to *V. cholerae* O139, resistance of *V. cholerae* O1 strains to co-trimoxazole (trimethoprim-sulfamethoxazole), nalidixic acid, and chloramphenicol increased dramatically compared to O1 strains isolated prior to this epidemic (Mukhopadhyay et al., 1995). These findings suggest rapid emergence of drug resistance in *V. cholerae* facilitated by mobile genetic elements. However, studies have not shown a link between drug resistance in *V. cholerae* (non-O1) and plasmid carriage (Dalsgaard et al., 1995).

Early isolates of *V. cholerae* O139 from India and Bangladesh had different antibiotic susceptibilities (Yamamoto et al., 1995). Most strains were resistant to trimethoprim, sulfamethoxazole, and streptomycin. Six strains (3.5%) carried R factors mediating resistance to tetracycline, ampicillin, chloramphenicol, kanamycin, and gentamicin. Resistance markers were carried on a 200-kb self-transmissible plasmid of incompatibility group C. All plasmids were identical by restriction endonuclease analysis using *Eco*RI and *Sal*I. Most *V. cholerae* O139 strains isolated between 1993 and 1994 carried resistance to co-trimoxazole, furazolidone, and ampicillin (Mukhopadhyay et al., 1995; Albert et al., 1997; Vijayalakshmi et al., 1997). However, beginning in 1995 and continuing into 1996 with the resurgence of *V. cholerae* O139 in India, a change in susceptibility to antimicrobial agents was detected. Unlike previous isolates, strains isolated beginning in 1995 were susceptible to co-trimoxazole but still resistant to ampicillin and furazolidone (Mitra et al., 1996; Mukhopadhyay et al., 1996). These later strains were also resistant to neomycin (95%), streptomycin (85%), and to tetracycline (25%). These data indicate continued temporal shifts in phenotypes and resistance patterns associated with *V. cholerae* O139.

Sensitivity to pteridine compounds, particularly 2,4-diamino-6,7-diisopropylpteridine (commonly known as vibriostatic agent O/129, or simply as O129), varies among vibrios. Intrinsic resistance to O/129 occurs in a number of *Vibrio* species including *V. furnissii*, and *V. fluvialis* (Farmer and Hickman-Brenner, 1992). Recently acquired resistance to pteridine compounds has risen dramatically in previously susceptible species. Studies from Japan and India on *V. cholerae* O1 and non-O1 isolates recovered in Southeast Asia between 1973 and 1983 found only rare strains (1.3–1.8%) resistant to both the 10 μg and 150 μg concentrations of O/129 available in commercial discs (Sundaram and Murthy, 1983; Matsushita et al., 1984). By the early 1990s, widespread resistance (63–83%) to O/129 at both concentrations had been found in water, plankton, and fecal isolates of *V. cholerae* O1 from India, Bangladesh, and Malaysia (Huq et al., 1992; Ramamurthy et al., 1992; Mahalingam et al., 1993). Resistance to O/129 has been associated with concomitant resistance to co-trimoxazole and/or trimethoprim and has been found to be associated with transmissible R plasmids (Matsushita et al., 1984; Ramamurthy et al., 1992; Mahalingam et al., 1993).

TABLE BXII.γ.156. Antibiotic susceptibility patterns of the 12 *Vibrio* species that occur in human clinical specimens*

Antibiotic[b]	Percentage of strains susceptible:[a] *V. cholerae*[c] (480)	*V. alginolyticus* (69)	*V. cincinnatiensis* (14)	*Vibrio damsela* (21)	*V. fluvialis* (25)	*V. furnissii* (9)	*V. harveyi* (2)	*V. hollisae* (34)	*V. metschnikovii* (22)	*V. mimicus* (75)	*V. parahaemolyticus* (144)	*V. vulnificus* (130)
Penicillin G (12–21)	2	0	0	0	0	0	0	97	9	3	0	2
Ampicillin (12–13)	87	0	36	52	32	11	0	100	31	97	12	99
Carbenicillin (18–22)	64	0	7	14	16	0	0	100	27	8	1	54
Cephalothin (15–17)	98	32	100	76	40	0	100	100	100	100	17	65
Colistin (9–10)	4	25	93	76	100	100	0	100	91	61	11	2
Tetracycline (15–18)	98	94	93	86	88	89	100	97	73	100	98	99
Sulfadiazine (13–16)	26	16	36	71	36	11	50	56	5	17	3	28
Chloramphenicol (13–17)	99	100	100	10	88	100	100	100	100	100	100	100
Streptomycin (12–14)	60	54	86	24	84	100	50	100	32	61	17	42
Kanamycin (14–17)	92	62	79	43	88	100	100	100	14	89	37	53

Nalidixic acid (14–18)	99	97	100	100	100	100	100	100	100	99	99	99

[a]Studied at the CDC *Vibrio* Laboratory and done on Mueller–Hinton agar (with no added NaCl) at 35–37°C.

[b]The numbers in parentheses give the zone size range for the category intermediate. For example, (12–21) means that resistant strains have 6- to 11-mm zones, strains of intermediate susceptibility have zones that are 12- to 21-mm, and susceptible strains have zones of 22 mm or larger. These particular break points are the ones established in the early 1970s for each antibiotic, and they have been used in the CDC *Vibrio* Reference Laboratory for almost 30 years for taxonomic studies. They may differ slightly from current break points for use in treating human infections. Therefore, these data should only be used as an aid in identifying cultures.

[c]The number of strains studied is given in parentheses.

**Editorial Note: Photobacterium damselae* subsp. *damselae* is a junior objective synonym of *Vibrio damsela*.

Pathogenicity Several *Vibrio* species cause diarrhea or infections of the gastrointestinal tract (Table BXII.γ.157) and a number of reviews are available (Morris and Black, 1985; Janda et al., 1988; Kaper et al., 1995). Symptoms can range from mild bouts of enteritis to a fulminant secretory diarrhea with vomiting such as cholera gravis, which is associated with some *V. cholerae* O1 infections (Kaper et al., 1995). The two most frequently isolated enteric pathogens of this group are *V. cholerae*, the etiologic agent of pandemic cholera, and *V. parahaemolyticus*, a major cause of foodborne disease, particularly in Japan and South East Asia (Joseph et al., 1982). Epidemiologic and other data strongly suggest that *V. mimicus*, *V. hollisae*, and *V. fluvialis* can cause diarrhea or infections of the gastrointestinal tract (Abbott and Janda, 1994b; Hlady and Klontz, 1996). *Vibrio furnissii* and occasionally other species have been isolated from feces of people with diarrhea, but there is no strong evidence that these other species can actually cause intestinal infections.

TABLE BXII.γ.157. Worldwide occurrence of 12 *Vibrio* species in human clinical specimens*

Species	Occurrence in human clinical specimens:[a] Intestinal	Extraintestinal
V. cholerae		
Serogroups O1 and O139	+ + + +	+
Serogroup non-O1	+ +	+ +
V. alginolyticus	+	+ +
V. cincinnatiensis	−	+
V. damsela	−	+ +
V. fluvialis	+ +	−
V. furnissii	+ +	−
V. harveyi (*V. carchariae*)	−	+
V. hollisae	+ +	−
V. metschnikovii	−	+
V. mimicus	+ +	+
V. parahaemolyticus	+ + + +	+
V. vulnificus	+	+ + +

[a]The symbols +, + +, + + +, and + + + + give the relative frequency of each organism in specimens, and apply to the world, rather than to a particular country.

**Editorial Note: Photobacterium damselae* subsp. *damselae* is a junior objective synonym of *Vibrio damsela*.

V. cholerae O1 is the causative agent of pandemic cholera. Of the seven pandemics recorded since 1817, both the fifth (1881–1896) and sixth (1899–1923) pandemics were attributed to the classical biovar (Kaper et al., 1995). The seventh pandemic, which is ongoing (1961–present), is caused by *V. cholerae* O1 biogroup El Tor. It has been suggested that a second serogroup, O139, has pandemic potential, but O139 is currently restricted to epidemic disease in the Indian subcontinent and South East Asia (Swerdlow and Ries, 1993; Albert, 1994). Despite their similarities in disease presentation, significant evolutionary divergence exists between these groups. Differences in chromosomal structure and DNA sequences of housekeeping genes indicate that the classical and El Tor biotypes are only distantly related to each other on a short-term evolutionary basis (Mekalanos et al., 1997). Representational difference analysis further indicates that *V. cholerae* O139 is more closely related to the El Tor biogroup than the classical and El Tor biogroups are related to each other (Calia et al., 1998).

Infection with *V. cholerae* O1 and O139 can result in gastrointestinal disease of varying severity (mild diarrhea, enteritis, cholera) although most infected persons (60–75%) are clinically asymptomatic (Kaper et al., 1995). Detection and control of such unapparent illnesses can be critical in preventing the spread of sporadic cases to produce outbreaks or epidemics. Two critical regions of DNA on the chromosomes of both *V. cholerae* O1 and O139 are responsible for the pandemic potential of strains of

these biotypes as well as the ability to cause cholera in susceptible populations. Both regions are located in pathogenicity islands (Groisman and Ochman, 1996; Mekalanos et al., 1997). The first island, designated CTXΦ (cholera toxin), is a 7000–9700 bp region encoding at least six genes (Waldor and Mekalanos, 1996; Mekalanos et al., 1997). The most important of these gene products is cholera toxin, an oligomeric protein (MW 84,000) composed of five B subunits (*ctxB*) and one A subunit (*ctxA*). The B subunit binds holotoxin to the cell receptor, whereas the A subunit provides toxigenic activity intracellularly after proteolytic cleavage into 2 peptides, A_1 and A_2. Internal activation of the A_1 peptide results in ADP-ribosyltransferase activity leading to altered ion transport and hypersecretion of water and Cl^- into the lumen of the intestine. A number of excellent reviews on various aspects of the cholera toxin have been published (Spangler, 1992; Kaper et al., 1995; Sears and Kaper, 1996; Scott et al., 1996). The structural genes for the CTX element have recently been shown to reside on a filamentous phage, CTXΦ (Waldor and Mekalanos, 1996). This indicates that toxigenic *V. cholerae* can arise *de novo* by horizontal gene transfer, which presumably occurs in the gastrointestinal tract. Other genes located in this virulence cassette region include an accessory cholera toxin (*ace*), a zonula occludens toxin (*zot*), core encoded pilin (*cep*), and an open reading frame of unknown function (Janda, 1998). An RTX toxin gene cluster (hemolysins/leukotoxins) in *V. cholerae* El Tor is tightly linked to the cholera toxin prophage but is enzymatically independent of the CTX element (Lin et al., 1999). The toxin RtxA exhibits cytotoxic activity against HEp-2 cells. Classic strains that lack this cytotoxic activity contain a deletion in the RTX gene cluster involving *rtxA* (toxin) and *rtxC* (activator).

The second pathogenicity island is designated VPI and is associated with epidemic and pandemic strains of *V. cholerae*. VPI is 39.5 Kb in size and contains two ToxR-regulated genes: a regulator of virulence genes (ToxT) and a gene cluster containing essential colonization factors, including the toxin co-regulated pilus (TCP) (Karaolis et al., 1998). There is some genetic evidence that this island can be transferred from *V. cholerae* O1 to non-O1 strains. The *tcp* gene encodes for a 20.5-kDa protein that forms bundles of long filamentous pili 6–7 nm in diameter (Kaper et al., 1995; Janda, 1998). Both *in vitro* and *in vivo* experimentation indicates that TCP is essential for colonization and, therefore, for infectivity. Volunteers fed mutant strains lacking TCP failed to become colonized with *V. cholerae* O1, and no diarrhea was observed. Codon usage within this pathogenicity island differs from that of the rest of the *V. cholerae* chromosome; this finding suggests that the island may have been acquired by *V. cholerae* by horizontal transfer from an unrelated microorganism (Mekalanos et al., 1997).

V. cholerae O139, an emerging agent of epidemic cholera, is another important cause of diarrhea (Morris, 1995). Like serogroup O1 strains, O139 strains carry the structural genes encoded by the CTX operon and TCP (Hall et al., 1994; Janda, 1998). However, these two groups differ in several ways. The number of copies of *ctxA* gene(s) and their arrangement in O139 strains differ from that of serotype O1. In addition, a maltose-inducible outer-membrane protein, OmpS, is constitutively expressed (Janda, 1998) and O139 strains are encapsulated and lack specific genes (*rfbR*, *rfbS*) involved in O1 antigen synthesis (Johnson et al., 1994). Serotype O139 appears to have resulted from a number of genetic rearrangements in an O1 strain including deletion of the O1 *rfb* region and acquisition by horizontal transfer from a non-O1 strain of a 35 Kb DNA region that encodes the surface polysaccharide (Bik et al., 1995; Comstock et al., 1996). The recent reemergence of *V. cholerae* O139 in late 1996 has been associated with a number of chromosomal (genomic) rearrangements. When compared with O139 strains isolated in 1992, reemergent strains harbor three copies of the CTX genetic element connected by a single direct repeat sequence and carry an additional restriction site in the ribosomal RNA operon (Khetawat et al., 1999).

Isolates of *Vibrio cholerae* belonging to serogroups other than O1 and O139 normally lack cholera toxin genes and have never been found to carry TCP. These isolates can cause sporadic cases of gastroenteritis but have not spread as epidemics or pandemics of diarrheal disease. Pathogenic mechanisms include the production of "non-cholera enterotoxins", most of which are poorly characterized. However, unlike O1 strains, non-O1 strains of *V. cholerae* are commonly involved in invasive disease such as septicemia in immunocompromised hosts (Safrin et al., 1988; Lin et al., 1996).

V. parahaemolyticus has caused numerous cases of gastroenteritis, including many outbreaks. Cases are associated with the consumption of raw or undercooked shellfish such as oysters, shrimp, crabs, and lobster. Early studies suggested an association between human strains causing diarrhea and production of a positive hemolytic reaction on a special medium, Watgatsuma agar. This reaction, termed the Kanagawa phenomenon (KP), was positive for virtually all clinical isolates, whereas most non-clinical strains were "Kanagawa negative". Subsequent studies demonstrated a direct correlation between "Kanagawa positive" strains and the elaboration of a thermostable direct hemolysin (TDH). This hemolysin is enterotoxigenic in rabbit ileal loops and appears to alter ion flux in intestinal cells, thereby causing a secretory response and gastroenteritis (Nishibuchi and Kaper, 1995). Strains classified as "Kanagawa strong positive" have two copies of the TDH gene (*tdh1*, *tdh2x*), whereas strains classified as "Kanagawa weak" have only a single copy. "Kanagawa negative" strains lack this gene (Nishibuchi and Kaper, 1995). In the mid-1980s however, "Kanagawa negative" strains associated with gastroenteritis began to appear from many different geographic areas, including the Maldives (Honda et al., 1987). It was later found that these "Kanagawa negative" strains produced a different hemolysin named "TDH-related hemolysin" and abbreviated as "TRH". The gene for the TDH-related hemolysin, *trh*, has 70–80% homology to *tdh*, and appears to be closely associated with urease expression (Nishibuchi and Kaper, 1995; Suthienkul et al., 1995). Thus, "Kanagawa negative" strains of *V. parahaemolyticus* can apparently also cause gastroenteritis if they have the *trh* gene. The *tdh* gene is also found in several unrelated vibrios, including *V. hollisae*, *V. mimicus*, and *V. cholerae* non-O1 (Nishibuchi et al., 1996). This finding suggests that horizontal transfer of *tdh* genes to other species is a possible common enteropathogenic mechanism.

V. vulnificus is an important pathogen that causes wound infections and septicemia (Hollis et al., 1976; Blake et al., 1979; Tacket et al., 1984; Klontz et al., 1988). Wound infections result from direct inoculation of the organism into traumatized cutaneous surfaces after contact with marine animals or the marine or estuary environment. Septicemia commonly develops in immunodeficient persons with hepatic disease who consume raw or improperly cooked oysters. On rare occasions, a classic secretory diarrhea, typically observed with other vibrio species, has been reported in patients with *V. vulnificus* in their feces (Klontz et al., 1988), but the etiological role of *V. vulnificus* as a cause of

diarrhea is not proved. Other rare complications of *V. vulnificus* infection include meningitis, myositis, endometritis, peritonitis, and ocular disease. Despite intense investigation, the pathogenic mechanisms of *V. vulnificus* are poorly defined. A unique *V. vulnificus* cytotoxin-hemolysin apparently does not play a major role in microbial pathogenesis (Wright and Morris, 1991), although it is a highly sensitive and specific genetic marker for the species *V. vulnificus*. Other postulated virulence factors include a capsule, iron-scavenging systems, and resistance to complement-mediated lysis.

Two distinct biogroups of *Vibrio vulnificus* have also been described, and both can infect humans. Strains of *Vibrio vulnificus* biogroup 2 have caused outbreaks in eels in Taiwan, Japan, and Spain and apparently cause human wound infections (Tison et al., 1982; Amaro and Biosca, 1996). Strains of *Vibrio vulnificus* biogroup 3 have caused outbreaks of severe wound infection in Israel (Bisharat et al., 1999). The infections occurred when people purchased living, pond-raised, "Saint Peter's fish" (*Talapia* spp.) from local vendors and then were inoculated with the organism through an existing skin break or trauma incurred while handling the fish. Interestingly, the halophilic strains of *V. vulnificus* biogroup 3 were able to grow in the "fresh water" inland fishponds. However, these ponds had a high salt content because of the source of the water and evaporation during the hot dry summer months.

Vibrio damsela is a rare but important pathogen of fish and mammals, including humans. Originally described as the causative agent of ulcerative disease in damselfish (Love et al., 1981), *Vibrio damsela* causes wound infections in bottlenose dolphins, leatherback turtles, yellowtail, sea bream, barramundi, turbot, brown shark, and rainbow trout (Pedersen et al., 1997). Damselfish infected with *Vibrio damsela* after scarification of the dermis develop large ulcers within three days, and death follows shortly thereafter (Love et al., 1981). In humans, wound infections due to *Vibrio damsela* are occasionally reported. Illnesses commonly result from traumas sustained in contact with objects in contaminated waters (e.g., a reef), and from penetrating injuries resulting from catfish barbs or stings from stingrays (Morris et al., 1982). A less frequent but serious complication is fulminant *Vibrio damsela* septicemia, which mimics *V. vulnificus* septicemia (Clarridge and Zighelboim-Daum, 1985; Lang, 1992; Shin et al., 1996). A hemolytic cytolysin with phospholipase D activity is postulated to be a virulence factor in wound pathology and subsequent invasive infections (Kreger et al., 1987).

Many non-clinical *Vibrio* species cause serious infections in a variety of marine animals including shellfish and fish. The best studied of these pathogens is *V. anguillarum*, the causative agent of epizootic disease in marine fish and shellfish (Austin and Austin, 1993). The general term vibriosis is used to describe fulminant septicemic infections produced by a number of vibrio species in marine fish. The etiologic agent of the disease may be specific for a single type of aquatic life or may have a very broad host range. Table BXII.γ.158 summarizes the important pathogens of marine animals (Hada et al., 1984; Ishimaru et al., 1995, 1996; Iwamoto et al., 1995; Borrego et al., 1996; Liu et al., 1996a; Yii et al., 1997).

TABLE BXII.γ.158. Diseases in marine fish and invertebrates caused by or associated with *Vibrio* species

Disease(s)	Susceptible Animals	Species
Whitespot disease	Kuruma prawns, tiger prawns	*V. alginolyticus*
Terminal hemorrhagic septicemia	Eels, ayu, rainbow trout, salmonids	*V. anguillarum*
Gastroenteritis	Groupers	*V. harveyi*
Vibriosis (larvae and juveniles)	Kuruma prawns	*V. harveyi*
Intestinal necrosis (larvae)	Flounders	*V. ichthyoenteri*
Brown spot disease	Kuruma prawns	*V. penaeicida*
Brown ring disease	Manila and fine clams	*V. tapetis*
Intestinal hemorrhage, skin discoloration	Japanese horse mackerel	*V. trachuri*
Diseased larvae	Clams, oysters, scallops	*V. pectenicida, V. tubiashii*

Ecology Water (and its associated microorganisms, animals and plants) is the natural habitat of most of the nonhalophilic and marine vibrios. Environmental factors regulating vibrio concentrations and distribution in both freshwater and seawater ecosystems include the concentration of organic and inorganic chemicals, pH, temperature, salinity, oxygen tension, and exposure to UV light (Chakraborty et al., 1997). However, salinity (specifically, the concentration of Na^+) is the most important factor governing the environmental distribution of vibrios. Na^+ concentrations required for optimal growth of *Vibrio* spp (Fig. BXII.γ.164) range from a low of 5–15 mM (0.029–0.087%) for *V. cholerae* and *V. metschnikovii* to a high of 600–700 mM (3.5–4.1%) for the halophile *Salinivibrio costicola* (Baumann et al., 1984b). This wide range partially explains why *V. cholerae, V. mimicus, V. fluvialis*, and *V. furnissii* are recovered from freshwater rivers, streams, and ponds; other species such as *V. vulnificus* prefer moderate salinity and grow in shellfish beds in coastal areas (Kaysner et al., 1987; Chakraborty et al., 1997; Motes et al., 1998). Although salinity is a critical parameter, it does not completely explain the environmental distribution of all vibrios because halophilic species such as *V. parahaemolyticus* can survive in suboptimal Na^+ concentrations. Other *Vibrio* species have been implicated in human infections resulting from apparent contact with freshwater catfish (Lowry et al., 1986; Chakraborty et al., 1997). *V. mimicus*, a nonhalophilic species, is found in aquatic environments where the average salinity is less than 1% (Chakraborty et al., 1997).

Independent of salinity, vibrio densities tend to increase in warmer waters when enough inorganic and organic nutrients are present for growth. Vibrios are typically more common in geographic regions having temperate or tropical climates. Studies of northern Gulf of Mexico and Atlantic coast oysters indicate that large populations of *V. vulnificus* occur in shellfish meats from May through October; populations then decline until late March (Motes et al., 1998). This seasonality is apparent in most *Vibrio* species, with larger populations being observed from late spring to early fall. In one study, *V. fluvialis, V. furnissii, V. mimicus*, and *V. parahaemolyticus* survived in sea water at 20°C for 15 days without a detectable reduction in cell viability (Munro et al., 1994). Although *V. metschnikovii* and *V. cholerae* numbers initially declined for 2–6 days after inoculation into seawater, a regrowth phase occurred, and populations then rose to initial values. In contrast, *V. vulnificus* survived poorly under identical conditions, with viability being reduced >10,000-fold within the same interval.

The microbial ecology of vibrios is best exemplified by *V. chol-*

erae. *V. cholerae* can survive in a "free living state" in both freshwater and saline environments. It is widely distributed in habitats such as sewage, brackish water, estuaries, and coastal inlets, as well as in polluted streams, rivers, ponds, and lakes. *V. cholerae* can also persist in an epibiotic form associated with various microscopic life (Hood et al., 1984). Common microorganisms associated with *V. cholerae* include cyanobacteria, phytoplankton (diatoms, fresh water algae), and zooplankton (Huq et al., 1995; Chakraborty et al., 1997). *V. cholerae* may attach to the tissues or chitinous exoskeleton of crustaceans and production of the enzyme chitinase might be important in this process. All these combined niches provide a continuous environmental source for the maintenance and dissemination of *V. cholerae* throughout the world.

Transmission of *V. cholerae* O1 and O139 to humans usually occurs through consumption of contaminated water or foods. An outbreak of cholera in South America caused by *V. cholerae* O1 is a grim reminder of the rapidity with which cholera can spread in naive (susceptible) populations. The initial source of this epidemic, which began in 1991, is unknown, but the disease rapidly became waterborne and was quickly disseminated throughout the continent by introduction into water, unwashed fruits and vegetables, raw seafood, and cooked crab (Mujica et al., 1994; Weber et al., 1994). Cholera can be introduced into industrialized countries through the importation of contaminated foods brought by travelers from affected areas (Finelli et al., 1992).

Strains of non-O1 *V. cholerae* greatly outnumber O1 strains in the environment. *V. cholerae* non-O1 has been recovered from birds, amphibians, herbivores, and freshwater fish (Baumann et al., 1984b; Rhodes et al., 1985). A majority of these isolates lacks the classic virulence factors that are present in O1 strains, such as cholera toxin and the toxin co-regulated pilus (Baumann et al., 1984b; Kaysner et al., 1987).

V. parahaemolyticus inhabits inshore coastal areas and estuaries and has only rarely been recovered from pelagic (open ocean) regions (Joseph et al., 1982). It has been isolated from various parts of the water column, sediment, zooplankton, shellfish, and fish. Occasionally, *V. parahaemolyticus* has been recovered from fresh water in Indonesia and India (Chakraborty et al., 1997). It has also been recovered from inland bodies of water in the United States where the Na^+ content is high. Like *V. cholerae*, growth of *V. parahaemolyticus* in the marine environment is favored by warmer temperatures and saline concentrations approximating 12 parts per thousand (ppt) (Joseph et al., 1982). *V. parahaemolyticus* has been isolated from a variety of marine animals including clam, oyster, lobster, scallop, sardine, squid, eel, crab, and shrimp (Joseph et al., 1982). Most outbreaks of gastroenteritis caused by *V. parahaemolyticus* have been linked to the consumption of crabs, shrimp, oysters, and lobsters. In Japan, *V. parahaemolyticus* is a major cause of food poisoning and is associated with the ingestion of raw fish such as sashimi and sushi (Chakraborty et al., 1997). Most strains of *V. parahaemolyticus* isolated from human infections are "Kanagawa positive," and most environmental isolates are "Kanagawa negative." This distinction was originally thought to indicate that "Kanagawa negative" strains do not cause human disease; however, as mentioned previously, it is now known that some strains produce a thermostable-related hemolysin, a virulence factor that has significant homology to the thermostable direct hemolysin responsible for a positive Kanagawa reaction.

V. vulnificus has been isolated from various locales around the world, including Europe and the Pacific and Atlantic coasts of the United States as far north as Washington and Maine, respectively (O'Neill et al., 1990; Veenstra et al., 1994; Chakraborty et al., 1997). *V. vulnificus* is typically found in waters having intermediate salinities (5–25 ppt) and temperatures up to 26°C (Motes et al., 1998); it does not grow at temperatures less than 10°C (Chakraborty et al., 1997). DePaola et al. (1994) isolated *V. vulnificus* from seawater, crustacea, and estuarine fish from U.S. waters in the Gulf of Mexico. The highest concentration of *V. vulnificus* in one study was found in the intestinal contents of bottom-feeding estuarine fish (sea catfish, sheepshead, Atlantic croaker) that consume mollusks and crustacea (DePaola et al., 1994); it is rarely recovered from offshore fish. *V. vulnificus* populations decline as coastal and estuary water temperatures cool in late fall. The presence of *V. vulnificus* in shellfish may result from the constant filtering by these organisms of seawater containing vibrios rather than the active multiplication of *V. vulnificus* in shellfish tissues (Kelly and Dinuzzo, 1985). However, *V. vulnificus* can survive in oysters for 10–14 d when they are held at 2–10°C (Kaysner et al., 1989). In humans, *V. vulnificus* septicemia is almost exclusively associated with the consumption of raw oysters (Klontz et al., 1988). Some indirect evidence suggests that counts of approximately 10^3 bacteria/gm oyster meat are associated with human disease (Jackson et al., 1997). Strains of *Vibrio vulnificus* biotype 2 strains are pathogenic for eels (Amaro et al., 1995).

Few studies have addressed the environmental distribution of other *Vibrio* species. *V. fluvialis* was identified in 40% of 177 samples collected from rivers, ponds, swamp, estuaries, sewage, sediment, and crabs in Louisiana (Nishibuchi et al., 1983). Data on the association of many pathogenic and marine vibrios with aquatic microbiota suggest that they are widely dispersed in the marine environment. *V. fischeri* has developed a symbiotic association with the bobtail sepiolid squid, *Euprymna scolopes* (Ruby and Lee, 1998). *Vibrio damsela* causes ulcerative disease in the damselfish, *Chromis punctipinnis*, as well as in rainbow trout and in a number of other marine animals (Love et al., 1981; Pedersen et al., 1997). Many other vibrios cause disease in crustacea and fish (Table BXII.γ.158).

Enrichment and Isolation Procedures

Much has been written about the isolation of *Vibrio* cultures, and several good reviews and manuals are available (see Further Reading). These topics have also been covered in detail by Farmer and Hickman-Brenner (1992). Two different sets of methods have been used, depending on whether the sample was taken from a human clinical specimen or from the marine environment. Species of *Vibrio* and *Photobacterium* will grow in many microbiological media; however, the low Na^+ content of some media (some have no added NaCl, others have a final concentration of 0.5–0.85%) will prevent growth of some marine species that require a higher concentration (Fig. BXII.γ.164). Only limited data exist on the growth of the species isolated from human diseases on many of the media traditionally used by marine microbiologists. In spite of the differences in Na^+ requirement/tolerance, several media are useful for all types of vibrio work.

There are several good general media for isolation of *Vibrio* and *Photobacterium* (Table BXII.γ.159). Marine agar is a nonselective medium, and almost all *Vibrio* strains will grow on it. Dozens of other media been described and are useful in particular instances, but are not in general use.

Marine agar is probably the most useful general medium for

TABLE BXII.γ.159. General and selective media for the genera *Vibrio*, *Photobacterium*, *Aeromonas*, and *Plesiomonas*[a]

Medium	*Vibrio*	*Photobacterium*	*Aeromonas*	*Plesiomonas*
Media and enrichments often used in clinical microbiology laboratories:				
Sheep blood agar	+ + + +	+ +	+ + + +	+ + + +
MacConkey agar	+ +		+ + + +	+ + + +
Alkaline peptone water	+ + + +	+ +	+ + +	+ + +
Nonselective "marine" media:				
Marine broth	+ + + +	+ + + +	+ +	+ +
Marine agar	+ + + +	+ + + +	+ +	+ +
Photobacterium agar	+ + + +	+ + + +	+ +	+ +
Photobacterium broth	+ + + +	+ + + +	+ +	+ +
Selective media for Vibrio:[b]				
TCBS agar	+ + + +	+ +	no growth	no growth
Vibrio agar	+ + + +			
Selective media for Aeromonas and Plesiomonas:				
Bile salts-brilliant green agar			+ + + +	+ + + +
Dextrin-fuchsin-sulfite medium			+ + + +	
Rimler-Shotts medium			+ + + +	
Aeromonas agar:			+ + + +	
Blood agar plus ampicillin			+ + + +	
DNase agar plus ampicillin and toluidine blue			+ + + +	
MacConkey agar plus ampicillin and Tween 80			+ + + +	
Pril–xylose–ampicillin agar			+ + + +	
Starch–ampicillin agar			+ + + +	

[a]The symbols "+ + + +" to "+" and "−" indicate the general usefulness of the medium and apply to most species in the genera; however, some species and strains may be exceptions and may differ on a particular medium. For example, most strains of *V. hollisae* do not grow well on TCBS agar (see the following chapter). A blank space indicates that data are not available or are contradictory.

[b]Most of the media formulated for *Vibrio* isolation were specifically designed to isolate *V. cholerae*.

Vibrio and *Photobacterium*. It is also useful for the isolation and growth of organisms whose natural habitat is marine or other environments with a high content of Na^+. It is particularly useful for the species of *Vibrio* and *Photobacterium* (Fig. BXII.γ.164) that require Na^+ in amounts higher than the usual content of bacteriological media (0.5–1.0%).

Marine semisolid medium (marine broth plus 0.4% agar) is a convenient semisolid medium for maintaining "working cultures" of *Vibrio*, *Photobacterium*, or other marine organisms that require added Na^+ and other ions for growth.

TCBS (thiosulfate–citrate–bile salts–sucrose) agar is useful for the isolation of *V. cholerae* and *V. parahaemolyticus* from fecal specimens. It is probably the medium most widely used as a general isolation medium for *Vibrio* strains from human clinical specimens and from the environment (Fig. BXII.γ.166). Some *Vibrio* strains do not grow on TCBS agar or have a low plating efficiency; others are inhibited and grow as small colonies. Details regarding the growth characteristics of *Vibrio* species on TCBS agar are given in Table BXII.γ.160. Enterococci and some other bacteria will sometimes grow on TCBS agar, but most other bacteria are inhibited. Dehydrated TCBS agar is available from several commercial companies.. The exact composition of the medium varies from manufacturer to manufacturer and from lot to lot of the same manufacturer. This variation will influence the medium's selectivity, thus affecting both sensitivity and specificity.

The routine use of TCBS medium for isolation is too expensive for many laboratories that do not isolate vibrios frequently. Kelly (described in Farmer et al., 1985d) found that *Vibrio* isolates obtained on TCBS medium were always obtained on other media also, so long as oxidase-positive colonies were screened.

Alkaline peptone water is probably the most useful liquid medium for isolating and growing vibrios (Colwell 1984; Furniss et al., 1978). This medium is used as an enrichment for *Vibrio cholerae* and other *Vibrio* species, which often grow better than undesired organisms at high pH. Vibrios also tend to grow better than most other organisms at the meniscus. Enrichment in alkaline peptone water is usually followed by spreading onto TCBS

FIGURE BXII.γ.166. Growth of vibrios on TCBS agar. 0.01 ml of seawater collected about 10 m from shore was spread on the agar surface and incubated for 3 days at ambient temperature (about 25°C). Note the many different sizes and shapes of the colonies, which also very considerably in color depending on whether they ferment sucrose. (Reproduced with permission from J.J. Farmer III and F.W. Hickman-Brenner, *In* Balows, Trüper, Dworkin, Harder and Schleifer (Editors), The Prokaryotes: A Handbook on the Biology of Bacteria: Ecophysiology, Isolation, Identification, Applications, 2nd Edition, Volume III, ©Springer-Verlag, New York, 1992, pp. 2952–3011.)

TABLE BXII.γ.160. Growth of *Vibrio* species on TCBS agar*

Organism	Colony appearance on TCBS (%)		Growth-plating efficiency
	Green	Yellow	
V. cholerae	0[a]	100[a]	Good
V. alginolyticus	0	100	Good
V. cincinnatiensis	0	100	Very poor
V. damsela	95	5	Reduced at 36°C
V. fluvialis	0	100	Good
V. furnissii	0	100	Good
V. harveyi	0	100	Good
V. hollisae	100	0	Very poor
V. metschnikovii	0	100	May be reduced
V. mimicus	100	0	Good
V. parahaemolyticus	99	1	Good
V. vulnificus	90[b]	10[b]	Good
"Marine vibrios"	Variable	Variable	Variable

[a]Percentage of strains that produce green colonies and yellow colonies, respectively.

[b]The original report describing this species gave the percentage positive for sucrose fermentation as 3%. At the CDC *Vibrio* laboratory, about 15% of the strains have been sucrose positive.

**Editorial Note: Photobacterium damselae* subsp. *damselae* is a junior objective synonym of *Vibrio damsela.*

agar or onto a similar plating medium selective for *Vibrio*. The NaCl content of alkaline peptone water is not standardized but is usually 0.5–1%. It can be increased to 2% to enhance the growth of marine vibrios. If the NaCl is omitted ("alkaline peptone water-saltless"), the medium becomes much more selective for *V. cholerae* and *V. mimicus*. The type of peptone used in the medium has also varied depending on several factors including local availability. The formula given below (Formula 1494[2] of the CDC Vibrio Laboratory) is the one used by CDC's *Vibrio* Laboratory for many years. Other formulations may be equally effective.

It is often desirable to use a growth or suspending medium with all of the inorganic constituents of seawater, but without organic compounds or toxic contaminants found in natural sea water. Many artificial types of seawater have been described.

Artificial Sea Water #1 (MacLeod's formula)[3] does not contain several of the ingredients found in formulas for "complete" artificial seawater. Some of the missing components are trace metals. This medium is satisfactory for most strains of *Vibrio* and *Photobacterium*. Artificial Sea Water #2, "Instant Ocean"[4], is a commercial packaged salt mixture available from Aquarium Systems (33208 Lakeland Blvd., Eastlake, Ohio 44094). Stores that have supplies for marine aquariums also sell it. Marine cation solutions[5] are useful alternatives to artificial sea waters, and the *Vibrio* laboratory uses them for making "marine media" used for biochemical testing.

Standard techniques used in clinical microbiology laboratories are suitable for isolating *Vibrio* species from human clinical specimens. Benenson et al. (1964), Hugh and Sakazaki (1972), Morris et al. (1979), World Health Organization (1983), Wachsmuth (1984), and Barua and Greenough (1992)) should be consulted for specialized information. It is important to note that some *Vibrio* cultures do not grow readily on the selective media used for the isolation of enteric pathogens and that most *Vibrio* species require added NaCl for growth (Baumann et al., 1984b; Fig. BXII.γ.164). Many laboratory media have amounts of Na^+ less than 0.5% NaCl.

There are no special procedures for *Vibrio* in regard to the collection, transport, and storage of specimens. Fecal specimens should be obtained within 24 h of the onset of illness and prior to antibiotic treatment. Specimens should be spread on an isolation medium as soon as possible. Vibrios survive longer in the alkaline rice-water stool of cholera patients than in formed stools. *Vibrio* strains are easily killed by desiccation. Samples can be transported in alkaline peptone water or in Cary Blair transport medium, which maintains viability of *Vibrio* cultures for up to 4 weeks. "Buffered glycerol–saline" medium is unsatisfactory. Tellurite–taurocholate–peptone broth has also been used as a transport medium. *Vibrio* strains can survive up to 5 weeks on strips of blotting paper soaked in liquid stool and stored at ambient temperature in airtight plastic bags.

Medically important *Vibrio* strains from fecal specimens grow readily on blood agar. Most strains of *V. cholerae* have a characteristic appearance on blood agar (Fig. BXII.γ.167) and are strongly hemolytic, except for strains of the classical biogroup of *V. cholerae*, which are nonhemolytic. Inclusion of oxidase testing and/or inclusion of TCBS medium in the isolation scheme are recommended for more thorough searches.

Medically important *Vibrio* strains from fecal specimens can grow on blood agar where they may be beta-hemolytic (*V. cholerae* non-O1 and some *V. cholerae* O1 El Tor), alpha-hemolytic (*V. vulnificus* and many others), or nonhemolytic. Vibrios also usually grow on MacConkey agar and produce colorless (lactose-negative) colonies. Colonies grown on blood agar and lactose-negative colonies grown on MacConkey medium should be tested for oxidase activity.

2. Formula 1494 for alkaline peptone water: dissolve peptone (10 g) and sodium chloride (5 g) in 994 ml water. Adjust pH to 8.4 with 1N NaOH (about 6 ml will be required). Dispense into tubes and autoclave at 121°C for 15 min. The final medium will be clear and amber colored.

3. Artificial Sea Water #1, MacLeod's formula, contains (g/l) NaCl (23.38 g), $MgSO_4 \cdot 7H_2O$ (24.65 g), KCl (1.49 g), and $CaCl_2 \cdot 2H_2O$ (2.94 g). A clear, colorless solution with a pH of about 6.6 will result. Dispense into screw cap bottles or tubes and autoclave at 121°C for 15 min. Store at room temperature.

4. Artificial Sea Water #2, "Instant Ocean", is prepared by adding 40 g Instant Ocean to 1 liter of water and stirring until all the salt dissolves. Dispense and autoclave at 121°C for 15 min. Store at room temperature.

5. Marine cations supplement 1558 (Na^+, K^+, Mg^{2+}, and Ca^{2+} (10 X) was modified by the CDC *Vibrio* Laboratory from the "electrolyte supplement" of Furniss et al. (1978)). In 912 ml water, dissolve (in the order listed) NaCl (150 g), KCl (3.7 g), $MgCl_2 \cdot 6H_2O$ (51 g), and $CaCl_2 \cdot 2H_2O$ (7.4 g). Aseptically add one volume to 9 volumes of sterile medium to be supplemented and mix thoroughly. Marine cations supplement 1559 (Na^+, K^+, and Mg^{2+} (10X)) is the same as marine cations supplement 1558 except that it lacks the calcium chloride.

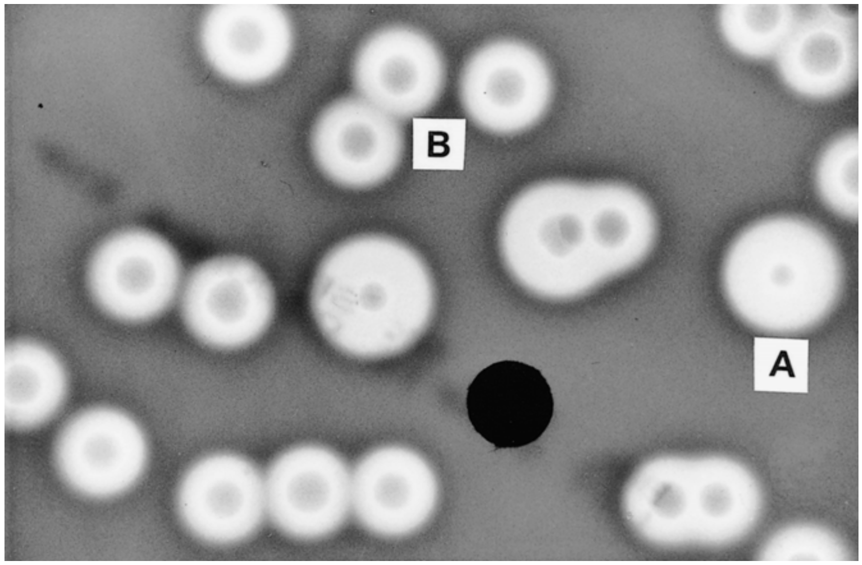

FIGURE BXII.γ.167. Strong hemolytic reaction of the Gulf Coast strain of *Vibrio cholerae* incubated overnight at 36°C on sheep blood agar. Note that the small colony type has a much larger zone of hemolysis *(A)* than the large colony type *(B)*. (Reproduced with permission from J.J. Farmer III and F.W. Hickman-Brenner, *In* Balows, Trüper, Dworkin, Harder and Schleifer (Editors), The Prokaryotes: A Handbook on the Biology of Bacteria: Ecophysiology, Isolation, Identification, Applications, 2nd Edition, Volume III, ©Springer-Verlag, New York, 1992, pp. 2952–3011.)

Fig. BXII.γ.168 gives a plan for isolating vibrios. Simply testing the oxidase reaction of hemolytic colonies on sheep blood agar plates will detect many *Vibrio* strains as well as many *Aeromonas* strains. Nonhemolytic colonies can also be tested. Procedures for oxidase testing are given in Farmer and Hickman-Brenner (1992).

A protocol adapted from Wachsmuth (1980) and Furniss et al. (1978) for the isolation of *V. cholerae* from stool specimens is shown in Fig. BXII.γ.168. This protocol is also applicable to the isolation of vibrios from other specimens. The use of TCBS agar as the primary plating medium and use of an enrichment step in alkaline peptone water would also enhance recovery of vibrios.

Rapid detection of *Vibrio cholerae* O1 in feces can be accomplished by using a latex bead agglutination test that detects the O1 antigen of *V. cholerae*. Antisera to *V. cholerae* O139 could also be used. A confirmatory culture is needed for the definitive diagnosis of cholera.

Direct detection of *Vibrio* species in feces can be accomplished by microscopic examination. In 1883, Koch described small curved rods that could be observed in the stools of cholera patients but not in the feces of patients without cholera. Later it was observed that sera from convalescent cholera patients stopped the characteristic motility of *V. cholerae* in rice water stools. Later still, antiserum produced in animals was used in this "microscopic vibriocidal assay". The cellular morphology of *V. cholerae* cells varies and typical curved rods, straight rods, short noncurved rods, and "involution forms" can all be seen in the same culture.

Methods for the enrichment of vibrios from seawater have been described by Baumann et al. (1984b). Many of the marine species can be obtained from enrichments involving the addition of 500-ml seawater samples to sterile 2-liter Erlenmeyer flasks containing 25 ml 1 M Tris-HCl (pH 7.5), 0.5 g NH_4Cl, 0.38 g $K_2HPO_4 \cdot 7H_2O$, 14 mg $FeSO_4 \cdot 7H_2O$, and 0.5 g or 0.5 ml of one of a variety of different organic carbon and energy sources. Material from flasks with visible turbidity (generally within 10 days at 20–25°C) is spread onto basal medium agar (BMA; Baumann and Baumann, 1981a) containing 0.1–0.2% (w/v for solids and v/v for liquids) of the homologous carbon and energy source. Suitable organic compounds include sugars, sugar alcohols, sugar acids, tricarboxylic acid cycle intermediates, fatty acids, and amino acids. Strains of marine vibrios have also been obtained by direct isolation from seawater. Seawater is passed through nitrocellulose filters having a pore size of 0.22 or 0.45 μm; the filters are then placed on BMA containing 0.1 or 0.2% of an appropriate carbon and energy source or on yeast extract agar or marine agar. After 2–10 days incubation at 20–25°C, colonies are transferred to homologous medium. Vibrios have also been isolated by plating onto nonselective seawater-based media. For additional information on the isolation of marine vibrios, see Baumann and Baumann (1981a) and Baumann et al. (1984b).

Some strains of *Vibrio* swarm on complex solid media, and isolated colonies cannot be obtained when this occurs. Swarming can be inhibited or greatly reduced by increasing the concentration of agar in complex media to 4% (w/v) (Reichelt and Baumann, 1973b) or by streaking the organism onto a minimal medium such as BMA containing 0.2% (v/v) glycerol (Baumann et al., 1971a).

The isolation of bioluminescent strains of *Vibrio* from seawater does not involve enrichment procedures. Instead, samples are placed directly onto a suitable complex medium and luminescence is detected visually. A solid medium (luminous medium or LM) that promotes luminescence of marine isolates consists of BMA modified by the addition of 0.3% (v/v) glycerol and (in g/l) 5.0 g yeast extract, 5.0 g tryptone, 1.0 g $CaCO_3$, and 20.0 g agar). Because there is strain variation with respect to the intensity and duration of light emission and because some strains will only luminesce as isolated colonies, it is best to examine cultures periodically within 12–36 h of inoculation. A suitable incubation temperature is 15°C; many strains do not produce luminescence

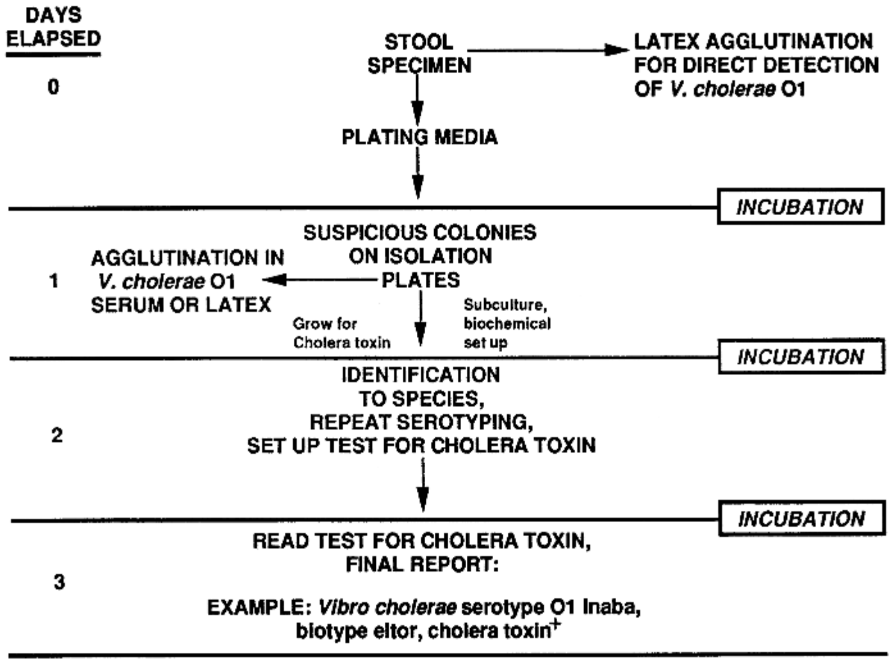

FIGURE BXII.γ.168. Overall plan and special steps for the isolation and identification of *Vibrio cholerae* and other *Vibrio* cultures from feces. (Reproduced with permission from J.J. Farmer III and F.W. Hickman-Brenner, *In* Balows, Trüper, Dworkin, Harder and Schleifer (Editors), The Prokaryotes: A Handbook on the Biology of Bacteria: Ecophysiology, Isolation, Identification, Applications, 2nd Edition, Volume III, ©Springer-Verlag, New York, 1992, pp. 2952–3011.)

at 20°C or 25°C. Sources of luminous isolates include seawater, the surfaces and intestinal contents of marine animals, luminous organs and, more rarely, freshwater sources. Additional details for the isolation of luminous bacteria are given by Cosenza and Buck (1966), Baumann and Baumann (1981a), Hastings and Nealson (1981), Ruby et al. (1980), and Desmarchelier and Reichelt (1981).

Maintenance Procedures

The following procedures have been used for many years in the Enteric Reference Laboratory, US Centers for Disease Control and Prevention. The methods of two other laboratories with many years of experience in *Vibrio* work have been described in considerable detail and are highly recommended (Furniss et al., 1978; Baumann et al., 1984b).

Strains of *Vibrio* are easy to grow and maintain compared to many other organisms. However, strains will die if allowed to dry on agar plates, in agar slants, or in agar "deeps." Freezing and storage at low temperature is the method of choice for long-term preservation and maintenance. Lyophilization and storage at 4°C are used routinely by the American Type Culture Collection with good results.

If liquid nitrogen storage is not available, *Vibrio* cultures can be stored in a laboratory freezer at −70°C, or even at −10 to −20°C. The lowest temperature available should be used for storage. The culture to be preserved is first inoculated heavily and grown on a marine agar plate for at least 24 h. Cultures of *V. cholerae* and *V. mimicus* can be grown on sheep blood agar instead of marine agar because of their low salt requirement. Growth is removed with a cotton swab and a dense suspension is made in 10% skim milk or other suspending medium. One ml of this suspension is then placed in a sterile plastic freezer vial. The vial is frozen in an alcohol bath that has been kept in the freezer. The vial is stored a divided box that holds 81–100 vials and kept at the lowest temperature available.

For preparation of a "working stock" culture, growth from the top of a single, isolated colony is touched and stabbed to the bottom of 13 × 100-mm screw cap tube of marine semisolid medium. This medium can also be used for *V. cholerae* and *V. mimicus*. Marine semisolid medium is used for the halophilic vibrios. The culture is grown overnight and checked to insure good growth. The tube is sealed by closing the cap tightly. To avoid the problem of drying, two alternative methods are used. First, a small volume (about 0.3 ml) of sterile mineral oil can be added to cover the surface to a depth of about 3 mm above the interface. A second sealing method is to insert a number "000" white rubber stopper into the neck of the screw-cap tube to seal it. After they are sealed, cultures are conveniently stored at room temperature in the dark. Many, but not necessarily all, species of *Vibrio* survive for years in such sealed tubes.

Procedures for Testing Special Characters

Many different procedures have been described for testing the phenotypic characteristics of *Vibrio* strains. The three most important variables are (1) medium composition, (2) addition of Na^+, K^+, Mg^+, and other cations as supplements, and (3) the temperature of incubation. Most clinical and public health laboratories use media and tests designed to identify *Enterobacteriaceae* for *Vibrio* strains. These methods are successful for *V. cholerae* and *V. mimicus* because these species do not require added Na^+. However, most halophilic vibrios require additional Na^+ for growth and expression of various metabolic traits (Fig. BXII.γ.164). In Table BXII.γ.161, results obtained using standard enteric test media are listed first and the percentage of strains positive for each test is given for each species; these data are followed by the percentage of strains positive for the same strains

TABLE BXII.γ.161. The effect of media (especially Na% content) and test conditions on biochemical test results for 10 species of *Vibrio**

Test or property	Percentage positive for:[a]

[a]The number indicates the percentage positive after 48 h of incubation at 36°C; NG, most cultures do not grow in the medium.

**Editorial Note: Photobacterium damselae* subsp. *damselae* is a junior objective synonym of *Vibrio damsela*.

tested in a modified medium with 1% NaCl added. The table also shows other effects of different test conditions; for example, more *Vibrio* species are indole positive when grown in heart infusion broth than when grown in peptone water. More strains are positive for the Voges–Proskauer test when the reagent for detecting acetylmethylcarbinol contains α-naphthol (Barritt method).

Bioluminescence test A bioluminescence test has been described by Baumann et al. (1984b). Several *Vibrio* and *Photobacterium* species usually produce bioluminescence (*V. fischeri*, *V. logei*, *V. orientalis*, *V. splendidus* biogroup 1, *Photobacterium phosphoreum*, and *P. leiognathi*), in contrast to most other *Vibrio* species. Some strains of *V. harveyi* and rare strains of *V. cholerae* and *V. vulnificus* are luminescent (Oliver et al., 1986). Details concerning growth conditions and observation of cultures for bioluminescence have been described by Farmer and Hickman-Brenner (1992).

Carbon assimilation tests Methods for carbon assimilation tests were described by Baumann and Baumann (1981a), who used artificial sea water #1 as a basal medium in their extensive studies to determine the growth of marine bacteria on different substrates. The carbon sources are added to the basal medium at a final concentration of 0.1 to 0.2%.

Susceptibility to vibriostatic compound O/129 Susceptibility to 2,4-diamino-6,7-diisopropyl-pteridine phosphate (vibriostatic compound O/129) is used to differentiate *Vibrio* isolates (usually susceptible) from *Aeromonas* isolates (usually resistant) by means of a disc diffusion assay. This test can also be used to differentiate some *Vibrio* species from each other. Details concerning growth conditions and interpretation of results have been given by Farmer and Hickman-Brenner (1992).

Salt requirement (Na^+ requirement) and tolerance Salt requirement (Na^+ requirement) and tolerance form the basis of useful differential tests for the species of *Vibrio* and *Photobacterium*. In contrast to the halophilic *Vibrio* species, *V. cholerae* and *V. mimicus* are able to grow in 0% NaCl. The data are based on the media and methods given by Farmer and Hickman-Brenner (1992); use of other media may lead to different results.

String test Cells grown on agar medium are suspended in 0.5% sodium deoxycholate. Lysis of the cells is shown by the formation of "strings" of DNA that can be drawn from the suspension with a loop. Isolates that lyse within 60 sec are considered positive. Many *Vibrio* species are positive; *Aeromonas hydrophila* is negative.

Serotyping Serotyping of *Vibrio* was discussed in the section on antigenic structure. Simonson and Siebeling (1988) developed a latex slide agglutination test based on antisera to the flagellin portion of the flagella for the routine identification of several of the *Vibrio* species. *V. cholerae* O1 and O139 antisera are used to confirm isolation of *V. cholerae* O1 or O139 for reporting to health authorities.

Antibiotic susceptibility Clinically important *Vibrio* species can be tested for antibiotic susceptibility using a disk diffusion susceptibility test on Mueller–Hinton agar. However, some marine vibrio species grow poorly on Mueller–Hinton agar, presumably because of their higher requirement for Na^+. Broth dilution susceptibility tests for most *Vibrio* species can usually be done in

unmodified Mueller–Hinton broth, because the broth contains sufficient Na^+ (Hollis et al., 1976).

Antibiotic resistance is relatively rare in *Vibrio* species (Table BXII.γ.156). The term "resistant" is used with the note that the zone size breakpoints that define resistance and susceptibility have been based primarily on isolates of *Enterobacteriaceae* rather than *Vibrio*. In most cases, "resistance" appears to be an intrinsic property of the species rather than a trait acquired through plasmid transfer or mutation. An exception to this generalization is the antibiotic resistance found in some outbreak or imported strains of *V. cholerae* O1 that have become resistant through the acquisition of R factors. Resistance to polymyxin B and colistin can be useful in identifying *V. cholerae* El Tor and *V. vulnificus*. Most other *Vibrio* species are more susceptible.

Differentiation of the genus *Vibrio* from other genera

In this section of the last edition of this *Manual*, Baumann et al. (1984b) stated: "While the number of readily determinable diagnostic traits between these genera is limited, there is little difficulty in their differentiation since the constituent species are generally well defined." We believe that this statement is no longer true and that it is now very difficult to write operational definitions for the genera *Vibrio* and *Photobacterium* that apply to all the species included, and to devise a useful but accurate differential table.

Table BXII.γ.153 in the chapter on *Vibrionaceae* lists the characteristics that distinguish *Vibrio* from *Photobacterium*, *Aeromonas*, *Plesiomonas*, and *Enterobacteriaceae*. However, the reader is warned that some of the *Vibrio* and *Photobacterium* species that have been named recently are incompletely described, and some characteristics have not been determined for all species. Additional data and the eventual subdivision of these two genera into more logical phylogenetic units should make it easier to devise an accurate differential table. Full descriptions and additional information on *Photobacterium*, *Moritella* and *Salinivibrio* can be found in the chapters describing those genera.

Taxonomic Comments

Over the years there has been much speculation on the phylogeny of the genus *Vibrio*. However, only recently has it been possible to do systematic studies that operationally define the evolutionary relatedness of the species in *Vibrio*, *Photobacterium*, and related genera. This topic was introduced in the chapter describing the family *Vibrionaceae*. Many phylogenetic analyses based on the 16S rDNA sequences of the genera *Vibrio* and *Photobacterium* and their relatives have appeared in recent years (Aznar et al., 1994; Cerdà-Cuéllar et al., 1997; Raguénès et al., 1997a; Lambert et al., 1998; Nogi et al., 1998a, b; Sawabe et al., 1998b; Urakawa et al., 1998, 1999a; Yumoto et al., 1999a).

The concept of the genus *Vibrio* itself has changed drastically over the years. For many years organisms were classified in *Vibrio* based on a single morphological property, "curved rods". However, over the years many of these species have been reclassified in other genera with closer phylogenetic relatives. For example, *"Vibrio fetus"* (Smith and Taylor 1919, 301) is now classified in the genus *Campylobacter* (Sebald and Véron, 1963) as *C. fetus* and is the type species for that genus of curved rods, which differ from true *Vibrio* species in being microaerophilic. Similarly, the pink-pigmented methanol-oxidizing bacterium *"Vibrio extorquens"* (Stocks and McCleskey 1964) is now usually classified with other methanol-oxidizing bacteria in the genus *Methylobacterium*. Another species *Vibrio succinogenes* is a microaerophile and is now the type species of the genus *Wolinella*. Today, the trend is to include the term "vibrio" as part of a new genus name to indicate morphologies that include "comma-shaped", "curved", or "slightly curved". Examples include *Bdellovibrio*, *Cellvibrio*, *Halovibrio*, *Micavibrio*, *Vampirovibrio*, *Acetivibrio*, *Anaerovibrio*, *Butyrivibrio*, *Succinivibrio*, *Desulfovibrio*, *"Nitrosovibrio"*, and *Falcivibrio*. These organisms have many different types of metabolism and are found throughout the phylogenetic tree. Clearly, the circumscription of the genus *Vibrio* has evolved over the decades.

Three techniques introduced in the 1960s and 1970s greatly aided our understanding of the phylogeny of the genus *Vibrio*: DNA–DNA hybridization, rRNA–DNA hybridization, and the immunological relationship of enzymes and other proteins (Farmer and Hickman-Brenner, 1992; Baumann et al., 1984b). There is good agreement on many aspects of the classification and phylogeny of *Vibrio*, and the main problem today is how it should be subdivided. Before this issue is discussed, it is helpful to consider the relationships among the species of the genus *Vibrio*.

rRNA–DNA hybridization studies by Baumann and Baumann (1981a), Baumann et al. (1984b), and Fox et al. (1980) of the relationships among *Vibrio*, *Photobacterium*, *Aeromonas*, *Plesiomonas*, and *Enterobacteriaceae* indicated that the genus most closely related to *Vibrio* was *Photobacterium*, and that species of the genera *Pasteurella* and *Aeromonas*, and of the family *Enterobacteriaceae* are more distantly related.

Fig. BXII.γ.169 in this chapter shows that *Vibrio cholerae* is highly related to *Vibrio mimicus* by DNA–DNA hybridization but is much less closely related to the other *Vibrio* species. All other techniques agree that *V. cholerae* and *V. mimicus* are extremely closely related, except that the results of one study that employed 5S rRNA sequencing suggested that *V. cholerae* and *V. mimicus* are separated by a considerable distance and that other *Vibrio* species are closer relatives of *V. cholerae* than *V. mimicus* MacDonell and Colwell (1985).

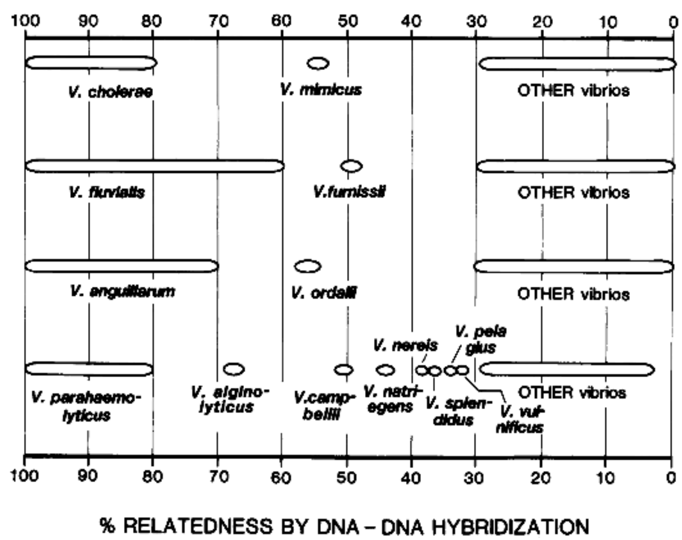

FIGURE BXII.γ.169. Relatedness of several *Vibrio* species by DNA–DNA hybridization. (Conditions: hydroxyapatite, ^{32}P, 60°C). The figure was redrawn from published and unpublished data summarized by Brenner et al. (1983b). (Reproduced with permission from J.J. Farmer III and F.W. Hickman-Brenner, *In* Balows, Trüper, Dworkin, Harder and Schleifer (Editors), The Prokaryotes: A Handbook on the Biology of Bacteria: Ecophysiology, Isolation, Identification, Applications, 2nd Edition, Volume III, ©Springer-Verlag, New York, 1992, pp. 2952–3011.)

Most of the phylogenetic analyses of the genus *Vibrio* currently being published are based solely on 16S rRNA gene sequences. However, phylogenetic trees rarely agree with each other *in toto*. Inconsistencies can be due to a number of factors, such as failure to use type strains; use of incorrectly identified or mislabeled strains; use of incorrect sequences, including ones obtained from databases; use of incorrect sequence alignments; and use of different methods of calculation in data analysis. For all these reasons data from 16S rRNA sequencing should be examined critically before being used as the basis for any taxonomic proposal.

Subdivision of the genus Over the years reclassifications of the organisms included in the genus *Vibrio* have resulted in proposals of at least 11 new genera (Table BXII.γ.162). Six of these have standing in nomenclature: *Allomonas* (Kalina et al., 1984), *Beneckea* (Campbell, 1957), *Listonella* (MacDonell and Colwell, 1985), *Lucibacterium* (Hendrie et al., 1970), *Moritella* (Urakawa et al., 1998), and *Salinivibrio* (Mellado et al., 1996). Five of the proposed genera are older, do not have standing in nomenclature, and so are written in quotation marks. These are *"Agarbacterium"* (Angst, 1929), *"Alginomonas"* (Thjøtta and Kåss, 1945), *"Alginobacter"* (Thjøtta and Kåss, 1945), *"Alginovibrio"* (Thjøtta and Kåss, 1945) and *"Oceanomonas"* (Miyamoto, et al., 1961).

The genus *Allomonas* was proposed by Kalina et al. (1984) and contained oxidase positive, fermentative organisms that had some properties of *Aeromonas* and some of *Vibrio*. Based on DNA–DNA hybridization experiments, the strains did not appear to be closely related to *Aeromonas hydrophila*, *Plesiomonas shigelloides*, *V. cholerae*, or eight other species in the family *Vibrionaceae*. However, the type strain of *Allomonas enterica* was later found to be highly related to *V. fluvialis* by DNA hybridization and phenotypic analysis (Subcommittee, 1975).

TABLE BXII.γ.162. Alternative classifications that have been proposed that would subdivide the genus *Vibrio*[a]

Genus	Species
Names with standing in the nomenclature:	
Allomonas	*A. enterica*[T]
Beneckea	*B. alginolytica*
	B. campbellii[T]
	B. gazogenes
	B. harveyi
	B. natriegens
	B. nereis (*B. nereida*)[b]
	B. nigripulchritudo (*B. nigripulchritudo*)
	B. parahaemolytica
	B. pelagia
	B. splendida
	B. vulnifica
Listonella	*L. anguillarum*[T] (*L. anguillara*)
	L. damsela
	L. pelagia
Lucibacterium	*L. harveyi*[T]
Moritella	*M. japonica*
	M. marina[T]
	M. viscosa
	M. yayanosii
Photobacterium[c]	
Salinivibrio	*S. costicola*[T]
	S. costicola subsp. *vallismortis*
Names without standing in nomenclature:	
"Listonella ordalii"	
"Agarbacterium"	
"Alginobacter"	
"Alginomonas"	
"Alginovibrio"	
"Oceanomonas"	

[a]The merits and deficiencies of these classifications are discussed in the text.

[b]Names in parentheses are alternative spellings.

[c]See the chapter describing the genus *Photobacterium*.

The genus *Beneckea* was proposed as a new genus in the family *"Achromobacteriaceae"* by Campbell (1957) and was defined as a genus of rod-shaped bacteria that were Gram negative, had peritrichous flagella, fermented carbohydrates, and digested chitin. Baumann et al. (1971a) studied a large group of "marine vibrios" and classified them in a redefined genus *Beneckea* along with *Vibrio alginolyticus* and *Vibrio parahaemolyticus*. However, as additional species of *Beneckea* were described the genus began to become heterogeneous, and Baumann et al. (1980b) concluded that all the *Beneckea* species should be classified in the genus *Vibrio*.

The genus *Listonella* was proposed by MacDonell and Colwell (1985) as new genus of *Vibrionaceae* that included three *Vibrio* species (Table BXII.γ.162): the type species *Listonella anguillarum* (*Vibrio anguillarum*), *Listonella damsela* (*Vibrio damsela*; *Photobacterium damselae*) and *Listonella pelagia* (*Vibrio pelagius*). *Listonella* included organisms fitting the following description: "Curved rods, Gram negative, motile by monotrichous or peritrichous flagella. Chemoorganotrophic, oxidase positive, associated with marine environments. Generally pathogenic for fish or eels. Do not grow at 40°C. Require NaCl for growth. G + C mol% 43–46." *V. anguillarum* is closely related to *V. ordalii* by DNA hybridization (Fig. BXII.γ.169).

The genus *Lucibacterium* was proposed in 1970 by Hendrie et al. (1970); this genus contains a single species, *Lucibacterium harveyi* (= *Vibrio harveyi*). The names *Lucibacterium* and *Lucibacterium harveyi* have standing in nomenclature but are rarely used.

The genus *Moritella* was proposed by Urakawa et al. (1998) based on 16S rRNA gene sequence divergence of 11 strains of *Moritella marina* from *Vibrio cholerae* and other *Vibrio* species. Three additional species, *Moritella japonica* (Nogi et al., 1998a), *Moritella yayanosii* (Nogi and Kato, 1999a), and *M. viscosa* (Benediktsdóttir et al., 2000) have been described.

The genus *Salinivibrio* was proposed by Mellado et al. (1996) based on 16S rRNA gene sequence divergence of six *S. costicola* (= *Vibrio costicola*) strains from *Vibrio cholerae* and other *Vibrio* species; these results were also in agreement with previous phenotypic and genotypic data.

Table BXII.γ.162 provides a summary of previous proposals that subdivided the *Vibrio* as it existed at the time each proposal was made. A successful classification should also be reconcilable with phenotypic data. It should be possible to classify newly discovered and described species into new genera that are limited so as to include only close relatives of the type species. The ideal grouping is illustrated by the pair *Vibrio cholerae* and *Vibrio mimicus* (Fig. BXII.γ.169).

Future of the genus The genus *Vibrio* and many other large heterogeneous genera such as *Pseudomonas* and *Bacillus* will change drastically in circumscription. These genera will eventually be limited to the type species and closely related species. Based on all data available we believe the following changes are likely to occur in the genus *Vibrio*, but it is difficult to determine a time frame for the changes and their acceptance by the scientific community.

The species *Vibrio cholerae* and *Vibrio mimicus* will be the basis of a more limited genus *Vibrio*; any redefinition of the genus will include these two species.

The *Vibrio* species not closely related to *Vibrio cholerae* will form the bases of many new genera, such as the genera *Salinivibrio* and *Moritella*. The figures in this chapter, the chapter describing the family *Vibrionaceae*, and the chapter on *Photobacterium* suggest other possible new genera.

We feel it is logical to include only *Listonella anguillarum* and *V. ordalii* in the genus *Listonella*. These two organisms are closely related by DNA–DNA hybridization (Fig. BXII.γ.169), the immunological relationship of superoxide dismutase (Fig. BXII.γ.170), 16S rDNA sequencing (Fig. BXII.γ.171), and phenotype. *Listonella damsela* and *Listonella pelagia* do not appear to be closely related to *Listonella anguillarum* and *"L. ordalii"*.

Vibrio fluvialis and *Vibrio furnissii* are closely related by DNA–DNA hybridization (Fig. BXII.γ.169), 16S rDNA sequencing (Fig. BXII.γ.171), the immunological relationship of superoxide dismutase (Fig. BXII.γ.170), and phenotype. These two closely related species could be used to define another new genus.

The marine species *Vibrio parahaemolyticus* and *Vibrio alginolyticus* are closely related by DNA–DNA hybridization (Fig. BXII.γ.169), DNA–RNA hybridization, the immunological relationship of superoxide dismutase (Fig. BXII.γ.170), and phenotype. However, data from 16S rRNA gene sequencing (Fig. BXII.γ.171) indicate that *Vibrio parahaemolyticus* is more closely related to other *Vibrio* species than to *Vibrio alginolyticus*. Data from DNA–DNA hybridization studies suggest that *Vibrio campbellii* is the closest relative of this pair. Gradations in digress of relatedness in the "marine vibrio group" will make it difficult to define a new genus.

As originally noted by Baumann and Baumann (1981a) *Vibrio pelagius* biogroups 1 and 2 are closely related and could form the basis of another genus. This close relationship is shown by DNA–DNA hybridization (Brenner et al., unpublished) and by the immunological relationship of superoxide dismutases (Fig. BXII.γ.170).

Vibrio metschnikovii and *Vibrio gazogenes* are unique among *Vibrio* species because they are nitrate negative and oxidase negative. They are distinct from other *Vibrio* species based on the immunological relationship of their superoxide dismutases (Fig. BXII.γ.170) and DNA–DNA hybridization (Fig. BXII.γ.172). In Figure 1 of Cerdà-Cuéllar et al. (1997) they form a tight cluster (B2) based on 16S rDNA sequencing; this cluster also includes *V. cincinnatiensis*. However, *V. metschnikovii* and *V. gazogenes* are less than 30% related by DNA–DNA hybridization (Brenner et al., unpublished). Further data are needed to determine whether *Vibrio metschnikovii* and *Vibrio gazogenes* form the basis of another new genus.

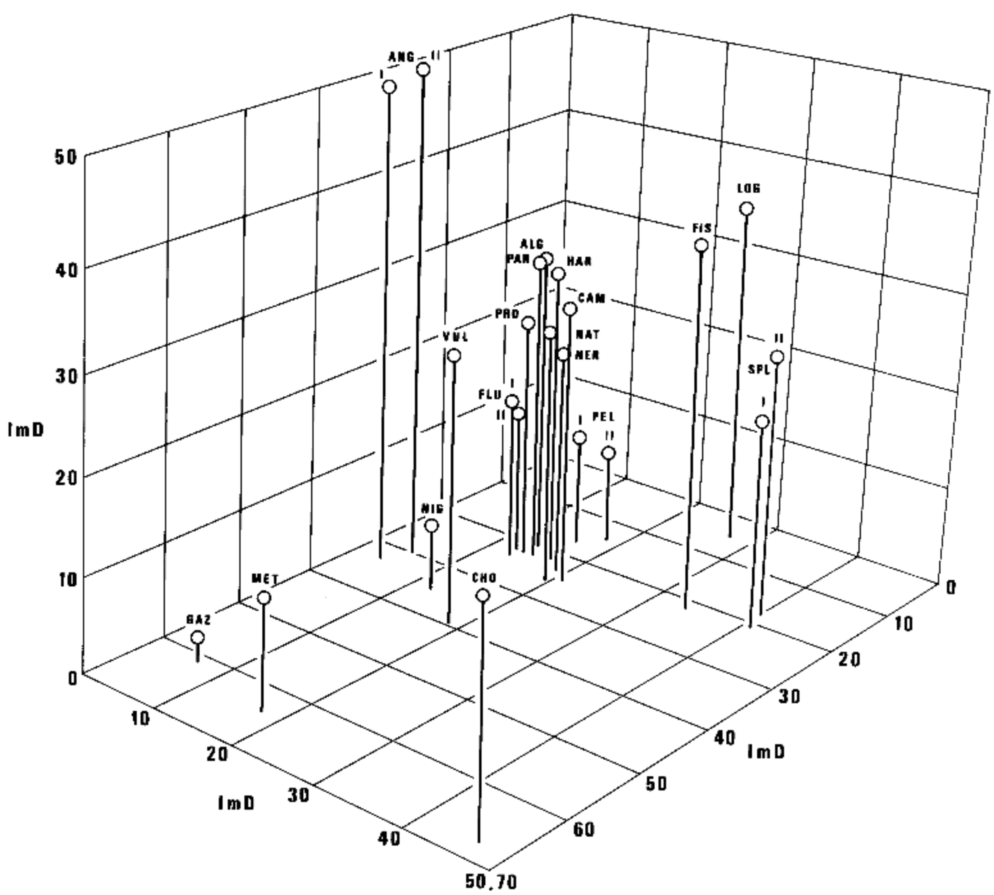

FIGURE BXII.γ.170. Relatedness of *Vibrio* species based on a three-dimensional representation of the immunological relationships of their superoxide dismutase. The spheres represent the relative positions of the species and biogroups. ImD, immunological distance, is a parameter related to percent amino acid sequence difference. *Vibrio* species are designated by the first three letters of their species name. "SPL I" and "SPL II" are *Vibrio splendidus* biogroups 1 and 2. "PEL I" and "PEL II' are *Vibrio pelagius* biogroups 1 and 2. "FLU I" and "FLU II" are *Vibrio fluvialis* biogroups 1 and 2; the latter is now usually classified as *Vibrio furnissii*. "ANG I" and "ANG II" are for *Vibrio anguillarum* biogroups 1 and 2; the latter is now usually classified as *Vibrio ordalii*. Three or four strains from each species or biogroup were used in the analysis; the maximal standard deviation was ± 1.2 ImD. *Salinivibrio costicola* was distant from all other species, and its position is not shown in this figure. (Source: Baumann et al., 1984b; the data were taken from Baumann et al. 1980a, and from S.S. Bang, L. Baumann, and P. Baumann, unpublished).

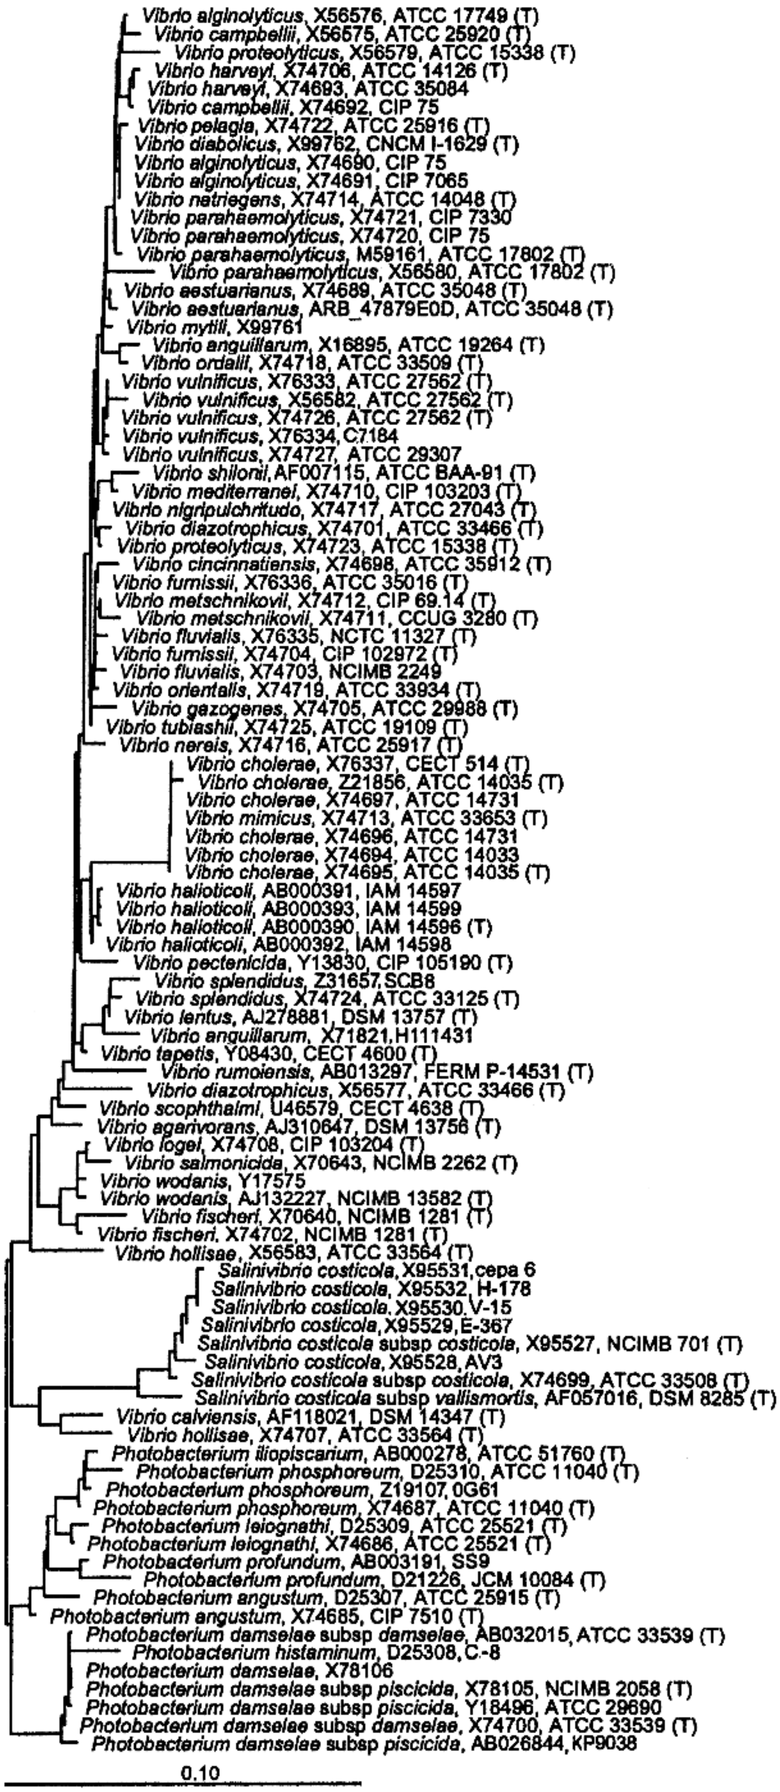

FIGURE BXII.γ.171. Relatedness of *Vibrio* and related species based on 16S rRNA gene sequences.* The distances in the tree were calculated using 1101 positions (the least-squares method, Jukes-Cantor model). (Courtesy T. Lilburn of the Ribosomal Database Project.)

**Editorial Note: Photobacterium damselae* subsp. *damselae* is a junior objective synonym of *Vibrio damsela. Vibrio pelagius* and *Vibrio anguillarum* are synonyms of *Listonella pelagia* and *Listonella anguillarum*, respectively.

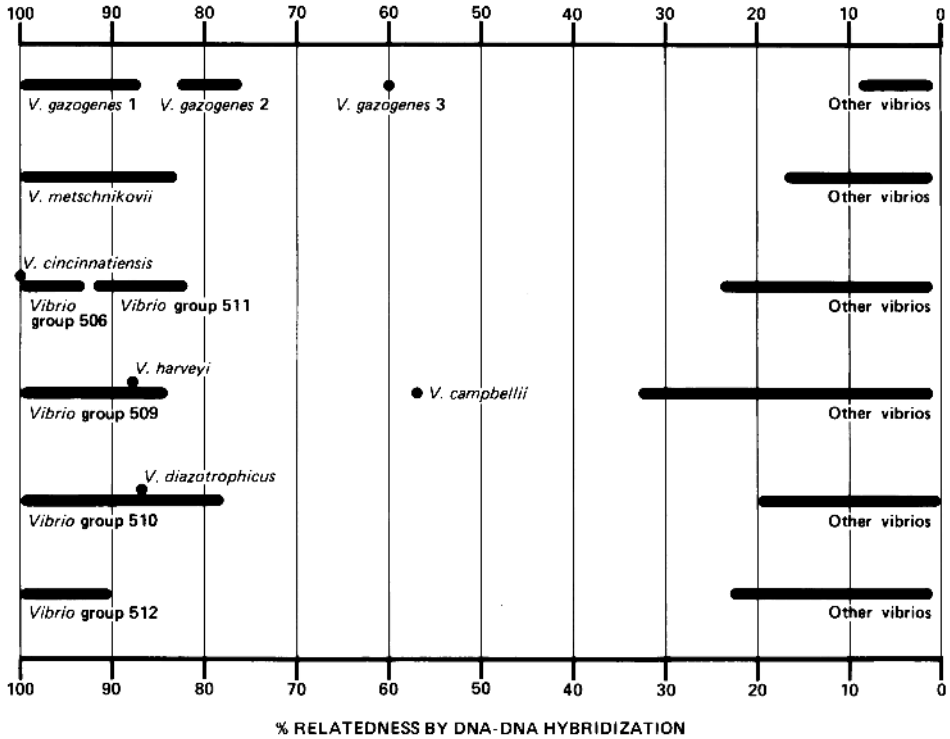

FIGURE BXII.γ.172. DNA relatedness of *Vibrio gazogenes*, *V. metschnikovii*, and five "*Vibrio* groups".

Acknowledgments

We are grateful to Paul Baumann, Linda Baumann, A.L. Furniss and John Lee and to the Bergey's Manual Trust for allowing us to use some of the data, text, tables, and figures from the *Vibrio* chapter in the first edition of *Bergey's Manual of Systematic Bacteriology*. We acknowledged this in our text with the citation Baumann et al. (1984b). We believe these contributions greatly enhance our chapter. We thank Frances Brenner and Don J. Brenner and their collaborators for the detailed information on the relatedness of all the *Vibrio* species by DNA–DNA hybridization; these data are cited in the text as Brenner et al., unpublished. We thank Ed Ewing, George Garrity, and I. Yumoto for figures; and R.D. Allen, S.S. Bang, W.E. de Boer, C. Golten, K.H. Nealson, J.L. Reichelt, W.A. Schaffers, B.M. Tebo, I. Yumoto and S.W. Watson for figures previously used in the first edition; and Don Brenner for a very helpful review of the manuscript.

We dedicate this chapter to Linda Baumann, Paul Baumann, Don J. Brenner, G. Richard Fanning, J.L. Reichelt, and Arnold J. Steigerwalt (and to their many collaborators). Their pioneering studies using nucleic hybridization methods have formed the basis of our current understanding of the circumscription and classification of the genera *Vibrio* and *Photobacterium* and their relatives.

Differentiation of the species of the genus *Vibrio**

Tables BXII.γ.163 and BXII.γ.164 summarize the characteristics of *Vibrio* spp. and include data on *Salinivibrio*, *Photobacterium*, and *Moritella* spp. for purposes of comparison. Phenotypic characteristics useful for the differentiation of the 12 *Vibrio* species that occur in human clinical specimens are given in Tables BXII.γ.156, BXII.γ.165, and BXII.γ.166. Table BXII.γ.161 gives data on the effects of such factors as basal medium, NaCl concentration, and test method on the results of nine biochemical tests for ten *Vibrio* species.

Species-specific probes have been developed for a number of vibrios. A 17-base pair oligonucleotide probe based on 5S rRNA sequence data is highly specific for the fish pathogens *V. anguillarum* and *V. ordalii* (Ito et al., 1995). However, the limit of detection is 1.5×10^5 viable cells. 16S rRNA gene sequences have also been used to detect *V. anguillarum* (Martínez-Picado et al., 1994). A number of probes designed to detect virulence-associated genes have been described for pathogenic vibrios. A 3.2-Kb probe containing the structural gene for the cytotoxin-hemolysin of *V. vulnificus* is species-specific (Morris et al., 1987). It is highly sensitive (60 viable cells can be detected) and detects all three *Vibrio vulnificus* biogroups. A 0.69-kb probe for the damselysin gene reacts with all hemolytic strains of *Vibrio damsela* but not with nonhemolytic strains or with hemolytic isolates of other vibrios such as *V. cholerae* and *V. fluvialis* (Cutter and Kreger, 1990). A 19-base-pair oligonucleotide probe has been developed that spans an 11-base-pair deletion in the *hlyA* gene in classical biotype strains of *V. cholerae* (Alm and Manning, 1990). This probe detects all O1 El Tor and non-O1 *V. cholerae* strains but not strains of the classical biotype. Two DNA probes (100 and 1000 bp) specific for the chromosomal region that encodes genes for the synthesis of the lipopolysaccharide side chain region of all *V. cholerae* O139 strains detects >99% of O139 strains but not those belonging to other serogroups or species (Nair et al., 1995).

Molecular techniques have also been used to subtype strains of *V. cholerae*, *V. parahaemolyticus*, and some environmental species such as *V. ordalii*. These techniques include pulsed-field gel electrophoresis, restriction fragment length polymorphism, ribotyping, multilocus enzyme electrophoresis, and arbitrarily primed polymerase chain reaction (Koblavi et al., 1990; Faruque et al., 1994; Mahalingam et al., 1994; Evins et al., 1995; Popovic et al., 1995; Kurazono et al., 1996; Pedersen et al., 1996b, c; Okuda et al., 1997).

**Editorial Note: Photobacterium damselae* subsp. *damselae* is a junior objective synonym of *Vibrio damsela*.

List of species of the genus Vibrio

1. **Vibrio cholerae** Pacini 1854, 411[AL]
chol′ er.ae. Gr. n. *cholera* cholera; M.L. gen. n. *cholerae* of cholera, a severe diarrheal disease.

The characteristics are as described for the genus and as listed in Tables BXII.γ.163 and BXII.γ.164. Fig. BXII.γ.158 shows the polar flagellum; Fig. BXII.γ.173 shows colonies of *V. cholerae* on TCBS agar. The antigenic types of *V. cholerae* are listed in Table BXII.γ.155; the division of *V. cholerae* strains into serogroups is given in Table BXII.γ.167. Characters that differentiate the classical and El Tor biotypes of *V. cholerae* are given in Table BXII.γ.168. Characters that distinguish *V. cholerae* from *V. mimicus* are given in Table BXII.γ.169. Characters that distinguish *V. cholerae* from other *Vibrio* spp. found in human clinical specimens are given in Tables BXII.γ.156, BXII.γ.157, BXII.γ.160, BXII.γ.161, BXII.γ.165 and BXII.γ.166. A few *V. cholerae* strains are bioluminescent, and were formerly classified as *Vibrio albensis* or *Vibrio cholerae* biovar albensis.

V. cholerae causes a diarrhea that has a wide range of severity and symptoms. In severe cholera (cholera gravis), there is severe diarrhea with rice water stools, devastating dehydration and electrolyte imbalance. There can also be cholera that is less severe and even a mild diarrhea with rapid recovery. Current strains that cause pandemic cholera produce cholera toxin and belong to serogroup O1 and to serogroup O139, which emerged recently. Epidemic strains of *V. cholerae* O1 are usually the El Tor biotype, but in some areas of the world, the classical biotype still occurs. The original El Tor strains hemolyzed sheep erythrocytes strongly, but "pandemic" strains isolated in recent years have been very poorly hemolytic or even nonhemolytic. Nontoxigenic strains of *V. cholerae* O1 may be isolated from cases of diarrhea and from the environment in areas where cholera is absent. These strains are usually hemolytic. Fig. BXII.γ.168 shows a procedure for the isolation of *V. cholerae* from feces.

The mol% G + C of the DNA is: 47–49 (T_m, Bd).

Type strain: ATCC 14035, CDC 9061-79, NCTC 8021.

GenBank accession number (16S rRNA): X74695, Z21856.

Additional Remarks: Reference strain, ATCC 14033 (NCTC 8457, CDC 9061-79), is a representative of the El Tor biotype, and was isolated from pilgrims in the El Tor quarantine camp. It was used in the extensive DNA–DNA hybridization studies of Davis et al. (1981a). It is characterized as: serogroup: O1 Inaba, biogroup: El Tor, pathogen classification: Class III, and is listed as nontoxigenic in the 1996 ATCC Catalog.

2. **Vibrio aerogenes** Shieh, Chen and Chiu 2000, 327[VP]
a.e.ro′ ge.nes. Gr. masc. n. *aer* air; Gr. v. *gennanio* to produce; M. L. adj. *aerogenes* gas-producing.

The properties of *V. aerogenes* are given in Table BXII.γ.164. Rods or curved rods 0.6–0.8 × 2–3 μm. Motile by double-sheathed polar flagella. Does not swarm. Not bioluminescent. Facultatively anaerobic; produces organic acids, H_2 and CO_2 during fermentation of carbohydrates. No growth factors required. No PHB granules formed. Grows in media containing 1–7% NaCl; does not grow in 1% or 10% NaCl. The major fatty acid is $C_{12:0}$.

Isolated from sediment in a stand of seagrass, Nanwan Bay, Kenting National Park, Taiwan.

A 16S rDNA sequence analysis that included 35 *Vibrio* species showed that *V. aerogenes* was most closely related to *V. mytili* (Shieh et al., 2000).

The mol% G + C of the DNA is: 46

Type strain: FG1, ATCC 700797, CCRC 17041.

GenBank accession number (16S rRNA): AF124055.

[a]The strains for *V. fluvialis* and *V. furnissii* grew in 0% NaCl when incubated at 25°C but not at 36°C.

[b]*V. logei* was tested at 15°C.

[c]Each number is the % positive for the test after 48 h of incubation, except for oxidase and reduction of nitrate to nitrite, which were done only at 24 h. All species except *V. logei* were tested at 25°C. All testing was done in the CDC *Vibrio* Reference Laboratory using standardized "enteric" media supplemented with marine cations (Na^+, K^+, and Mg^{++}). Results in this table may differ from those in the original descriptions of organisms due to variables in media, incubation temperature, reading time, and salt content.

**Editorial Note: Photobacterium damselae* subsp. *damselae* is a junior objective synonym of *Vibrio damsela*.

[a]The strains for *V. fluvialis* and *V. furnissii* grew in 0% NaCl when incubated at 25°C but not at 36°C.

[b]*V. logei* was tested at 15°C.

[c]Each number is the % positive for the test after 48 h of incubation, except for oxidase and reduction of nitrate to nitrite, which were done only at 24 h. All species except *V. logei* were tested at 25°C. All testing was done in the CDC *Vibrio* Reference Laboratory using standardized "enteric" media supplemented with marine cations (Na^+, K^+, and Mg^{++}). Results in this table may differ from those in the original descriptions of organisms due to variables in media, incubation temperature, reading time, and salt content.

**Editorial Note: Photobacterium damselae* subsp. *damselae* is a junior objective synonym of *Vibrio damsela*.

[a]Symbols: see standard definitions; w, weak; blank, data not determined or not applicable. Precautionary note: limitations of this table for identifying "unknown" cultures. This table is an attempt to revise and update Table 5.58 (pp. 532–533) of the *Vibrio* chapter in the first edition of this *Manual*, in which Baumann et al. studied each of the 20 *Vibrio* species. The data in their Table 5.58 were based on over 500 cultures tested under essentially identical conditions. Authors who described new *Vibrio* species since 1984 did not perform all of these tests and may have used different sets of media and methods. The following are probably the most important variables in the new data: media and methods used, incubation temperature, incubation time (final reading at 1–2 days vs 28 days or more), NaCl or "artificial seawater" added to media to speed growth and enhance metabolism, inoculation method and size, and "endpoint definition" (criteria for coding a test as positive or negative).

[b]Straight rods in exponential phase of growth becoming curved in stationary phase.

[c]Originally defined by Baumann et al. (1984b) as "the anaerobic production of ornithine from arginine." These authors have described the problems associated with the Thornley method, which measures alkali production from arginine.

[d]Luminous strains of this species have been found by Desmarchelier and Reichelt (1981).

[e]Wild-type strains are unable to utilize lactose, but many strains acquire this property by mutation. Most strains ferment lactose in "peptone type" media.

**Editorial Note: Photobacterium damselae* subsp. *damselae* is a junior objective synonym of *Vibrio damsela*.

[a]Symbols: +, most strains (generally about 90–100%) positive; −, most strains negative (generally about 0–10% positive); 1% NaCl in parentheses indicates 1% NaCl has been added to the standard media to enhance growth; HIB, heart infusion broth; TSI, triple sugar iron agar; ONPG, *o*-nitrophenyl-β-D-galactopyranoside.

[b]The number gives the percentage positive after 48 h of incubation at 36°C (unless other conditions are indicated). Most of the positive reactions occur during the first 24 hours. NG (no growth) means that the organism does not grow, probably because the NaCl concentration is too low.

[c]Tests recommended as part of the routine set for *Vibrio* identification.

**Editorial Note: Photobacterium damselae* subsp. *damselae* is a junior objective synonym of *Vibrio damsela*.

TABLE BXII.γ.166. Differential tests that divide the 12 *Vibrio* species found in clinical specimens into six groups[a,b]*

	Group 1		Group 2	Group 3	Group 4	Group 5			Group 6

Arginine dihydrolase					−	+	+	+	−	−	−	−
Lysine decarboxylase					−				+	+	+	+

[a]All data are for reactions within 2 days at 35–37°C, unless otherwise specified.

[b]Symbols: +, most strains (generally about 90–100%) positive; d, strain-to-strain variation (generally about 25–75% positive); −, most strains negative (generally about 0–10% positive).

**Editorial Note: Photobacterium damselae* subsp. *damselae* is a junior objective synonym of *Vibrio damsela*.

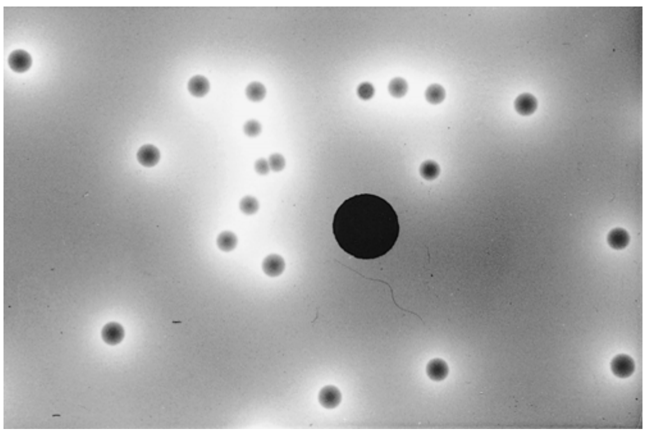

FIGURE BXII.γ.173. Colonies of *Vibrio cholerae* on TCBS agar. Yellow colonies, 2- to 3-mm in diameter are present after overnight incubation at 36°C. (Reproduced with permission from J.J. Farmer III and F.W. Hickman-Brenner, *In* Balows, Trüper, Dworkin, Harder and Schleifer (Editors), The Prokaryotes: A Handbook on the Biology of Bacteria: Ecophysiology, Isolation, Identification, Applications, 2nd Edition, Volume III, ©Springer-Verlag, New York, 1992, pp. 2952–3011.)

TABLE BXII.γ.167. Subdivision of *Vibrio cholerae* below the level of species

Serogroup	Serotype	Biogroup
V. cholerae serogroup O1[a]	Inaba	Classical
	Inaba	El Tor
	Ogawa	Classical
	Ogawa	El Tor
V. cholerae serogroup O139		
V. cholerae "non-O1, non-O139" (≈150 serogroups)		

[a]A third serotype of serogroup O1 named Hikojima is recognized by a few authors.

3. **Vibrio aestuarianus** Tison and Seidler 1983, 699[VP]
aes.tu.a.ri.a′ nus. L. n. *aestuarium* estuary; N.L. masc. adj. *aestuarianus* pertaining to an estuary.

The characteristics are as described for the genus and as listed in Tables BXII.γ.163 and BXII.γ.164. Straight or curved rods 0.5 × 1.5–2.0 μm; motile by a single polar flagellum. Colonies are β-hemolytic on sheep blood agar.

TABLE BXII.γ.168. Properties and differentiation of the classical and El Tor biogroups of *V. cholerae* serogroup O1[a]

	Biogroup	
Tests or property	Classical	El Tor
Frequency of isolation:		
On the Indian subcontinent	Occasional[b]	Common
In the rest of the world	Very rare	Common
Differential tests:		
Hemolysis of red blood cells	−	+
Voges–Proskauer test	−	+
Inhibition by polymyxin B (50-unit disks)	+	−
Agglutination of chicken red blood cells	−	+
Lysis by bacteriophage:		
Classical IV	+	−
FK	+	−
El Tor 5	−	+

[a]Symbols +, most strains (generally about 90–100%) positive; −, most strains negative (generally about 0–10 % positive).

[b]The classical biotype has reappeared on the Indian subcontinent, and has been isolated in some locations there.

TABLE BXII.γ.169. Key characteristics of *Vibrio cholerae* and *V. mimicus* and tests for their differentiation[a]

Tests or property	*V. cholerae*	*V. mimicus*
Frequency of isolation	Very common	Occasional
Oxidase	+	+
Growth in nutrient broth with:		
No added NaCl	+	+
1% NaCl	+	+
Lysine decarboxylase	+	+
Arginine dihydrolase	−	
Ornithine decarboxylase	+	+
Differentiation of the species:		
Sucrose fermentation	+[b]	−
Lipase (corn oil)	+	−
Voges–Proskauer	+[c]	−
Lactose fermentation (1–2 days)	−	d
Lactose fermentation (3–7 days)	d	d

[a]All data are for reactions within 2 days at 35–37°C unless otherwise specified. Symbols: +, 90–100% positive; d, 11–89% positive; −, 0–10% positive.

[b]Most of the positive reactions occur during the first 24 h of incubation

[c]Almost all strains of *V. cholerae* non-O1 and most strains of *V. cholerae* O1currently isolated are of the El Tor biogroup, which is almost always positive for the Voges–Proskauer test. The classical biogroup is negative for the Voges–Proskauer test.

Isolated from estuary water, shellfish, and crabs off the coast of Oregon, USA. The type strain was isolated from an oyster.

Based on the results of DNA–DNA hybridization experiments, strains of *Vibrio aestuarianus* are highly related to the type strain (Tison and Seidler, 1983; Brenner et al., unpublished) and less than 25% related to other *Vibrio* species, including *V. anguillarum*, *V. nereis*, and *V. splendidus* which have similar phenotypic characteristics. The closest relative is *Vibrio anguillarum* to which it is 30–41% related (Brenner et al., personal communication). Fig. BXII.γ.171 illustrates the relationship of *Vibrio aestuarianus* to other *Vibrio* species, based on 16S rRNA gene sequence analysis (Brenner, personal communication).

The mol% G + C of the DNA is: 43–44 (T_m).

Type strain: OY-0-002, ATCC 35048.

GenBank accession number (16S rRNA): X74689.

4. **Vibrio alginolyticus** (Miyamoto, Nakamura and Takizawa 1961) Sakazaki 1968, 360[AL] (*"Oceanomonas alginolytica"* Miyamoto, Nakamura and Takizawa 1961, 481; *Beneckea alginolytica* (Miyamoto, Nakamura and Takizawa 1961, 481) Baumann, Baumann and Mandel 1971a, 289.)
al.gi.no.ly'ti.cus. L. fem. n. *alga* seaweed; M.L. adj. *alginolyticus* pertaining to alginic acid from seaweed; Gr. adj. *lyticus* dissolving; M.L. adj. *alginolyticus* alginic acid-dissolving.

The characteristics are as described for the genus and as listed in Tables BXII.γ.163 and BXII.γ.164. The morphology is illustrated in Figs. BXII.γ.159 and BXII.γ.162. Characters that differentiate *V. alginolyticus* from *V. harveyi*, *V. parahaemolyticus*, and *V. vulnificus* are given in Table BXII.γ.170. Characters that distinguish *V. alginolyticus* from other *Vibrio* spp. found in human clinical specimens are given in Tables BXII.γ.156, BXII.γ.157, BXII.γ.160, BXII.γ.161, BXII.γ.165 and BXII.γ.166.

Occurs in human clinical specimens, particularly in soft tissue infections (Table BXII.γ.157) and in the marine environment.

Many reports describe the isolation of *V. alginolyticus* from soft tissue infections (Rubin and Tilton, 1975; Pien et al., 1977). Wound infections and ear infections are usually mentioned, with eye infections mentioned much less frequently. There is a clear association of *V. alginolyticus* with infection at these sites; however, the etiological role of *V. alginolyticus* has rarely been shown conclusively and little has been reported about the pathogenesis of these infections. Most authors list *V. alginolyticus* as a pathogen, particularly of wound and ear infections. Antibiotic treatment has been used in most cases; surgical debridement has been used in some.

The mol% G + C of the DNA is: 45–47 (T_m, Bd).

Type strain: 118, ATCC 17749, CCM 2578, DSM 2171, IMET 11295.

GenBank accession number (16S rRNA): X56576, X74690.

5. **Vibrio anguillarum** Bergman 1909, 28[AL] (*Listonella anguillarum* (Bergman 1909) MacDonell and Colwell 1986, 354; *Listonella anguillara* (sic) (Bergman 1909) MacDonell and Colwell 1985, 180.)*
an.guil.la'rum. L. n. *anguilla* eel; L. gen. pl. n. *anguillarum* of eels.

The characteristics are as described for the genus and as listed in Tables BXII.γ.163, BXII.γ.164, and BXII.γ.171. In contrast to *V. ordalii*, whose strains belong only to O antigen group 2, *V. anguillarum* strains belong to O antigen groups 1–16.

Based on the results of DNA–DNA hybridization experiments, the type strain of *V. anguillarum* is closely related to other strains of this species. The closest relative is *V. ordalii* (Schiewe et al., 1981; also see Fig. BXII.γ.169, based on Brenner et al., 1983b) to which it is 58–76% related with T_m values of 2.5–4.0 (Brenner et al., unpublished). This close relationship has been confirmed by the structural similarity of superoxide dismutase (Fig. BXII.γ.170) and by 16S rRNA gene sequencing (Fig. BXII.γ.171). Although *V. an-*

**Editorial Note:* In the last edition of this *Manual*, Baumann et al. (1984b) used the names *V. anguillarum* biovar I and *V. anguillarum* biovar II. In this edition, these organisms are classified as *V. anguillarum* and *V. ordalii*, respectively. *V. anguillarum* has also been known as *Vibrio anguillarum* biotype 1 (Schiewe et al., 1977), *Beneckea anguillara* biotype I (Baumann et al., 1978), *Vibrio anguillarum* biotype I (Baumann et al., 1980b), and *Vibrio anguillarum* biovar I (Baumann et al., 1984b). In addition, the name *Listonella anguillarum* has standing in the nomenclature (MacDonell and Colwell, 1985); see description of *V. pelagius.*

TABLE BXII.γ.170. Differentiation of the arginine-negative, lysine-positive species *V. alginolyticus*, *V. parahaemolyticus*, *V. vulnificus*, and *V. harveyi* [a]

Test or property	*V. alginolyticus*	*V. harveyi*	*V. parahaemolyticus*	*V. vulnificus*
Voges–Proskauer test	+	−	−	−
Growth in nutrient broth with:				
8% NaCl	+	−	(+)	−
10% NaCl	d	−	−	−
Fermentation of:				
Sucrose	+	+	−	(−)
Salicin	−	−	−	+
Cellobiose	−	−	−	+
Lactose	−	−	−	(+)
L-Arabinose	−	−	(+)	−
Swarming (marine agar, 25°C)	+	+	+	−
Size of zone of inhibition around:				
Colistin	Large	Small	Large	Small
Ampicillin	Small	Small	Small	Large
Carbenicillin	Small	Small	Small	Large

[a]All data for biochemical reactions are within 2 days at 35–37°C. Symbols: +, 90–100% positive, (+), 75–89.9% positive; d, 25.1–74.9% positive; (−), 10.1–25% positive; −, 0–10% positive.

guillarum and *V. ordalii* are closely related in a phylogenetic sense, they differ considerably in phenotypic properties (Table BXII.γ.171). *Vibrio anguillarum* is more versatile biochemically, has more diverse O antigens, and is less fastidious.

The mol% G + C of the DNA is: 44–46 (T_m, Bd).

Type strain: ATCC 19264, IFO 13266, LMG 4437, NCCB 72050.

GenBank accession number (16S rRNA): X16895.

6. **Vibrio campbellii** (Baumann, Baumann and Mandel 1971a) Baumann, Baumann, Bang and Woolkalis 1981, 217[VP] (Effective publication: Baumann, Baumann, Bang and Woolkalis 1980b, 128) (*Beneckea campbellii* Baumann, Baumann and Mandel 1971a, 288.)
camp.bel′ li.i. M.L. gen. n. *campbelli* named to honor L.L. Campbell, an American bacteriologist.

The characteristics are as described for the genus and as listed in Tables BXII.γ.163 and BXII.γ.164. The cell morphology is illustrated in Fig. BXII.γ.174.

Occurs in ocean water some distance from the cost of Hawaii (Baumann et al., 1971a) and in open waters of the Atlantic ocean (Grimes et al., 1986).

Phylogenetically, *Vibrio campbellii* is one of the marine *Vibrio* species (Figs. BXII.γ.170 and BXII.γ.171). By DNA–DNA hybridization, it is most closely related to *V. harveyi* (61–74%); this result agrees with the close relationship indicated by 16S rRNA gene sequence analysis (Fig. BXII.γ.171). Based on the results of DNA–DNA hybridization experiments *V. campbellii* is 40–57% related to several of the marine *Vibrio* species (Reichelt et al., 1976; Brenner et al., 1983b).

TABLE BXII.γ.171. Properties and differentiation of *Vibrio anguillarum* and *V. ordalii*[a]

Test or property	*V. anguillarum*	*V. ordalii*
Number of strains studied	12	11
O antigens represented	O1–O16	O2 only
Colony size on TSA after 48 hours	3–5 mm	Barely visible
Growth at 37°C	92	0
Growth at 25°C	100	100
Growth at 22°C	100	100
Growth at 15°C	100	100
Growth in 0% NaCl	0	0
Growth in 0.5% NaCl	100	100
Growth in 3% NaCl	100	100
Growth in 7% NaCl	0	0
Indole production	58	0
Voges–Proskauer	100	0
Arginine dihydrolase	100	0
Nitrate reduction to nitrite	100	66
Citrate utilization (Simmons)	75	0
Citrate utilization (Christensen)	100	0
Starch hydrolysis	100	0
ONPG test	100	0
Lipase	100	0
L-Arabinose fermentation	58	0
Cellobiose fermentation	92	0
D-Galactose fermentation	100	55
Glycerol fermentation	100	0
D-Sorbitol fermentation	100	0
Trehalose fermentation	100	0

[a]Data are summarized from Table 2 of Schiewe et al. (1981). Conditions: incubation at 22°C; media were supplemented with NaCl to final concentration of 1.5%; final reading for negative tests was 14 days. Each number gives the percentage of strains that were positive for the test.

The mol% G + C of the DNA is: 46–48 (T_m, Bd).

Type strain: ATCC 25920, IFO 15631, LMG 11216, NCCB 73002.

GenBank accession number (16S rRNA): X56575.

7. **Vibrio cincinnatiensis** Brayton, Bode, Colwell, MacDonell, Hall, Grimes, West and Bryant 1986a, 355[VP] (Effective publication: Brayton, Bode, Colwell, MacDonell, Hall, Grimes, West and Bryant 1986b, 107.)
cin.cin.nat.i.en′ sis. L. masc. adj. *cincinnatiensis* derived from Society of Cincinnati, from which the city of Cincinnati, Ohio, was named.

The characteristics are as described for the genus and as listed in Tables BXII.γ.163 and BXII.γ.164. Characters that distinguish *V. cincinnatiensis* from other *Vibrio* spp. found in human clinical specimens are given in Tables BXII.γ.156, BXII.γ.157, BXII.γ.160, BXII.γ.165 and BXII.γ.166. Small rods approximately 0.7–2.0 μm; motile; single polar flagellum. Colonies on nutrient agar are 1–2 mm in diameter, round, smooth, glossy, and cream colored. Grows poorly on TCBS medium (Table BXII.γ.160), but isolates from extraintestinal clinical specimens should grow on one of the non-selective plating media such as blood agar. Requires NaCl for growth (Tables BXII.γ.163 and BXII.γ.165). Ferments *myo*-inositol (Table BXII.γ.163).

Rarely isolated from human clinical specimens.

This organism was isolated by Brayton et al. (1986b) from blood and cerebral spinal fluid of a 70-year-old man with no known contact with seafood or saltwater. Biochemical testing and the 5S rRNA sequence led to the conclusion that this was a new species, which they named *V. cincinnatiensis*. Comparative 5S rRNA sequence analysis indicated that *V. cincinnatiensis* shared a recent ancestor with *V. gazogenes* (98% homology), but this postulated relationship has not been confirmed by other techniques including 16S rRNA gene sequencing (Fig. BXII.γ.171).

The mol% G + C of the DNA is: 45.0.

Type strain: ATCC 35912, CIP 104173, LMG 789.

GenBank accession number (16S rRNA): X74698.

FIGURE BXII.γ.174. Electron micrograph of *Vibrio campbellii* illustrating the appearance of the tubular appendages that are also observed in some other marine vibrios. Negatively stained preparation. × 36,000. (Reproduced with permission from R.D. Allen and P. Baumann, Journal of Bacteriology *107:* 295–302, 1971, ©American Society for Microbiology.)

8. **Vibrio cyclitrophicus** Hedlund and Staley 2001, 65[VP] (*Vibrio cyclotrophicus* (sic) Hedlund and Staley 2001, 65.)
cy′ cli.tro′ phi.cus. Gr. n. *kyklos* circle or ring; Gr. adj. *trophikos* pertaining to food.

Properties of *V. cyclitrophicus* are given in Table BXII.γ.164. Rods 0.6 × 1.5–2.5 μm. Motile by 1–2 polar or subpolar flagella. Grows in media containing ≥ 1.75% NaCl. Utilizes some polycyclic aromatic hydrocarbons as carbon and energy sources.

The type strain was isolated from creosote-contaminated marine sediment, Eagle Harbor, Puget Sound, Washington, USA, in 1993.

An analysis of the 16S rDNA sequences of 10 *Vibrio* species indicated that the closest relative of *V. cyclitrophicus* was *V. splendidus* (Hedlund and Staley, 2001). Fig. BXII.γ.171 illustrates the relationship of *V. cyclitrophicus* to other species of *Vibrio*.

The mol% G + C of the DNA is: 39 (T_m).
Type strain: P-2P44, ATCC 700982, CIP 106644.
GenBank accession number (16S rRNA): U57919.

9. **Vibrio damsela** Love, Teebken-Fisher, Hose, Farmer, Hickman, and Fanning 1982, 267[VP] (Effective publication: Love, Teebken-Fisher, Hose, Farmer, Hickman, and Fanning 1981, 1140.)*
dam.sel′ a. M.L. n. *damsela* from the modern zoological term damselfish.

Classified as *Listonella damsela* by MacDonell and Colwell (1985, 1986) and as *Photobacterium damselae* by Smith et al. (1991); Trüper and De' Clari (1997) corrected spelling of the species epithet of *Photobacterium damselae* to *damselae*.

Morphological, growth, physiological and biochemical characteristics are listed in Table BXII.γ.163. Biochemical and other phenotypic characteristics useful for identification are listed in Table BXII.γ.164. Additional characteristics are listed in Tables BXII.γ.156, BXII.γ.157, BXII.γ.160, BXII.γ.161, BXII.γ.165, BXII.γ.166, and BXII.γ.173. Causes skin ulcers on the blacksmith *Chromis punctipinnis* (a damselfish) and causes human wound infections. Isolated from marine algae, which may be important in disease transmission to fish.

V. damsela was described by Love et al. (1981) who isolated the type strain from skin lesions on *Chromis punctipinnis* off the California coast. Koch's postulates were fulfilled when it was documented that this organism alone caused the fish lesions. Strains of *V. damsela* were then compared to a large collection of unidentified *Vibrio* strains from human clinical specimens, which revealed that *V. damsela* had occurred in human infections (Love et al., 1981). Morris et al. (1982) reviewed the case histories of six patients with wound infections positive for *V. damsela*. All had been acquired in coastal areas. *V. damsela* appears to cause human wound infections, but its causal role needs to be further documented. Most of the clinical isolates have been from wounds, and 9 of 10 were from leg or foot wounds (Vibrio Laboratory, CDC, unpublished). Strains were also from marine animals, particularly marine fish. Other sources include: fish from Senegal, sewage, oysters, and a wound culture from a raccoon (Vibrio Laboratory, CDC, unpublished). By DNA–DNA hybridization, strains of *V. damsela* are 76–97% related to the type strain and only 0–26% related to all other *Vibrio* species (Brenner et al., personal communication). Based on 16S rDNA sequencing *V. damsela* is more closely related to several *Photobacterium* species than to *Vibrio cholerae*.

The mol% G + C of the DNA is: 43 (Bd).
Type strain: CDC 2588-80, ATCC 33539, DSM 7482.
GenBank accession number (16S rRNA): X74700.

10. **Vibrio diabolicus** Raguénès, Christen, Guezennec, Pignet and Barbier 1997a, 994[VP]
di.a.bol′ i.cus. L. adj. *diabolicus* devilish, diabolic.

The morphological, growth, physiological and biochemical characteristics are listed in Tables BXII.γ.154 and BXII.γ.164. Small cells 0.8 × 2.2 μm, motile via a single polar flagellum in liquid media. Produce swarming colonies on solid media; the cells from these colonies have lateral flagella. The organisms synthesize a novel exopolysaccharide that contains high levels of uronic acids and hexosamines when grown in batch culture with glucose.

Only a single strain of this species has been described. This strain was isolated from the polychaete annelid *Alvinella pompejana* from a deep-sea (2600 m) hydrothermal vent in the East Pacific Rise and was found during a search for novel exopolysaccharides of marine origin.

Based on DNA–DNA hybridization experiments Raguénès et al., 1997a found that the closest relatives of *V. diabolicus* were *V. mytili* (27% relatedness) and *V. nereis* (15%). The closest relatives indicated by the results of 16S rRNA gene sequence analysis were *V. mytili* (98.9%), *V. alginolyticus* (98.9%), *V. pelagius* (98.9%), *V. parahaemolyticus* (98.8%), *V. natriegens* (98.7%), *V. nereis* (98.5%), *V. campbellii* (98.5%), and *V. tubiashii* (98.4%). The authors concluded that "*Vibrio diabolicus* belongs to a well-defined monophyletic unit that also includes *V. tubiashii*, *V. nereis*, and *V. mytili*." Fig. BXII.γ.171 illustrates the relationship of *V. diabolicus* to other *Vibrio* species based on 16S rRNA gene sequence analysis.

The mol% G + C of the DNA is: 49.6 (T_m).
Type strain: HE800, CNCM I-1629.
GenBank accession number (16S rRNA): X99762.

11. **Vibrio diazotrophicus** Guerinot, West, Lee and Colwell 1982, 356[VP]
di.a.zo.tro′ phi.cus. Gr. prefix *di* two, double; N.L. n. *azotum* nitrogen; Gr. n. *trophus* one that feeds; L. suffix *icus* relating to; M.L. adj. *diazotrophicus* one that feeds on dinitrogen, or less literally, nitrogen fixing.

The characteristics are as described for the genus and as listed in Tables BXII.γ.163 and BXII.γ.164. Small cells 0.5 × 1.5–2.0 μm. Motile by means of a sheathed polar flagellum when grown in broth. Cells grown on solid media produce unsheathed lateral flagella with a short wavelength. The organisms fix nitrogen.

Distributed throughout estuarine and marine environments. Isolated from the intestinal tract of sea urchins, river water, Chesapeake Bay water, ditch water and sediment, and the surface of reeds growing in a drainage ditch.

This organism may occur in human clinical specimens.

Editorial Note: Photobacterium damselae subsp. *damselae* is a junior objective synonym of *Vibrio damsela*.

Culture 2550-90 sent to the *Vibrio* Reference Laboratory was isolated from human blood and was reported as "*Vibrio diazotrophicus* group" (*Vibrio* Reference Laboratory, CDC, unpublished). If confirmed, it would be the first clinical isolate of this species.

Based on DNA–DNA hybridization experiments, Guerinot et al. (1982) found that four strains were 88–100% related to the type strain; however, one strain was only 62% related to the type strain. Also based on DNA–DNA hybridization experiments, Brenner et al. (unpublished) found that strains of *V. diazotrophicus* were highly related to the type strain (77–84% related), but distantly related to all other named *Vibrio* species. Unnamed "*Vibrio* group 510" was the closest relative (65–74% related).

The mol% G + C of the DNA is: 45.9–47.2 (T_m, Bd).

Type strain: NS1, ATCC 33466, DSM 2604, IAM 14402.

GenBank accession number (16S rRNA): X56577, X74701.

12. **Vibrio fischeri** (Beijerinck 1889) Lehmann and Neumann 1896, 342[AL] (*Photobacterium fischeri* Beijerinck 1889, 402.)
fisch′er.i. M.L. gen. n. *fischeri* named to honor Bernhard Fischer, one of the earliest microbiologists to study bioluminescent bacteria.

The characteristics are as described for the genus and as listed in Tables BXII.γ.163 and BXII.γ.164. The cell morphology is as depicted in Figs. BXII.γ.161, BXII.γ.165, and BXII.γ.175. Produces a cell-associated yellow-orange pigment.

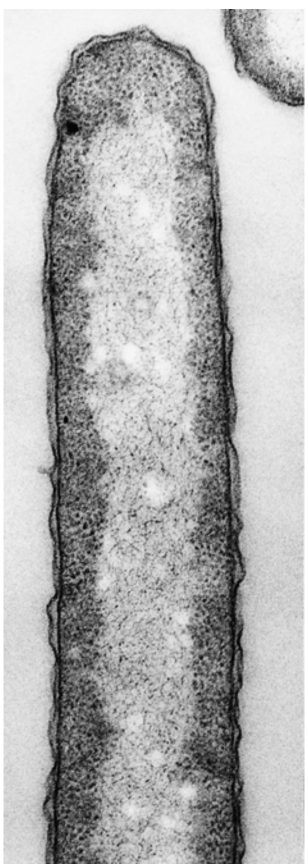

FIGURE BXII.γ.175. Ultrathin section of *Vibrio fischeri.* Exponential growth phase in yeast extract broth. × 40,000. (Courtesy of S.W. Watson.)

Isolated from seawater and marine animals.

Phenotypically and phylogenetically, *Vibrio fischeri* is closely related to *Vibrio logei* (Tables BXII.γ.163 and BXII.γ.164; Figs. BXII.γ.170 and BXII.γ.171). Based on DNA–DNA hybridization experiments, the two species are 36% related (Brenner et al., unpublished)

The mol% G + C of the DNA is: 39–41 (T_m, Bd).

Type strain: ATCC 7744 (strain 398, DSM 507.

GenBank accession number (16S rRNA): X70640.

13. **Vibrio fluvialis** Lee, Shread, Furniss and Bryant 1981c, 217[VP] (Effective publication: Lee, Shread, Furniss and Bryant 1981b, 92.)
flu.vi.a′lis. L. adj. *fluvialis* of or belonging to a river.

The characteristics are as described for the genus and as listed in Tables BXII.γ.163 and BXII.γ.164. Characters that distinguish *V. fluvialis* from *V. furnissii* are given in Tables BXII.γ.172 and BXII.γ.173. Characters that distinguish *V. fluvialis* from *Vibrio damsela* and *Aeromonas* spp. are given in Table BXII.γ.173. Characters that distinguish *V. fluvialis* from other *Vibrio* spp. found in human clinical specimens are given in Tables BXII.γ.156, BXII.γ.157, BXII.γ.160, BXII.γ.161, BXII.γ.165 and BXII.γ.166.

Causes sporadic cases of human diarrhea and occasional outbreaks. Also isolated from natural waters (often from estuaries) and animals that live there.

Lee et al. (1981b) gave the name *Vibrio fluvialis* to a group of halophilic vibrios that had been previously been known as "marine aeromonads" and "Group F" in the United Kingdom (Furniss et al., 1977) and as "Group EF6" at the Special Bacteriology Laboratory, CDC (Huq et al., 1980). These organisms had been isolated from a number of sources throughout the world and from humans with diarrhea. Lee et al. (1981b) defined two biogroups in this species based on the source of isolation and the results of certain biochemical tests. *V. fluvialis* biogroup I strains did not produce gas during fermentation and were isolated from cases of human diarrhea as well as from the environment. *V. fluvialis* biogroup II strains produced gas during fermentation and were isolated from the environment, but not from humans with diarrhea. Brenner et al. (1983c) later used DNA–DNA hybridization to show that strains of *V.*

TABLE BXII.γ.172. Differentiation of *Vibrio fluvialis* and *V. furnissii*

Test or property	Percentage positive for:	
	V. fluvialis	*V. furnissii*
Simple tests:[a]		
Gas production during fermentation	0	99
Esculin hydrolysis	72	0
Carbon source utilization:[b]		
Citrulline	97	4
D-Glucuronic acid	94	4
Putrescine	31	100
δ-Aminovalerate	0	63
Cellobiose	63	4
Glutaric acid[c]	−	+

[a]For the two simple tests, each number gives the percentage positive after 48h incubation at 35–37°C. Most of the positive reactions occur during the first 24 hours.

[b]Data from Lee et al. (1981b) except for glutaric acid, which is from Baumann et al. (1984b). These carbon-source utilization tests are usually done in research laboratories rather than in public health or clinical laboratories.

[c]Percentage data not available.

TABLE BXII.γ.173. Differentiation of the arginine-positive species *V. fluvialis*, *V. furnissii*, and *V. damsela* and comparison with *Aeromonas*[a]

Test or property	*V. damsela*	*V. fluvialis*	*V. furnissii*	*Aeromonas*
Growth in nutrient broth with:				
No added NaCl	−	−	−	+
1% NaCl	+	+	+	+
6% NaCl	+	+	+	−
Voges–Proskauer test	+	−	−	d
Citrate, Simmons	−	+	+	d
Fermentation of:				
D-Galacturonate	−	+	+	−
L-Arabinose	−	+	+	d
D-Mannitol	−	+	+	+
Sucrose	−	+	+	(+)
Gas production during fermentation	d	−	+	d

[a]All data are for reactions within 2 days at 35–37°C unless otherwise specified. Symbols: +, 90–100% positive, (+), 75–89.9% positive; d, 25.1–74.9 positive; −, 0–10% positive.

fluvialis biogroup II were related to strains of *V. fluvialis* biogroup I, but they were sufficiently different to be a new species, which was named *V. furnissii*.

The sources of early clinical isolates of *V. fluvialis* showed a marked association with diarrhea (Lee et al., 1981b), and further studies have strengthened its causative role. One difficulty in assessing the clinical symptoms and epidemiology of *V. fluvialis* has been the presence of other possible pathogens; most reports have come from geographical areas where several possible pathogens are often present in feces. Gastroenteritis associated with *V. fluvialis* is usually described as "cholera-like". Symptoms include watery diarrhea with vomiting (97% of patients), abdominal pain (75%), moderate to severe dehydration (67%), and fever (35%). Usually infants, children, and young adults are affected. Frank blood is found in a small percentage of stool samples, but red or white blood cells are found in most cases (75%). The pathogenesis of *V. fluvialis* diarrhea is beginning to be studied. Assays for heat-labile and heat-stable enterotoxin (LT and ST) and invasiveness have generally been negative. About 20% of isolates give a positive rabbit ileal loop test for enterotoxin. Recent studies have provided additional evidence for enterotoxin or for "enterotoxin-like" molecules (Lockwood et al., 1982; Nishibuchi et al., 1983).

The mol% G + C of the DNA is: 49.3–50.3 (T_m, Bd).

Type strain: VL 5125, ATCC 33809, IMET 11293, NCTC 11327.

GenBank accession number (16S rRNA): X74703, X76335.

14. **Vibrio furnissii** Brenner, Hickman-Brenner, Lee, Steigerwalt, Fanning, Hollis, Farmer, Weaver, Joseph and Seidler 1984b, 91[VP] (Effective publication: Brenner, Hickman-Brenner, Lee, Steigerwalt, Fanning, Hollis, Farmer, Weaver, Joseph and Seidler 1983c, 823.)
fur.niss′i.i. L. gen. n. *furnissii* of Furniss; named to honor A.L. Furniss, Maidstone Public Health Laboratories, Maidstone, England who was involved in the original discovery and naming of the "group F" vibrios.

The characteristics are as described for the genus and as listed in Tables BXII.γ.163 and BXII.γ.164. Characters that distinguish *V. furnissii* from *V. fluvialis* are given in Tables BXII.γ.172 and BXII.γ.173. Characters that distinguish *V. furnissii* from *Vibrio damsela* and *Aeromonas* spp. are given in Table BXII.γ.173. Characters that distinguish *V. furnissii* from other *Vibrio* spp. found in human clinical specimens are given in Tables BXII.γ.156, BXII.γ.157, BXII.γ.160, BXII.γ.161, BXII.γ.165 and BXII.γ.166.

Widely distributed in natural waters (often in estuaries) and animals that live there; occasionally isolated from animal feces. Although *V. furnissii* strains were isolated from two outbreaks of acute gastroenteritis, other pathogens or possible pathogens were also isolated (*V. parahaemolyticus*, *V. cholerae* non-O1, *V. fluvialis*, *Salmonella*, and *Plesiomonas*). Therefore, the role of *V. furnissii* as the actual cause of the diarrhea was only speculative.

V. furnissii was established for strains that resembled *V. fluvialis* but produced gas during fermentation. Based on DNA–DNA hybridization experiments, three strains of *V. furnissii* were shown to be 79% or more related to the type strain of *V. furnissii* but only 50% related to the type strain of *V. fluvialis* (Brenner et al., 1984b).

The mol% G + C of the DNA is: 50.4 (T_m).

Type strain: ATCC 35016, CDC B3215, CIP 102972, LMG 7910.

GenBank accession number (16S rRNA): X74704, X76336.

15. **Vibrio gazogenes** (Harwood, Bang, Baumann and Nealson 1980) Baumann, Baumann, Bang and Woolkalis 1981, 217[VP] (Effective publication: Baumann, Baumann, Bang and Woolkalis 1980b, 128) (*Beneckea gazogenes* (ex Harwood 1978) Harwood, Bang, Baumann and Nealson 1980, 655.)
gaz.og′e.nes. Fr. n. *gaz* gas; L. n. *genesis* birth; M.L. adj. *gazogenes* gas-producing.

The characteristics are as described for the genus and as listed in Tables BXII.γ.163 and BXII.γ.164. Relatedness of strains based on DNA–DNA hybridization experiments is given in Figs. BXII.γ.172 and BXII.γ.176. Three characters distinguish *V. gazogenes* from all other *Vibrio* species: production of a non-diffusible red ("prodigiosin-like") pigment, a negative reaction for oxidase, and an inability to reduce NO_3^- to NO_2^-. The determination of the oxidase reaction is complicated by the red pigmentation of colonies; this difficulty can be overcome by testing spontaneous white colonial mutants, which are produced by most cultures held for long periods in agar slants or deeps.

Isolated from estuary water and salt marsh mud off the eastern coast of the United States (Farmer et al., 1988),

and from a hypersaline lake in Baja California (Giovannoni and Margulis, 1981).

DNA–DNA hybridization experiments (Figs. BXII.γ.172 and BXII.γ.176) showed that strains of *V. gazogenes* fall into three highly related groups (Farmer et al., 1988). However, the three groups cannot be completely differentiated by phenotype. The type strain is less than 15% related to other *Vibrio* species tested (Brenner et al., unpublished). Analysis of 16S rRNA gene sequences showed that *V. gazogenes* is not closely related to other *Vibrio* species (Fig. BXII.γ.171).

The mol% G + C of the DNA is: 47.1 (T_m).

Type strain: PB1, ATCC 29988.

GenBank accession number (16S rRNA): X74705.

16. **Vibrio halioticoli** Sawabe, Sugimura, Ohtsuka, Nakano, Tajima, Ezura and Christen 1998b, 578[VP]
hal.i.o.ti' co.li. M.L. n. *Haliotis* genus name for abalone, a rock-climbing gastropod mollusk; Gr. n. *colon* gut; M.L. gen. n. *halioticoli* pertaining to the gut of *Haliotis.*

The morphological, growth, physiological and biochemical characteristics are listed in Tables BXII.γ.154 and BXII.γ.164. Cells are rod shaped with rounded ends when grown in Zobell's medium 2216A but are spherical when grown in this medium with added alginate. Nonmotile. Cells bind to and utilize alginic acid.

Isolated from gut of the abalone *Haliotis discus hannai*, where this bacterium may aid in the digestion of algae that contain alginic acid.

Sawabe et al. (1998b) concluded that *Vibrio halioticoli* is a separate *Vibrio* species with no close relatives based on DNA–DNA hybridization experiments and 16S rRNA gene sequence analysis (also see Fig. BXII.γ.171).

The mol% G + C of the DNA is: 41.6–43.1 (HPLC).

Type strain: A431, ATCC 700680, IAM 14596.

GenBank accession number (16S rRNA): AB000390.

17. **Vibrio harveyi** (Johnson and Shunk 1936) Baumann, Baumann, Bang and Woolkalis 1981, 217[VP] (Effective publication: Baumann, Baumann, Bang and Woolkalis 1980b, 128) (*"Achromobacter harveyi"* Johnson and Shunk 1936, 587; *Lucibacterium harveyi* (Johnson and Shunk 1936) Hendrie, Hodgkiss and Shewan 1970, 166; *Beneckea harveyi* (Johnson and Shunk 1936) Reichelt and Baumann 1973b, 320; *Vibrio carchariae* Grimes, Stemmler, Hada, May, Maneval, Hetrick, Jones, Stoskopf and Colwell 1985, 224.)
har' vey.i. M.L. gen. n. *harveyi* of Harvey; named to honor E.N. Harvey, a biologist who was a pioneer in the systematic study of bioluminescence.

The characteristics are as described for the genus and as listed in Tables BXII.γ.163 and BXII.γ.164. Characters that differentiate *V. harveyi* from *V. alginolyticus*, *V. parahaemolyticus*, and *V. vulnificus* are given in Table BXII.γ.170. Characters that distinguish *V. harveyi* from other *Vibrio* spp. found in human clinical specimens are given in Tables BXII.γ.156, BXII.γ.157, BXII.γ.160, BXII.γ.165 and BXII.γ.166. The morphology is as illustrated in Figs. BXII.γ.163 and BXII.γ.177.

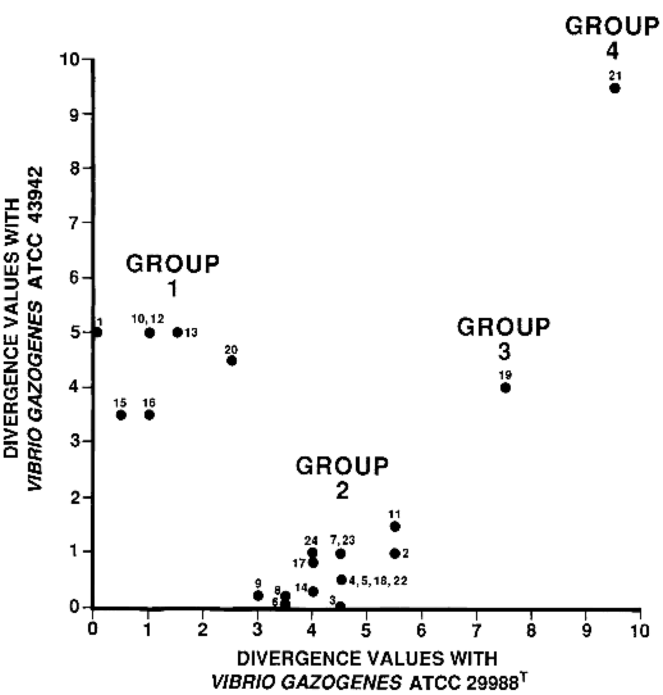

FIGURE BXII.γ.176. Subgroups in the species *Vibrio gazogenes* based on divergence values in DNA–DNA hybridization experiments. Divergence values reflect non-hybridizing DNA sequences. The numbers above or beside the dots are the strain numbers given in Farmer et al. (1988). (Reproduced with permission from J.J. Farmer III et al., Journal of Clinical Microbiology *2l:* 46–76, 1988, ©American Society for Microbiology.)

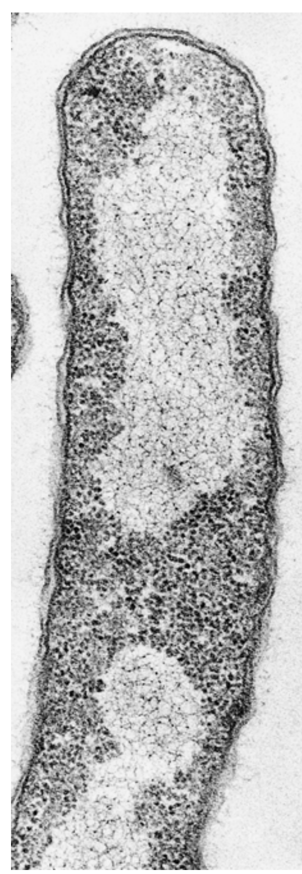

FIGURE BXII.γ.177. Ultrathin section of *Vibrio harveyi*. Exponential growth phase in yeast extract broth. × 43,000. (Courtesy of S.W. Watson.)

Occurs in marine animals, the mouth of sharks (reported as *Vibrio carchariae*), and the marine environment. Isolated from a human wound infection (reported as *Vibrio carchariae*) associated with a shark bite. The type strain was isolated from an amphipod (*Talorchestia* sp.).

Grimes et al. (1984), studied two urease-positive halophilic vibrios isolated from a brown shark (*Carcharhinus plumbeus*) that had died in captivity in a large aquarium. One of the organisms (strain 1116a) was identified as *V. damsela*, but the other (strain 1116b) could not be identified. After further phenotypic testing and DNA–DNA hybridization, Grimes et al. (1984) concluded that this was a new species and named it *V. carchariae*. *V. carchariae* has been isolated from other sharks since the original report, but it was recently shown to occur in human clinical specimens. Pavia et al. (1989) described a case in which the organism was isolated from a wound following a shark bite.

The name *Vibrio carchariae* was used for this organism until the identity of *V. carchariae* with *V. harveyi* was shown conclusively (Farmer and Hickman-Brenner, 1992; Pedersen et al., 1998; Brenner et al., unpublished; see Fig. BXII.γ.171). *Vibrio carchariae* and *Vibrio harveyi* are objective synonyms.

The mol% G + C of the DNA is: 46–48 (T_m).

Type strain: 384, ATCC 14126, CCUG 28584, CIP 103192, IFO 15634, LMG 4044, NCMB 1280.

GenBank accession number (16S rRNA): X56578, X74706.

18. **Vibrio hollisae** Hickman, Farmer, Hollis, Fanning, Steigerwalt Weaver, and Brenner 1982b, 384[VP] (Effective publication: Hickman, Farmer, Hollis, Fanning, Steigerwalt, Weaver and Brenner 1982a, 398.)

hol′ lis.ae. M.L. gen. n. *hollisae* of Hollis; named to honor Dannie G. Hollis, who first recognized this organism as a new and distinct vibrio.

The characteristics are as described for the genus and as listed in Tables BXII.γ.163 and BXII.γ.164. Characters that distinguish *V. hollisae* from other *Vibrio* spp. found in human clinical specimens are given in Tables BXII.γ.156, BXII.γ.157, BXII.γ.160, BXII.γ.161, BXII.γ.165 and BXII.γ.166. Small cells, 0.5 × 1.5–2 μm with a single polar flagellum when grown in liquid media. On sheep blood agar colonies are 1–2 mm in diameter and are weakly hemolytic. Does not grow on TCBS or MacConkey agar.

Appears to cause sporadic cases of diarrhea in humans and has been isolated from blood. Rarely isolated from other human or environmental sources. The type strain was isolated from human feces.

V. hollisae is strongly associated with human diarrhea, but additional evidence is needed to further document the causal role and pathogenic mechanisms of this organism. Fifteen of the original sixteen strains were from feces; many of those patients had diarrhea (Hickman et al., 1982a). Morris et al. (1982) described the clinical and epidemiological features of 11 cases of diarrhea from which *V. hollisae* was isolated.

Based on DNA–DNA hybridization experiments, strains of *V. hollisae* are 76–97% related to the type strain and only 0–4% related to all other *Vibrio* species (Brenner et al. unpublished). 16S rRNA gene sequence analysis indicates that *V. hollisae* is not closely related to other *Vibrio* species (Fig. BXII.γ.171).

V. hollisae has also been known as "Group EF-13" of the Special Bacteriology Laboratory, CDC, unpublished (see Hickman et al., 1982a).

The mol% G + C of the DNA is: 49.3–51.0.

Type strain: ATCC 33564, CDC 0075-80, IMET 12291.

GenBank accession number (16S rRNA): X56583, X74707.

19. **Vibrio ichthyoenteri** Ishimaru, Akagawa-Matsushita and Muroga 1996, 159[VP]

ich.thy.o.er′ te.ri. Gr. n. *ichthys* fish; Gr. n. *enteron* gut; Gr. gen. n. *ichthyoenteri* of fish gut.

The characteristics are as described for the genus and as listed in Tables BXII.γ.154, BXII.γ.163 and BXII.γ.164. Short rods, straight or slightly curved, 1.6–2.5 × 0.6–0.8 μm. Motile by a single polar flagellum. No lateral flagella are produced when grown on solid media. Most strains produce yellow colonies on TCBS agar, but the type strain is a weak sucrose fermenter and produces green colonies.

Causes opaque intestines, intestinal necrosis, and enteritis with high mortality rates in Japanese flounder larvae (*Paralichthys olivaceus*) reared in marine hatcheries.

V. ichthyoenteri was previously known as "*Vibrio* species INFL" (Masumura et al., 1989). Ishimaru et al. (1996) found that five strains were 89–100% related to the type strain based on DNA–DNA hybridization experiments. There was only one close relative; strain P-8706 of "*Vibrio* species INFL-2" from a diseased flounder larva, which was 37% related. Other *Vibrio* species were only 3–18% related.

The mol% G + C of the DNA is: 43.4–44.3 (HPLC).

Type strain: : F-2, ATCC 700023, IFO 15847.

20. **Vibrio logei** (Harwood, Bang, Baumann and Nealson 1980) Baumann, Baumann, Bang and Woolkalis 1981, 217[VP] (Effective publication: Baumann, Baumann, Bang and Woolkalis 1980b, 128) (*Photobacterium logei* (ex Bang, Baumann and Nealson 1978) Harwood, Bang, Baumann and Nealson 1980, 655; *Vibrio salmonicida* Egidius, Wiik, Anderson, Hoff and Hjeltnes 1986, 519.)

log′ e.i. M.L. gen. n. *logei* of Loge; from the German Loge, Norse god of fire and mischief.

The characteristics are as described for the genus and as listed in Tables BXII.γ.163 and BXII.γ.164. Produces a characteristic yellow-orange pigment that is cell-associated.

Causes Hitra disease ("hemorrhagic syndrome")—a disease originally thought to be caused by *Vibrio salmonicida*—in salmonid fish raised in ponds in Norway. Isolated from scallops, intestinal contents of fish, marine sediments, and lesions of the exoskeleton of tanner crabs (Baumann and Baumann, 1981a). The type strain was isolated from the intestine of arctic mussel.

The mol% G + C of the DNA is: 40–42 (T_m, Bd).

Type strain: 584, ATCC 29985, CIP 104991.

21. **Vibrio mediterranei** Pujalte and Garay 1986, 279[VP]

me.di.ter.ra′ ne.i. L. gen. n. *mediterranei* of the Mediterranean Sea.

The characteristics are as described for the genus and as listed in Tables BXII.γ.154, BXII.γ.163, and BXII.γ.164. Cells are 0.5 × 1.0–2.0 μm and possess polar flagella when grown in liquid medium. Colonies are circular, translucent,

nonswarming, and nonpigmented on marine agar and yellow on TCBS agar.

Isolated from plankton, sediments, and seawater off the coast of Valencia, Spain.

Based on DNA–DNA hybridization experiments, the type strain of *V. mediterranei* is highly related (75–100%) to other strains included in the species but is not closely related to other *Vibrio* species. *V. harveyi* was the closest relative (11%) in the original study and *V. alginolyticus* was the closest relative (25%) in the DNA–DNA hybridization study of Brenner et al. (unpublished). Fig. BXII.γ.171 illustrates its relationships to other *Vibrio* species based on 16S rRNA gene sequence analysis.

The mol% G + C of the DNA is: 42–43 (T_m).

Type strain: ATCC 43341, CECT 621, CIP 103203, NCTC 11946.

GenBank accession number (16S rRNA): X74710.

22. **Vibrio metschnikovii** Gamaléia 1888, 485[AL] (*Vibrio cholerae* biovar proteus Shewan and Véron 1974, 344.)
metsch.ni.kov' i.i. M.L. masc. gen. n. *metschnikovii* of Metschnikoff; named to honor E. Metschnikoff, a Russian biologist.

The characteristics are as described for the genus and as listed in Tables BXII.γ.163 and BXII.γ.164. Characters that distinguish *V. metschnikovii* from other *Vibrio* spp. found in human clinical specimens are given in Tables BXII.γ.156, BXII.γ.157, BXII.γ.160, BXII.γ.161, BXII.γ.165 and BXII.γ.166. Oxidase negative. Does not reduce nitrate to nitrite.

Frequently isolated from fresh, brackish, and marine waters, but rarely from human clinical specimens (Lee et al., 1978). The type strain was isolated from fowl.

In 1888, Gamaléia reported the isolation of a new organism, *Vibrio metschnikovii*, from a fowl that had died of a "cholera-like" disease (Lee et al., 1978). Little was written about the organism until Lee et al. (1978) began isolating similar organisms from marine and fresh water environments in the United Kingdom. These strains were oxidase negative and did not reduce nitrate to nitrite but otherwise were typical halophilic vibrios. Lee et al. (1978) proposed that the strains be classified as *V. metschnikovii*, and emended the description of this organism. Lee et al. (1978) described 40 strains of *V. metschnikovii*, but none were from human clinical specimens. Jean-Jacques et al. (1981) reported the first clinically significant isolate of this newly redefined species. A blood culture from an 82-year-old woman with peritonitis and an inflamed gallbladder yielded *V. metschnikovii*. Nonhuman sources include rivers, sewage, cockles, shrimp, lobster, crab, and fowl (Lee et al., 1978; *Vibrio* Laboratory, CDC, unpublished). These data suggest that *V. metschnikovii* is widely distributed in the environment and that humans may acquire the organism from these sources.

The mol% G + C of the DNA is: 44–46 (T_m, Bd).

Type strain: ATCC 700040, LMG 11664, NCTC 8443.

23. **Vibrio mimicus** Davis, Fanning, Madden, Steigerwalt, Bradford, Smith and Brenner 1982, 267[VP] (Effective publication: Davis, Fanning, Madden, Steigerwalt, Bradford, Smith and Brenner 1981a, 636.)
mim' i.cus. M.L. adj. *mimicus* pertaining to a mimic; named to indicate its close phenotypic similarity to *V. cholerae*.

The characteristics are as described for the genus and as listed in Tables BXII.γ.163 and BXII.γ.164. Characters that distinguish *V. mimicus* from *V. cholerae* are given in Table BXII.γ.169. Characters that distinguish *V. mimicus* from other *Vibrio* spp. found in human clinical specimens are given in Tables BXII.γ.156, BXII.γ.157, BXII.γ.160, BXII.γ.161, BXII.γ.165 and BXII.γ.166. *V. mimicus* is similar to *Vibrio cholerae* non-O1 in its ecology, distribution, and pathogenicity. Does not require Na^+.

Occurs in aquatic environments. Some strains apparently cause diarrhea and human intestinal infections, and some virulence factors have been postulated. Occasionally causes extraintestinal human infections. The type strain was isolated from a human ear culture.

V. mimicus was discovered during a DNA–DNA hybridization study of "biochemically atypical" strains of *V. cholerae* (Davis et al., 1982). Strains that were originally characterized as "*Vibrio cholerae* sucrose$^+$" were highly related to, but distinct from, *V. cholerae* by DNA–DNA hybridization; the new species *V. mimicus* was based on these results (Davis et al., 1982).

The mol% G + C of the DNA is: unknown.

Type strain: ATCC 33653, CDC 1721-77.

GenBank accession number (16S rRNA): X74713.

24. **Vibrio mytili** Pujalte, Ortigosa, Urdaci, Garay and Grimont 1993, 360[VP]
my.ti' li. L. gen. n. *mytili* of mussels, from the genus name *Mytilus*.

The characteristics are as described for the genus and as listed in Tables BXII.γ.154, BXII.γ.163, and BXII.γ.164. Coccobacilli. Motile by a single polar flagellum. Colonies are nonpigmented on marine agar and yellow on TCBS agar. No growth occurs on MacConkey agar.

Isolated from mussels (*Mytilus edulis*) off the Atlantic coast of Spain.

Based on DNA–DNA hybridization experiments Pujalte et al. (1993) concluded that strains of *V. mytili* were highly related (94–100%) to the type strain but not closely related to 23 other species of *Vibrio* and *Photobacterium*. *Vibrio parahaemolyticus* was the closest relative (25%). Brenner et al. (unpublished) found 25–40% relatedness of *V. mytili* to *V. alginolyticus* and other marine *Vibrio* species. Fig. BXII.γ.171 illustrates the relationships of *V. mytili* to other *Vibrio* species based on 16S rRNA gene sequence analysis.

The mol% G + C of the DNA is: 45–46 (T_m).

Type strain: 165, ATCC 51288, CECT 632.

25. **Vibrio natriegens** (Payne, Eagon and Williams 1961) Baumann, Baumann, Bang and Woolkalis 1981, 217[VP] (Effective publication: Baumann, Baumann, Bang and Woolkalis 1980b, 128) (*"Pseudomonas natriegens"* Payne, Eagon and Williams 1961, 125; *"Vibrio natriegens"* (Payne, Eagon and Williams 1961) Webb and Payne 1971, 1080; *Beneckea natriegens* (Payne, Eagon and Williams 1961) Baumann, Baumann and Mandel 1971a, 291.)
na.tri.e' gens. M.L. *natrium* sodium; L. *egens* pres. part. *egere* to be in need; M.L. adj. *natriegens* sodium-requiring.

The characteristics are as described for the genus and as listed in Tables BXII.γ.163 and BXII.γ.164. Cells usually have a single, long, polar flagellum and occasionally 2–3

flagella. Cells often contain poly-β-hydroxybutyrate granules (Fig. BXII.γ.178). Doubling time (generation time) is 9.8 minutes (Eagon, 1962). *V. natriegens* is differentiated from other species of *Vibrio* by its short generation time and its ability to utilize a much wider variety of carbon sources than most other species (Table BXII.γ.163).

Isolated from salt marsh mud and coastal seawater (Payne et al., 1961; Furniss et al., 1978; Baumann and Baumann, 1981a). The type strain was isolated from a salt marsh mud, Sapelo Island, Georgia, USA.

Based on DNA–DNA hybridization experiments, strains of *V. natriegens* are highly related (83% or greater) to the type strain and 33–53% related (Fig. BXII.γ.169) to other marine *Vibrio* species (Reichelt and Baumann, 1973b). These results were confirmed by Brenner et al. (unpublished) who found the closest relatives of *V. natriegens* according to DNA–DNA hybridization data to be *V. alginolyticus*, *V. campbellii*, *V. harveyi*, and *V. parahaemolyticus* (31–45% related). Based on 16S rRNA gene sequence analysis (Fig. BXII.γ.171 and analysis of the immunological relationships of superoxide dismutase (Fig. BXII.γ.170), *Vibrio natriegens* falls into the marine *Vibrio* group.

The mol% G + C of the DNA is: 45.1–47 (T_m, Bd).
Type strain: ATCC 14048, DSM 759, NCMB 857.
GenBank accession number (16S rRNA): X74714.

26. **Vibrio navarrensis** Urdaci, Marchand, Ageron, Arcos, Sesma and Grimont 1991, 293[VP]
na.var.ren′sis. M. L. masc. adj. *navarrensis* pertaining to Navarra, Spain, the Spanish province where the organism was isolated.

Morphological, growth, physiological, and biochemical characteristics are listed in Tables BXII.γ.154 and BXII.γ.164. Cells are 0.8–1.0 × 1.0–2.0 μm and are motile by a single polar flagellum when grown on solid and liquid media. Colonies are 2–3 mm in diameter on nutrient agar with 2% NaCl after overnight incubation at 30°C and are round, opaque, and nonpigmented. Colonies on TCBS agar are yellow. Slight requirement for Na^+. Seven of ten strains studied grew weakly in peptone water without added NaCl. Synthesizes a unique fatty acid of undetermined structure not found in 22 other *Vibrio* species (Urdaci et al., 1991) that accounts for 1–3 % of the total fatty acids of *V. navarrensis*.

Isolated from sewage, irrigation water and river water in Spain.

Based on DNA–DNA hybridization experiments, Urdaci et al. (1991) found that eight strains of *V. navarrensis* were highly related (82–98% with T_m values of 0–2.0) to the type strain; another strain (1381-1) was 74% related.. The closest relative was *Vibrio natriegens*, which was 39% related. The other *Vibrio* species tested were only 3–15% related. Based on DNA–DNA hybridization experiments, Brenner et al. (unpublished) found 14–22% relatedness of *V. navarrensis* to *V. natriegens* and 28–36% relatedness of *V. navarrensis* to *V. harveyi*, *V. parahaemolyticus*, *V. pelagius*, and *V. vulnificus*. Fig. BXII.γ.171 illustrates the relationship of *V. navarrensis* to other species of *Vibrio*.

The mol% G + C of the DNA is: 45–47 (T_m).
Type strain: ATCC 51183, CIP 103381.
GenBank accession number (16S rRNA): X74715.

27. **Vibrio nereis** (Harwood, Bang, Baumann and Nealson 1980) Baumann, Baumann, Bang and Woolkalis 1981, 217[VP] (Effective publication: Baumann, Baumann, Bang and Woolkalis 1980b, 128) (*Beneckea nereida* (ex Baumann, Baumann and Mandel 1971a) Harwood, Bang, Baumann and Nealson 1980, 655.)
ne′re.is. L. n. *nereis* a sea nymph.

The characteristics are as described for the genus and as listed in Tables BXII.γ.163 and BXII.γ.164. The morphology is illustrated in Figs. BXII.γ.179 and BXII.γ.180.

Isolated from seawater off the coast of Hawaii. Kusuda et al. (1986) isolated *V. nereis* from an outbreak of fatal infections of sea bream (*Acanthopagrus schlegeli*) at hatcheries in western Japan, but did not think this organism was causing disease in the fish. The type strain was isolated from seawater off the coast of Hawaii.

Based on DNA–DNA hybridization experiments, Reichelt et al. (1976) found that strains of *Vibrio nereis* were

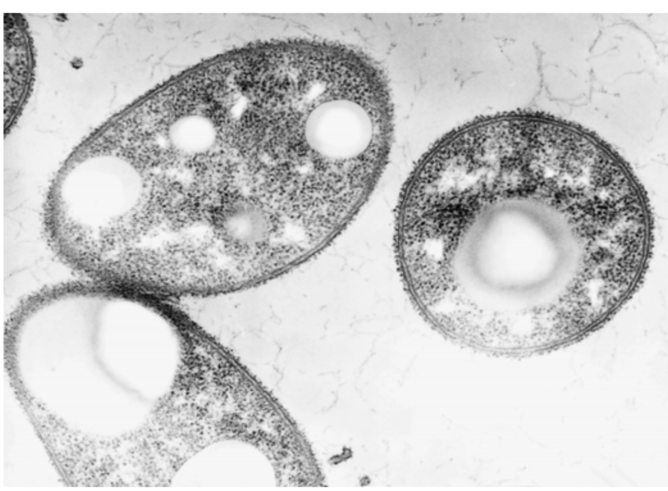

FIGURE BXII.γ.178. Ultrathin section of *Vibrio natriegens* containing granules of poly-β-hydroxybutyrate that accumulate during stationary phase of growth. Grown in basal medium containing limiting nitrogen and excess β-hydroxybutyrate. × 32,000. (Courtesy of R.D. Allen.)

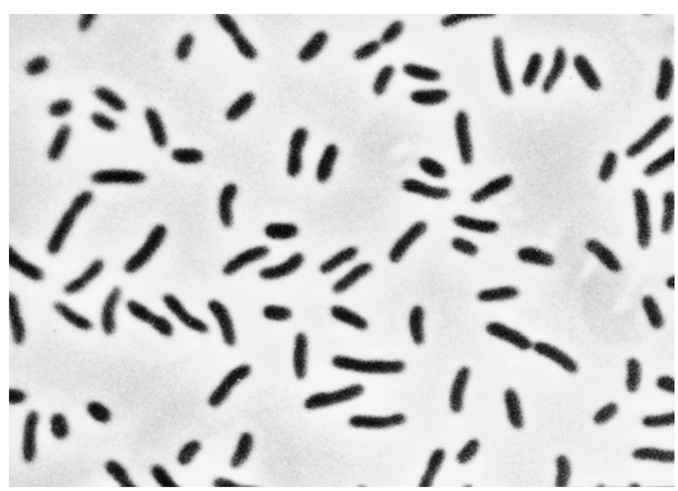

FIGURE BXII.γ.179. Phase contrast micrograph of *Vibrio nereis*. Exponential growth phase in yeast extract broth. × 3000.

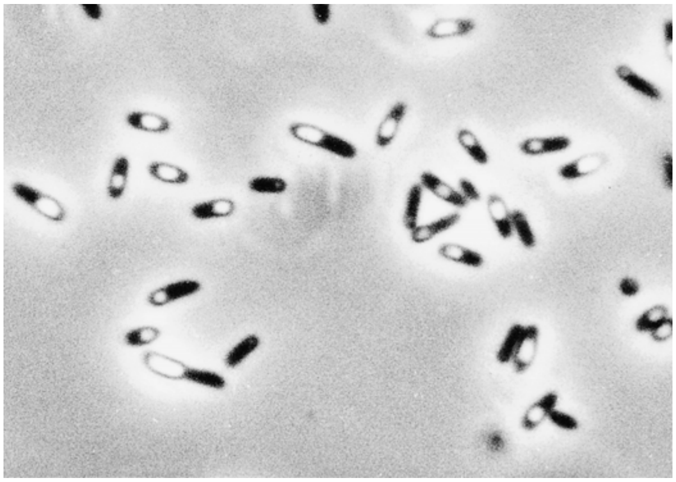

FIGURE BXII.γ.180. Phase contrast micrograph of *Vibrio nereis* containing refractile granules of poly-β-hydroxybutyrate that accumulate during stationary phase. The organisms were grown in basal medium containing limiting nitrogen and excess β-hydroxybutyrate. × 3000.

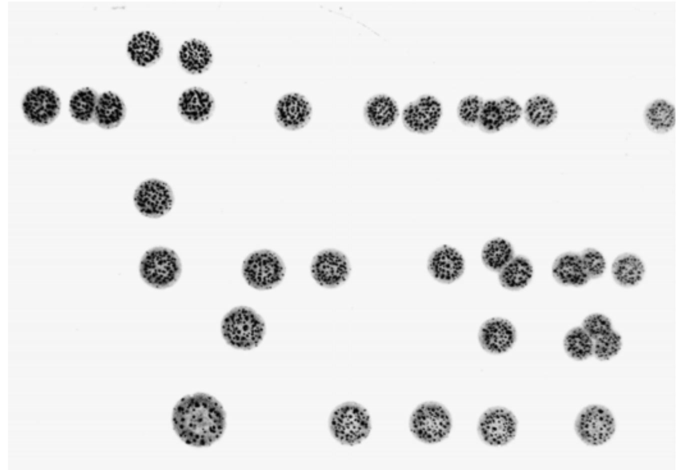

FIGURE BXII.γ.181. Colonies of *Vibrio nigripulchritudo* containing crystals of a blue-black pigment. Incubation for 2 days on basal medium agar with 0.2% [v/v] glycerol. × 4.5. (Reproduced with permission from P. Baumann et al., Journal of Bacteriology *108:* 1380–1383, 1971, ©American Society for Microbiology.)

highly related (87–94%) to the type strain and less than 30% related to 13 other *Vibrio* species. These results were confirmed by Brenner et al. (unpublished), who found the closest relatives by DNA–DNA hybridization to be *V. alginolyticus*, *V. parahaemolyticus*, *V. harveyi*, *V. proteolyticus*, and two unnamed *Vibrio* groups (all 22–40% related). By DNA–DNA hybridization (Fig. BXII.γ.169), 16S rRNA sequencing (Fig. BXII.γ.171), and the immunological relationship of superoxide dismutase (Fig. BXII.γ.170), *Vibrio nereis* falls into the marine *Vibrio* group.

The mol% G + C of the DNA is: 46–47 (T_m, Bd).

Type strain: ATCC 25917, CIP 103194, IFO 15637, LMG 3895, NCCB 73020.

GenBank accession number (16S rRNA): X74716.

28. **Vibrio nigripulchritudo** (Baumann, Baumann, Mandel and Allen 1971a) Baumann, Baumann, Bang and Woolkalis 1981, 217[VP] (Effective publication: Baumann, Baumann, Bang and Woolkalis 1980b, 128) (*Beneckea nigripulchritudo* Baumann, Baumann, Mandel and Allen 1971b, 1383.)
ni.gri.pul.chri.tu′ do. L. *niger* black; L. *pulchritudo* beauty; M.L. adj. *nigripulchritudo* black beauty, which refers to its striking blue-black colonies.

The characteristics are as described for the genus and as listed in Tables BXII.γ.163 and BXII.γ.164. Instantly recognizable and differentiated from other *Vibrio* species by its formation of striking blue-black colonies (Fig. BXII.γ.181).

Isolated from sea water off the coast of Hawaii.

Based on DNA–DNA hybridization experiments, Reichelt et al. (1976) found that strains of *Vibrio nigripulchritudo* were highly related (91–96%) to the type strain and less than 20% related to 15 other *Vibrio* species. These results were essentially confirmed by Brenner et al. (unpublished) who found the closest relative by DNA–DNA hybridization to be *V. penaeicida* (36% related). By 16S rRNA gene sequence analysis (Fig. BXII.γ.171 and the immunological relationship of superoxide dismutase (Fig. BXII.γ.170), *Vibrio nigripulchritudo* falls into the marine *Vibrio* group, but may have diverged slightly from that group.

The mol% G + C of the DNA is: 46–47 (T_m, Bd).

Type strain: ATCC 27043, CCUG 28586, CIP 103195, LMG 3896.

GenBank accession number (16S rRNA): X74717.

29. **Vibrio ordalii** Schiewe, Trust and Crosa 1982, 384[VP] (Effective publication: Schiewe, Trust and Crosa 1981, 347.)
or.dal′ i.i. M.L. gen. n. *ordalii* of Ordal; named to honor Erling J. Ordal for his many contributions to the current understanding of the biology of bacterial fish pathogens

The characteristics are as described for the genus and as listed in Tables BXII.γ.163 and BXII.γ.164. The cells are 2.5–3.0 × 1.0 μm in size and are motile by a single polar flagellum. Grows very slowly, forming visible colonies on trypticase soy agar only after 4–6 days (Table BXII.γ.171). Growth is enhanced by the addition of NaCl. All isolates of *V. ordalii* belong to O antigen group 2, in contrast to *V. anguillarum* (O antigen groups 1–16). Closely related phylogenetically to *V. anguillarum* (Figs. BXII.γ.169, BXII.γ.170, and BXII.γ.171), but less biochemically versatile and more likely to have additional nutritional requirements (Table BXII.γ.171).

Important fish pathogen isolated from diseased salmonid fish in Washington, Oregon, British Columbia, and Japan (Schiewe et al., 1981), and from ayu (*Plecoglossus altivelis*) and rockfish fingerlings (*Sebastes schlegeli*) in Japan (Muroga et al., 1986). The type strain was isolated from the kidney of a moribund Coho salmon (*Oncorhynchus kisutch*) at a commercial salmon farm in Puget Sound, Washington, U.S.A.

V. ordalii is a halophilic *Vibrio* species that is very closely related to *Vibrio anguillarum.* Previously, other investigators had studied vibriosis of marine fish and isolated a halophilic vibrio similar to, but less biochemically versatile than *V. anguillarum.* This organism was referred to as "*Vibrio* sp. 1669 group", "*Vibrio* sp. RT group", *"Beneckea anguillara"* biotype I or *Vibrio anguillarum* biotype 2. However, DNA–DNA hybridization studies by Schiewe et al. (1981) indi-

cated that, although closely related to *V. anguillarum*, *V. ordalii* was a separate species.

The mol% G + C of the DNA is: 43–44 (T_m).

Type strain: DF3K, ATCC 33509.

GenBank accession number (16S rRNA): X70641, X74718.

30. **Vibrio orientalis** Yang, Yeh, Cao, Baumann, Baumann, Tang and Beaman 1983b, 673[VP] (Effective publication: Yang, Yeh, Cao, Baumann, Baumann, Tang and Beaman 1983a, 98.)
or.i.en.ta'lis. L. adj. *orientalis* of or belonging to the Orient.

The characteristics are as described for the genus and as listed in Tables BXII.γ.163 and BXII.γ.164. Motile by a single, sheathed, polar flagellum. All the original strains were reported to be bioluminescent, but this property is apparently lost after storage and subculture. Differentiated from other bioluminescent *Vibrio* species because it accumulates poly-β-hydroxybutyrate and grows at 4°C.

Isolated from seawater and shrimp from the Yellow Sea, China.

V. orientalis was originally defined and named because it was distinct from other species of *Vibrio* and *Photobacterium* in phenotype and in the relationship of its superoxide dismutase (Yang et al., 1983a). Based on DNA–DNA hybridization experiments, the type strain of *Vibrio orientalis* was highly related (75% or greater with 0.5% divergence) to three other strains (Brenner et al., unpublished). The closest relatives were *V. parahaemolyticus*, *V. pelagius*, *V. tubiashii*, *Vibrio* group 515 and *Vibrio* group 9084-82 (19–37% related) (Brenner et al., unpublished). Fig. BXII.γ.171 illustrates the relationship of *V. orientalis* to other *Vibrio* species based on 16S rRNA gene sequence analysis. Based on the immunological relationship of its superoxide dismutase *V. orientalis* falls into the marine *Vibrio* group (see Fig. 3 of Yang et al., 1983a).

The mol% G + C of the DNA is: 45.3–45.8 (Bd).

Type strain: ATCC 33934, CCUG 16389, CIP 102891, IFO 15638, LMG 7897.

GenBank accession number (16S rRNA): X74719.

31. **Vibrio parahaemolyticus** (Fujino, Okuno, Nakada, Aoyama, Fukai, Mukai and Ueho 1951) Sakazaki, lwanami and Fukumi 1963, 181[AL] (*"Pasteurella parahaemolytica"* Fujino, Okuno, Nakada, Aoyama, Fukai, Mukai and Ueho 1951, 11; *"Oceanomonas parahaemolytica"* (Fujino, Okuno, Nakada, Aoyama, Fukai, Mukai and Ueho 1951) Miyamoto, Nakamura and Takizawa 1961, 477; *Beneckea parahaemolytica* (Fujino, Okuno, Nakada, Aoyama, Fukai, Mukai and Ueho 1951) Baumann, Baumann, and Mandel 1971a, 291.)
para.hae.mo.ly'ti.cus. Gr. prep. *para* by the side of, beside; Gr. n. *haema* blood; Gr. adj. *lyticus* dissolving; M.L. adj. *parahaemolyticus* dissolving blood.

The characteristics are as described for the genus and as listed in Tables BXII.γ.163 and BXII.γ.164. Characters that differentiate *V. parahaemolyticus* from *V. alginolyticus*, *V. harveyi*, and *V. vulnificus* are listed in Table BXII.γ.170. Characters that distinguish *V. parahaemolyticus* from other *Vibrio* spp. found in human clinical specimens are listed in Tables BXII.γ.156, BXII.γ.157, BXII.γ.160, BXII.γ.161, BXII.γ.165 and BXII.γ.166.

Occurs in human clinical specimens (Table BXII.γ.157) and is an important cause of diarrhea. Also occurs in marine environments.

Outbreaks of gastroenteritis caused by *V. parahaemolyticus* occur worldwide. In Japan, *V. parahaemolyticus* causes 50–70% of foodborne enteritis cases (Sakazaki and Balows, 1981), which are invariably associated with seafood. In the early 1970s, several articles described *V. parahaemolyticus* as the cause of severe wound infections and bacteremia (Roland, 1970, 1971; Zide et al., 1974; Weaver and Ehrenkranz, 1975). It is now known that the infectious agent in the case was really *Vibrio vulnificus* (Weaver and Ehrenkranz, 1975), not *V. parahaemolyticus*. Similarly, many ecological and environmental reports about *V. parahaemolyticus* may be incorrect because of our limited understanding of the large number of *Vibrio* species that inhabit these environments.

The mol% G + C of the DNA is: 46–47 (T_m, Bd).

Type strain: 113, ATCC 17802, DSM 30189, NCMB 1326.

GenBank accession number (16S rRNA): M59161, X56580, X74720.

32. **Vibrio pectenicida** Lambert, Nicolas, Cilia and Corre 1998, 486[VP]
pec.ten.i.ci'da. M.L. n. *Pecten* genus name of scallops; M.L. v. *caedo* to kill; *pectenicida* scallop-killer.

The characteristics are as described for the genus and as listed in Tables BXII.γ.163 and BXII.γ.164. Cells are curved rods with a large single polar flagellum when grown in liquid medium. Smaller, unsheathed, lateral flagella are produced during growth on solid medium. Colonies after 48 h of growth are circular, smooth, and unpigmented and exhibit waves of swarming. Isolated from moribund scallop (*Pecten maximus*) larvae during outbreaks of disease in a hatchery in France.

Lambert et al. (1998) compared the type strain of *Vibrio penaeicida* to the type strains of 30 other *Vibrio* and *Photobacterium* species by 16S rRNA gene sequence analysis. The two closest relatives were *Vibrio tapetis* (97.2% sequence similarity) and *V. splendidus* (95.5% sequence similarity). DNA–DNA hybridization was used to show that the type strain of *V. pectenicida* was 86–100% related to four other strains and less than 5% related to the type strains of *V. tapetis* and *V. splendidus*. Brenner et al. (unpublished) showed that the type strain of *V. pectenicida* was 98% related to one other strain, and 1–25% related to all other *Vibrio* species tested based on the results of DNA–DNA hybridization experiments. Fig. BXII.γ.171 shows the relationship of *Vibrio pectenicida* to other *Vibrio* species based on 16S rRNA gene sequence analysis. *V. logei* is the closest relative of *V. pectenicida* based on phenotypic similarities.

The mol% G + C of the DNA is: 39–41(T_m).

Type strain: A365, ATCC 700783, CIP 105190.

GenBank accession number (16S rRNA): Y13830.

33. **Vibrio pelagius** (Baumann, Baumann and Mandel 1971a) Baumann, Baumann, Bang and Woolkalis 1981, 217[VP] (Effective publication: Baumann, Baumann, Bang and Woolkalis 1980b, 128) (*Beneckea pelagia* Baumann, Baumann and Mandel 1971a, 291.)*
pe.la'gi.us. L. adj. *pelagius* of the sea.

Editorial Note: The name *Listonella pelagia* also has standing in the nomenclature (MacDonell and Colwell, 1985).

TABLE BXII.γ.174. Nomenclature, classification and differentiation of the two groups of *Vibrio pelagius* that are distinct by DNA hybridization and phenotype

Test or property	*Vibrio pelagius* group 1	*Vibrio pelagius* group 2
Type or reference strain	ATCC 25916[T] (strain 99)	ATCC 33786 (strain 106)[a]
Other strains in ATCC[b]	33781 (96)	33504 (105)
	33782 (100)	33784 (103)
	33783 (101)	33785 (104)
	33808 (97)	33786 (106)
Nomenclature and classification according to:		
Baumann et al. (1971a)	Group F, cluster 1	Group F, cluster 2
Baumann et al. (1971a)	*Vibrio pelagius*	*Vibrio pelagius*
Reichelt et al. (1976)	*Vibrio pelagius* biotype I	*Vibrio pelagius* biotype II
Baumann et al. (1984b)	*Vibrio pelagius* biotype I	*Vibrio pelagius* biotype II
MacDonell and Colwell (1985)	*Listonella pelagia*	*Listonella pelagia*
Differential tests:		
Cellular morphology	Straight rods	Curved rods
Amylase production	0	100
Gelatinase production	0	100
γ-Aminobutyrate utilization	0	100
δ-Aminovalerate utilization	0	100

[a]This strain was the labeled strain in the DNA hybridization study of Reichelt et al. (1976).

[b]The ATCC number is listed first. The strain number from Baumann et al. (1971a) is listed in parentheses.

The characteristics are as described for the genus and as listed in Tables BXII.γ.163 and BXII.γ.164. Nomenclature, classification, and differential phenotypic traits of the two groups of *Vibrio pelagius*, which are also distinct based on the results of DNA hybridization experiments (see Taxonomic Comments), are given in Table BXII.γ.174.

Isolated from seawater of the coast of Hawaii. Furniss et al. (1978) found that *V. pelagius* is one of the most common vibrios isolated along the British coasts.

Beneckea pelagia was first described and named by Baumann et al. (1971a). It was defined as a single species based on phenotypic properties of 11 strains isolated from waters off the coast of Hawaii; however, the authors noted that the strains "clustered in two groups." Reichelt et al. (1976) confirmed the existence of two groups by DNA–DNA hybridization experiments. The two groups were classified as biotypes and referred to as *Beneckea pelagia* I and II. Baumann et al. (1980b) "abolished" the genus *Beneckea*, and proposed that *Beneckea pelagia* be classified in the genus *Vibrio* as *V. pelagius*.

Brenner et al. (1983b) showed by DNA–DNA hybridization experiments that the type strain of *V. pelagius* was 30–45% related to type strains of *V. campbellii*, *V. harveyi*, *V. parahaemolyticus*, and *V. splendidus*. Recently Brenner et al. (unpublished) used DNA–DNA hybridization experiments to compare strains of the two groups of *V. pelagius* and other strains that had been identified as belonging to this species. They confirmed the results of Reichelt et al. (1976) that showed that *V. pelagius* II was distinct from *V. pelagius* I and suggested that the two groups be classified as subspecies of *V. pelagius*, rather than biogroups. They also showed that the most closely related species (20–44%) are "*V. algosus*", *V. harveyi* biogroup 2, *V. mytili*, *V. orientalis*, *V. parahaemolyticus*, *V. splendidus* biogroup 2, and *Vibrio* groups 514, 515, and 516. Fig. BXII.γ.171 shows the relationship of *Vibrio pelagius* to other *Vibrio* species based on 16S rRNA gene sequence analysis. Based on the immunological relationship of their superoxide dismutases (Fig. BXII.γ.170) the two groups of *Vibrio pelagius* are distinct, and both cluster in the marine *Vibrio* group (Baumann et al., 1984b).

Based on similarity of 5S rRNA sequences, MacDonell and Colwell (1985) proposed that *V. pelagius* should be united with *Vibrio anguillarum* and *Moritella marina* species in a new genus *Listonella*, and they proposed the name *Listonella pelagia*. Thus, *V. pelagius* currently has standing in nomenclature in three different genera as *Beneckea pelagia*, *Vibrio pelagius*, and *Listonella pelagia* (Table BXII.γ.162). All three names are based on the same type strain.

The mol% G + C of the DNA is: 45–47 (T_m, Bd).

Type strain: ATCC 25916, CECT 4202.

GenBank accession number (16S rRNA): X74722.

34. **Vibrio penaeicida** Ishimaru, Akagawa-Matsushita and Muroga 1995, 138[VP]

pe.nae.i.ci'da. L. n. *Penaeus* genus of kuruma prawns; L. v. *caedo* to kill; L. adj. *penaeicida Penaeus* killer.

The characteristics are as described for the genus and as listed in Tables BXII.γ.154, BXII.γ.163, and BXII.γ.164. Small rods, straight or slightly curved, 0.5–0.8 × 1.5–2.0 μm. Motile by means of a single polar flagellum. No lateral flagella are produced during growth on solid media. Colonies are low, cream colored, and translucent with entire margins. All reported isolates have the same O antigen.

Causes vibriosis of kuruma prawns (*Penaeus japonicus*) in Japan. Isolated from diseased and apparently healthy kuruma prawns and from water samples from ponds where prawns are grown.

V. penaeicida was formerly known as "*Vibrio* species PJ" (de la Peña et al., 1992). Ishimaru et al. (1995) showed by DNA–DNA hybridization experiments that the type strain of *V. penaeicida* was highly related (87–99%) to five other strains but was only 4–18% related to 29 other *Vibrio* and *Photobacterium* species tested. On the basis of DNA–DNA hybridization experiments, Brenner et al. (unpublished) also confirmed that *V. penaeicida* is a distinct species and found that its closest relative is *V. nigripulchritudo* (36% related).

The mol% G + C of the DNA is: 46.2–47 (HPLC).

Type strain: KH-1, ATCC 51841, IFO 15640, JCM 9123.

35. **Vibrio proteolyticus** (Merkel, Traganza, Mukherjee, Griffin and Prescott 1964) Baumann, Baumann, Bang and Woolkalis 1982, 267[VP] (Effective publication: Baumann, Baumann, Bang and Woolkalis 1980b, 128) (*"Aeromonas proteolytica"* Merkel, Traganza, Mukheriee, Griffin and Prescott 1964, 1230; *Aeromonas hydrophila* subsp. *proteolytica* (Merkel, Traganza, Mukheriee, Griffin and Prescott 1964) Schubert 1969, 412.)
pro.te.o.ly' ti.cus. Ger. *protein* from Gr. *protos* first; Gr. adj. *lyticus* dissolving; M.L. adj. *proteolyticus* protein-dissolving.

The characteristics are as described for the genus and as listed in Tables BXII.γ.163 and BXII.γ.164. Grows on solid media as swarming waves. Isolated from *Limnoria tripunctata* taken from wood pilings Charleston, South Carolina, U.S.A.

The type strain was isolated from the alimentary canal of the marine isopod crustacean.

Reichelt et al. (1976) showed by DNA–DNA hybridization that the type strain of *V. proteolyticus* was only 0–25% related to 11 other *Vibrio* species. These results were confirmed by Brenner et al. (1983b) who showed that the type strain was less than 5% related to type strains of 16 other *Vibrio* species. Brenner et al. (unpublished) studied almost all newly described *Vibrio* species and concluded that *V. proteolyticus* is a distinct species whose closest relatives are CDC *Vibrio* groups 515 and 516 (33% relatedness), which have not yet been described in the literature. Fig. BXII.γ.171 shows the relationship of *V. proteolyticus* to other *Vibrio* species based on 16S rRNA gene sequence analysis.

The mol% G + C of the DNA is: 50.5 (Bd).

Type strain: ATCC 15338, DSM 30189, IFO 13287, NCMB 1326.

GenBank accession number (16S rRNA): X56579, X74723.

36. **Vibrio rumoiensis** Yumoto, Iwata, Sawabe, Ueno, Ichise, Matsuyama, Okuyama and Kawasaki 1999b, 935[VP] (Effective publication: Yumoto, Iwata, Sawabe, Ueno, Ichise, Matsuyama, Okuyama and Kawasaki 1999a, 71.)
ru.moi.en' sis. L. adj. *rumoiensis* from Rumoi, location of isolation.

Morphological, growth, physiological, and biochemical characteristics are listed in Table BXII.γ.164. Cells 0.5–0.9 × 0.7–2.1 μm. No flagella. Numerous blebs occur on the cell surface (Fig. BXII.γ.182). Colonies are white and circular. Produces high level of catalase.

Isolated from a drainage pool at a fish product processing plant where hydrogen peroxide was used as a bleaching agent.

Based on DNA–DNA hybridization experiments carried out using the fluorometric method, Yumoto et al. (1999a) found that the type strain of *V. rumoiensis* was only 3.2–9.0% related to 11 other *Vibrio* species. Based on the results of 16S rRNA gene sequence analysis, the type strain of *V. rumoiensis* was 92.4–95.5% similar to *Vibrio* and *Photobacterium* species. Fig. BXII.γ.171 illustrates the relationship of *V. rumoiensis* to other species of *Vibrio*.

The mol% G + C of the DNA is: 43.2 (HPLC).

Type strain: S-1, FERM-P 14531.

GenBank accession number (16S rRNA): AB013297.

37. **Vibrio salmonicida** Egidius, Wiik, Andersen, Hoff and Hjeltnes 1986, 519[VP]
sal.mon.i.ci' da N. L. n. *salmon* salmon; L. v. *caedo* to kill; N. L. adj. *salmonicida* salmon killer.

See description of *V. logei*.

By DNA–DNA hybridization experiments, Brenner et al. (unpublished) showed that the type strain of *Vibrio salmonicida* was highly related to the type strain of *Vibrio logei* (see also Fig. BXII.γ.171) and concluded that these two organisms should be classified in the single species, *Vibrio logei*.

The mol% G + C of the DNA is: 42 (T_m).

Type strain: HI 7751, ATCC 43839, CIP 103166, LMG 14010, NCIMB 2262.

38. **Vibrio scophthalmi** Cerdà-Cuéllar, Rosselló-Mora, Lalucat, Jorfe and Blanch 1997, 60[VP]
scoph.thal' mi. L. gen. n. *scophthalmi* derived from the genus name *Scophthalmus* because all the original isolates were from the turbot (fish) species *Scophthalmus maximus*.

The characteristics are as described for the genus and as listed in Tables BXII.γ.154, BXII.γ.163, and BXII.γ.164. Halophilic; grows poorly in media containing ≤ 0.5% NaCl. Colonies are unpigmented on TSA and yellow on TCBS agar.

Isolated from the intestines of juvenile turbot (*Scophthalmus maximus*) in a hatchery in Spain.

Based on DNA–DNA hybridization experiments (dot hybridization method) Cerdà-Cuéllar et al. (1997) found that the type strain was highly related to five other strains. Brenner et al. (unpublished) confirmed these results and concluded that *V. scophthalmi* is a distinct species. They also found that the type strain of *Vibrio scophthalmi* was 99% related to the reference strain of *Vibrio* INFL-2. The closest other relative was *V. ichthyoenteri*, which was 32% related. Based on the results of 16S rRNA gene sequence analysis, Cerdà-Cuéllar et al. (1997) found that the closest relative was *V. aestuarianus*, which had a sequence similarity of 97.8%. Fig. BXII.γ.171 shows the relationship of *Vibrio scophthalmi* to other *Vibrio* species based on 16S rRNA gene sequence analysis.

The mol% G + C of the DNA is: 44–44.5 (HPLC).

Type strain: A089, CECT 4638.

GenBank accession number (16S rRNA): U46579.

39. **Vibrio splendidus** (Beijerinck 1900a) Baumann, Baumann, Bang and Woolkalis 1981, 217[VP] (Effective publication: Baumann, Baumann, Bang and Woolkalis 1980b, 128) (*"Photobacter splendidum"* Beijerinck 1900a, 362; *Beneckea splendida* (Beijerinck 1900a) Reichelt, Baumann and Baumann 1979, 80.)
splen' di.dus. L. adj. *splendidus* brilliant.

The characteristics are as described for the genus and as listed in Tables BXII.γ.163 and BXII.γ.164. The cell morphology is shown in Fig. BXII.γ.183. Properties and differentiation of the three biogroups described by Reichelt et al. (1976) are given in Table BXII.γ.175.

Isolated from marine fish and seawater.

Reichelt et al. (1976) determined that *V. splendidus* consisted of three distinct groups that could be defined on the basis of both phenotypic characteristics and DNA–DNA hybridization experiments. These groups were referred to as

FIGURE BXII.γ.182. Electron micrograph of *Vibrio rumoiensis* illustrating the appearance of "blebs" on the cell surface. Negatively stained preparation. Bar = 1 μm. (Reproduced with permission from Yumoto et al., Applied and Environmental Microbiology, *65:* 67–72, 1999a ©American Society for Microbiology.)

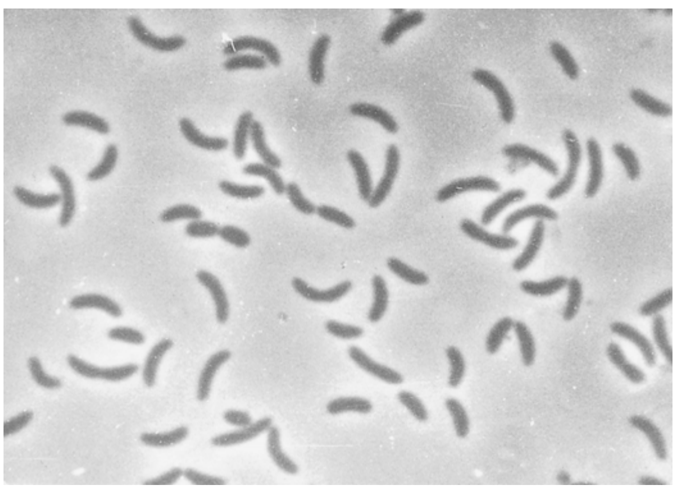

FIGURE BXII.γ.183. Phase contrast micrograph of *Vibrio splendidus* biogroup II. Exponential growth phase in yeast extract broth. × 3000.

biotypes I, II, and a third unnamed biotype (Table BXII.γ.175). Brenner et al. (unpublished) also confirmed that *Vibrio splendidus* is a distinct *Vibrio* species based on DNA–DNA hybridization experiments and showed that the type strain of *V. splendidus* was 30–45% related to the type strains of *V. campbellii*, *V. harveyi*, *V. parahaemolyticus*, and *V. pelagius*. Based on the immunological relationship of superoxide dismutases (Fig. BXII.γ.170). Baumann et al. (1984b) concluded that *V. splendidus* biogroups I and II are closely related, and (along with *V. fischeri* and *V. logei*) are more distantly related to the marine *Vibrio* group. Fig. BXII.γ.171 shows the relationship of the type strain of *V. splendidus*, which belongs to biogroup 1, to other *Vibrio* species based on 16S rRNA gene sequence analysis.

The mol% G + C of the DNA is: 45–46 (T_m, Bd).
Type strain: ATCC 33125, NCMB 1.
GenBank accession number (16S rRNA): X74724.

40. **Vibrio tapetis** Borrego, Castro, Luque, Paillard, Maes, Garcia and Ventosa 1996, 483[VP]
ta.pe′ tis. L. gen. n. *tapetis* of clams (the genus *Tapes*).

The characteristics are as described for the genus and as listed in Tables BXII.γ.154, BXII.γ.163, and BXII.γ.164. Coccobacilli, 0.5 × 1.0–1.5 μm. Motile by a single polar flagellum. Grows at 4–22°C; optimum growth at 22°C. Colonies on marine agar circular, translucent, and nonpigmented. Colonies on TCBS agar are green.

Causes brown ring disease in several species of wild and cultured clams. The type strain was isolated from cultured manila clam (*Tapes philippinarum*), Landeda, France.

Based on DNA–DNA hybridization experiments, Borrego et al. (1996) found that the type strain of *Vibrio tapetis* was highly related (100%) to eight other strains and less related to seven other *Vibrio* species. *Vibrio vulnificus* (58%), *V. alginolyticus* (53%), *V. fischeri* (48%), and *V. splendidus* (46%) were the closest relatives. Based on DNA–DNA hybridization experiments, Brenner et al., (unpublished) confirmed that *Vibrio tapetis* is a distinct species, and found that *V. wodanis* was the closest relative (19%). Results of this study indicated that *Vibrio tapetis* was 15% or less related to other *Vibrio* species, including the species listed above. Fig. BXII.γ.171 shows the relationship of *V. tapetis* to other *Vibrio* species based on 16S rRNA gene sequence analysis.

The mol% G + C of the DNA is: 42.9–45.5 (T_m).
Type strain: B1090, CECT 4600.
GenBank accession number (16S rRNA): Y08430.

41. **Vibrio trachuri** Iwamoto, Suzuki, Kurita, Watanabe, Shimizu, Ohgami and Yanagihara 1996, 625[VP] (Effective publication: Iwamoto, Suzuki, Kurita, Watanabe, Shimizu, Ohgami and Yanagihara 1995, 836.)

TABLE BXII.γ.175. The three biotypes (subgroups) of *Vibrio splendidus*

Test or property	Biotype I	Biotype II	Unnamed biotype
Type[a] or reference strain	ATCC 33125[T] = NCMB 1	ATCC 33789 (strain 2)[b]	Strain 16 (not in ATCC)
Other strains	ATCC 33869 (strain 378); ATCC 33870 (strain 379); ATCC 33871 (strain 380)	ATCC 25914 (strain 8)	
Differential tests:[c]

Arginine dihydrolase	+	−	
D-Mannose utilization	+	−	
D-Galactose utilization	+	−	
D-Glucuronate utilization	+	−	
L-Arginine utilization	+	−	
L-Citrulline utilization	+	−	
Heptonate utilization	+	−	

[a]The type strain for the species *Vibrio splendidus* is ATCC 33125.

[b]The strain numbers of Reichelt et al. (1976) are given in parentheses. Reichelt et al. (1976) labeled strain ATCC 33789 for DNA–DNA hybridization experiments and showed it was 82–91% related to the other four strains included in biotype II.

[c]Symbols: +, positive; −, negative.

tra' chu.ri. L. gen. masc. n. *trachuri* derived from *Trachurus japonicus*, Japanese horse mackerel (fish).

The characteristics are as described for the genus and as listed in Tables BXII.γ.154, BXII.γ.163, and BXII.γ.164.

Causes vibriosis of "ma-aji", Japanese horse mackerel (*Trachurus japonicus*). The type strain was isolated from Japanese horse mackerel grown at Uchiura Bay, Numazu, Japan.

Based on DNA–DNA hybridization experiments (fluorometric assay in microdilution plates), Iwamoto et al. (1995) found that the type strain of *Vibrio trachuri* was highly related (95–98%) to two other strains, but less related (1–40%) to 15 other *Vibrio* species tested. The closest relative was *V. harveyi*, to which *Vibrio trachuri* was 40% related. *Vibrio trachuri* was 24–25% related to *V. alginolyticus* and *V. campbellii*, and 10% or less related to 12 other *Vibrio* species. Based on DNA–DNA hybridization experiments, Brenner et al. (unpublished) also concluded that *Vibrio harveyi* is the closest relative of *V. trachuri*. However, they found "species level relatedness" between the type strain of *V. trachuri* and the type strain of *V. harveyi*. Since these two species have different type strains, they concluded that *V. trachuri* would probably become a junior objective synonym of *V. harveyi*. Different methods were used in the two DNA–DNA hybridization studies; this fact may account for the differences in the results.

The mol% G + C of the DNA is: 45.4–47.8 (HPLC after nuclease P1 digestion).

Type strain: T9210, JCM 9677.

42. **Vibrio tubiashii** Hada, West, Lee, Stemmler and Colwell 1984, 2[VP]
tu.bi.ash' i.i. L. gen. n. *tubiashii* of Tubiash; named to honor H.S. Tubiash who first isolated the organism.

The characteristics are as described for the genus and as listed in Tables BXII.γ.163 and BXII.γ.164. Short rods, 0.5 × 1.5 μm. Motile by means of a single polar flagellum when grown in liquid medium. Lateral short-wavelength flagella are synthesized when cultures are grown on solid medium. Colonies on marine agar smooth, circular, off-white and sometimes mucoid; yellow on TCBS agar.

Causes disease, with resulting economic losses, in larvae and juveniles of bivalve mollusks. Isolated from larvae and juveniles of the hard clam (*Mercenria mercenaria*), oyster spat (*Crassostrea virginica*), and adult oyster.

Based on DNA–DNA hybridization experiments (nitrocellulose method), Hada et al. (1984) found that the type strain of *V. tubiashii* was highly related (68–96%) to five other strains, but was only 28% related to *Vibrio anguillarum*. They also found that *V. tubiashii* strain NCMB 2166 was only 13–26% related to 11 other *Vibrio* species. Brenner et al. (unpublished) agreed that *V. tubiashii* is a distinct species, and found the closest relatives of *V. tubiashii* to be *V. orientalis* and *Vibrio* groups 515 and 516 (29–33% related). Fig. BXII.γ.171 illustrates the relationship of *V. tubiashii* to other *Vibrio* species based on 16S rRNA gene sequence analysis.

The mol% G + C of the DNA is: 43–45% (T_m).

Type strain: ATCC 19109, CCUG 38428, CIP 102760, IFO 15644, LMG 10936.

GenBank accession number (16S rRNA): X74725.

43. **Vibrio vulnificus** (Reichelt, Baumann and Baumann 1979) Farmer 1980, 656[VP] (*Beneckea vulnifica* Reichelt, Baumann and Baumann 1979, 80.)
vul.ni' fi.cus. L. adj. *vulnificus* inflicting wounds.

The characteristics are as described for the genus and as listed in Tables BXII.γ.163 and BXII.γ.164. Characters that differentiate *V. vulnificus* from *V. alginolyticus*, *V. harveyi*, and *V. parahaemolyticus* are given in Table BXII.γ.170. Characters that distinguish *V. vulnificus* from other *Vibrio* spp. found in human clinical specimens are given in Tables BXII.γ.156, BXII.γ.157, BXII.γ.160, BXII.γ.161, BXII.γ.165 and BXII.γ.166. Differential characteristics of the three biogroups of *V. vulnificus* are given in Table BXII.γ.176.

Occurs in human clinical specimens (Table BXII.γ.157) and the marine environment. Cause of wound infections, bacteremia, and septicemia. The type strain was isolated from human blood.

The type stain and most other strains belong to biogroup 1. All information given below on mol% G + C of the DNA, type strain accession numbers, and GenBank accession numbers pertains to biogroup 1. Biogroups 2 and 3 differ in phenotype, host range, ecology, and several other ways.

V. vulnificus biogroup 2 was described by Tison et al. (1982). Deposited strains include ATCC 33147, 33148, and

[b]ONPG, *o*-nitrophenyl-β-D-galactopyranoside.

33149. Strains of biogroup 2 were originally shown to be pathogenic for eels (Tison et al., 1982). Biogroup 2 appears to be a cause of human wound infections as well (Amaro and Biosca, 1996).

Biogroup 3 strains were described as a separate biogroup by Bisharat et al. (1999). Biogroup 3 strains were originally identified as a variety of different *Vibrio* species (Bisharat and Raz, 1996); all isolates were associated with human wound infections and exposure to cultured tilapia. There are no deposited strains.

The mol% G + C of the DNA is: 46–48 (T_m, Bd) (biogroup 1).

Type strain: B9629, ATCC 27562, DSM 10143, IMET 11292 (biogroup 1).

GenBank accession number (16S rRNA): X56582, X74726, X76333 (biogroup 1).

44. **Vibrio wodanis** Lunder, Sørum, Holstad, Steigerwalt, Mowinckel and Brenner 2000, 446[VP]
wo.da' nis. M. L. gen. n. *wodanis* from Wodan, the Norse god of art, culture, war, and the dead.

Morphological, growth, physiological, and biochemical characteristics are listed in Table BXII.γ.164. This is the second of the two new *Vibrio* species from Atlantic salmon with "winter ulcer" that were described by Lunder et al. (2000). Fig. BXII.γ.171 illustrates the relationship of *V. wodanis* to other species of *Vibrio*.

The mol% G + C of the DNA is: 40 (T_m).

Type strain: NVI 88/441, ATCC BAA-104, NCIMB 13582.

GenBank accession number (16S rRNA): AJ132227.

Other Organisms

1. Baumann Group E-3[1]

Properties are given in Table BXII.γ.163. This group was originally described and given the vernacular name "E-3" by Baumann et al. (1971a). The group included Baumann strains 94 and 95. Based on the immunological relationships of the enzyme superoxide dismutase from different *Vibrio* and *Photobacterium* species, Bang et al. (1981) showed that Group E-3 was more closely related to three *Photobacterium* species than to *V. cholerae*, *V. alginolyticus*, and other *Vibrio* species (see Fig. 4 of Bang et al., 1981). Group E-3 has been referred to as *Vibrio* group 513 by Farmer (unpublished).

Deposited strain: ATCC 33523 from seawater, Oahu, Hawaii (strain 95 of Baumann et al. [1971]; isolated with acetate enrichment).

2. *Vibrio* Group 509[2]

Properties are given in Table BXII.γ.163. The name "*Vibrio* Group 509" includes a group of four Na^+-requiring *Vibrio* strains isolated from blood cultures of Kemp's Ridley sea turtles during an outbreak at the National Marine Fisheries Services facilities, Galveston, Texas. The organisms were seen in stained sections of lung tissue and the animals were observed to vomit blood. This condition was thought to resemble "hemorrhagic septicemia". Based on DNA–DNA hybridization experiments, Brenner et al. (unpublished) found that the strains were 85% related under stringent hybridization conditions.. The strains of *Vibrio* Group 509 strains were later found to be closely related to the type strain of *V. harveyi* (Brenner et al., personal communication).

3. *Vibrio* group 510

Properties are given in Table BXII.γ.163. This group includes the reference strain, which was isolated from an infected human leg wound, and five additional strains. Based on DNA–DNA hybridization experiments (Brenner et al., personal communication), these strains had an average relatedness to the reference strain of 78% under stringent hybridization conditions. *Vibrio* group 510 is closely related to *V. diazotrophicus* and may eventually become a named biogroup (Table BXII.γ.164) or subspecies of *V. diazotrophicus*. *Vibrio* group 510 can be distinguished phenotypically from *V. diazotrophicus* by being arginine negative at 7 days, fermenting D-mannose, and failing to ferment salicin. *V. diazotrophicus* strains usually have the opposite reactions.

4. *Vibrio* group 511

Properties are given in Table BXII.γ.163. *Vibrio* group 511 appears closely related to or perhaps a synonym of *V. cincinnatiensis* (see Table BXII.γ.164, and *V. cincinnatiensis*).

5. *Vibrio* group 512

Properties are given in Table BXII.γ.163. Strains of *Vibrio* group 512 were isolated from seawater and mud in the

1. "Baumann Groups"—In the 1970s, many different vibrios were studied in the laboratories of Paul and Linda Baumann. Scientific names were assigned to many of their distinct groups. However, some groups were never given scientific names. Also, in the Other Organisms Section of the *Vibrio* chapter in the last edition of this *Manual*, Baumann et al. (1984b) discussed four strains or groups of strains that they considered were distinct from all the species and named groups known at that time. These four vibrio groups should be studied with the techniques now available.

2. For many years vernacular names such as "*Vibrio* group 509" were assigned by one of us (JJF) to a new or unusual strain or group of strains. This nomenclature is similar to the one that assigned a vernacular name "Enteric Group" to an organism thought to belong in the family *Enterobacteriaceae* (Farmer et al., 1985a). The "*Vibrio* group names" have been included for many years in the databases (see Table BXII.γ.163) and computer identification programs distributed by the *Vibrio* Reference Laboratory. Many have been included in various DNA–DNA hybridization studies (Brenner et al., 1983b; Brenner et al., unpublished). Four of the groups are described below. Additional groups have been defined but require further study and will be described in the future. The relationships of these groups to other *Vibrio* species as shown by DNA–DNA hybridization experiments are given in Fig. BXII.γ.172.

United Kingdom. Based on DNA–DNA hybridization experiments, five strains were found to be 89% related to the reference strain under stringent hybridization conditions (Brenner et al., unpublished). The closest relative of group 512 is *V. cincinnatiensis* (including *Vibrio* group 511), which is 15% related under stringent hybridization conditions.

Genus II. **Photobacterium** *Beijerinck 1889, 401*[AL]

AN THYSSEN AND FRANS OLLEVIER

Pho.to.bac.te' ri.um. Gr. n. *phos* light; Gr. neut. dim. n. *bakterion* a small rod; M.L. neut. n. *Photobacterium* light (-producing) bacterium.

Plump, straight rods, 0.8–1.3 × 1.8–2.4 µm; some coccobacillary and bipolar. Involution forms are usually seen in old cultures or under adverse conditions of cultivation. Gram negative. **Motile by 1–3 unsheathed polar flagella**; some species nonmotile. **Facultative anaerobic.** Chemoorganotrophic, having **both a respiratory and a fermentative type of metabolism**. Optimal growth temperature range appears to be 18–25°C, except for the psychrophilic species *P. profundum*. **Sodium ions are required for growth.** D-Glucose and D-mannose are catabolized with the production of acid and, in the case of *P. damselae* subsp. *damselae*, *P. iliopiscarium*, and *P. phosphoreum*, with gas. Oxidase reaction is variable. Most strains are lysine decarboxylase and arginine dihydrolase positive. Ornithine decarboxylase negative. **Accumulate poly-β-hydroxybutyrate** (PBH) under certain conditions of cultivation; **do not use the exogenous monomer β-hydroxybutyrate**. Most strains **grow in a minimal medium containing a seawater base, D-glucose, and NH_4Cl**; other strains also require L-methionine. Utilize D-glucose, D-fructose, glycerol, and D-mannose. Some species are bioluminescent.

The mol% G + C of the DNA is: 39–44 (Baumann and Baumann, 1977).

Type species: **Photobacterium phosphoreum** (Cohn 1878) Beijerinck 1889, 401 (*Micrococcus phosphoreus* Cohn 1878, 126.)

FURTHER DESCRIPTIVE INFORMATION

The genus *Photobacterium* is situated in the family *Vibrionaceae* and belongs to the class *Gammaproteobacteria*. Within the genus *Photobacterium*, the group of *P. damselae* subsp. *piscicida*, *P. damselae* subsp. *damselae*, and *P. leiognathi* forms a distinct subcluster (Nogi et al., 1998c). *P. phosphoreum*, *P. angustum*, and *P. profundum* are also closely related. High DNA–DNA hybridization values (which vary with the hybridization techniques used) have been reported between *P. damselae* subsp. *piscicida* and *P. damselae* subsp. *damselae* (Gauthier et al., 1995b; Thyssen et al., 2000). Low DNA–DNA hybridization values have been reported between (i) *P. damselae* subsp. *piscicida* and *P. leiognathi* (Thyssen et al., 2000), (ii) *P. damselae* subsp. *damselae* and *P. leiognathi* (Nogi et al., 1998c; Thyssen et al., 2000), (iii) *P. angustum* and *P. phosphoreum* (Baumann and Baumann, 1981b; Nogi et al., 1998c), (iv) *P. angustum* and *P. profundum* (Nogi et al., 1998c), (v) *P. phosphoreum* and *P. profundum* (Nogi et al., 1998c), (vi) *P. phosphoreum* and *P. leiognathi* (Baumann and Baumann, 1981b).

Photobacterium spp. display morphologic characteristics typical of members of the *Vibrionaceae*, appearing as straight rods; *P. damselae* subsp. *damselae*, and *P. leiognathi* appear as coccobacilli. In the early stationary phase of growth, PHB, which is stored by the cells as a reserve product, can be detected as discrete, refractile, intracellular granules (Reichelt and Baumann, 1973b). When a substantial amount of PHB is accumulated, the entire cell appears refractile. PHB is only formed when cells are grown in a basal medium with glucose as the sole carbon source; PHB is not formed when cells are grown in rich media containing peptone. Except for *P. damselae* subsp. *piscicida*, all *Photobacterium* species are motile. One to three polar flagella have been described (Reichelt and Baumann, 1973b). These flagella, unlike those of *Vibrio*, are not enclosed in a sheath.

The fatty acid profile of *Photobacterium* species has been recently determined by Nogi et al. (1998c), who found high concentrations of $C_{16:1}$ and $C_{16:0}$ fatty acids. Moreover, $C_{12:0}$, $C_{12:0\ 3OH}$, $C_{18:1}$, and to a lesser extent $C_{14:0}$, $C_{14:0\ 3OH}$, and $C_{14:1}$ fatty acids are detected. Q-8 and Q-7 have been reported as major isoprenoid quinones in *Photobacterium* species (Nogi et al., 1998c).

Colonies of *Photobacterium* are entire, smooth, semitranslucent, convex, and ivory. The color of the colonies is somewhat whiter than that of many other Gram-negative marine bacteria, probably due to a relatively low content of cytochromes.

Photobacterium species are unable to grow in the absence of Na^+. For optimal growth, 160–280 mM Na^+ is required. Most *Photobacterium* strains have no organic growth factor requirement; some *P. phosphoreum* strains, however, require L-methionine, either alone or in combination with other amino acids (Reichelt and Baumann, 1973b; Ruby et al., 1980). All species except *P. profundum* are able to grow at 20°C; *P. iliopiscarium*, *P. phosphoreum*, *P. profundum*, and some *P. angustum* strains are able to grow at 4°C.

The nutritional versatility of *Photobacterium* species is relatively limited; only 7–22 carbon compounds can be utilized as sole or principal sources of carbon and energy. These compounds include hexoses and a few pentoses, disaccharides, sugar acids, tricarboxylic acid cycle intermediates, and amino acids. Almost none of the *Photobacterium* species can utilize D-mannitol as the sole source of carbon energy; most species, however, except *P. damselae* subsp. *piscicida* and *P. leiognathi*, can utilize maltose. Most species are able to use *N*-acetyl-D-galactosamine, *N*-acetyl-D-glucosamine, D-fructose, glycerol, glycogen, DL-lactate, D-glucose, D-galactose, maltose, D-mannose, and turanose as sole carbon sources. Adonitol, L-arabinose, cellobiose, *myo*-inositol, α-D-lactose, raffinose, L-rhamnose, D-sorbitol, and sucrose are not used. Acid with gas from D-glucose fermentation is detected with some of the *Photobacterium* species. None of the species have an extra-

cellular gelatinase or alginase; some strains have an extracellular chitinase, lipase, or amylase. The methyl red and Voges–Proskauer tests are positive. Oxidase reaction is variable; catalase reaction is positive. Indole, hemolysin, and H_2S are not produced; except in the case of *P. profundum*, which is able to produce indole. Most species reduce nitrate, except *P. angustum* and *P. damselae* subsp. *piscicida* (Table BXII.γ.177).

Phylogenetic analyses based on the 5S rRNA, 16S rRNA, and 16S rDNA sequences have been carried out to clarify the taxonomic and phylogenetic position of members of the *Vibrionaceae* and species belonging to the genus *Photobacterium* (MacDonell and Colwell, 1985; Kita-Tsukamoto et al., 1993; Gauthier et al., 1995b; Nogi et al., 1998c). Moreover, the levels of homology of the chromosomal DNA of the different *Photobacterium* species have been intensively studied by Nogi et al. (1998c) and Thyssen et al. (2000).

Several serological typing systems have been developed, but these focus primarily on *P. damselae* subsp. *piscicida* and *P. damselae* subsp. *damselae* (Fouz et al., 1992; Magariños et al., 1992; Bakopoulos et al., 1997; Kawahara et al., 1998). In addition, plasmid profiling and a variety of DNA-based typing methods, such as amplified fragment length polymorphism (AFLP), restriction fragment length polymorphism (RFLP), and ribotyping, have been used in epidemiological studies (Magariños et al., 1992, 1997; Pedersen et al., 1997; Thyssen et al., 2000). Plasmids have been described in a variety of species, including *P. damselae* subsp. *piscicida* and *P. damselae* subsp. *damselae* (Fouz et al., 1992; Kim and Aoki, 1993; Pedersen et al., 1997). Chloramphenicol, tetracycline, sulfamonomethoxine, and kanamycin resistances have been shown to be plasmid mediated and transferable (Kim and Aoki, 1993).

Photobacterium species are susceptible to vibriostatic agent O/129 (10 μg and 150 μg). Drug resistance has been reported for many species, especially for *P. damselae* subsp. *piscicida*, which is resistant to a variety of antimicrobial agents (Aoki, 1992).

P. damselae subsp. *piscicida* and *P. damselae* subsp. *damselae* are pathogenic for several marine fish species. The polysaccharide capsular layer, iron uptake system, phopholipase activity of *P. damselae* subsp. *piscicida*, and extracellular products have been recognized as virulence factors (Romalde and Magariños, 1997). A phospholipase toxin with hemolytic and cytotoxic activities has been documented in *P. damselae* subsp. *damselae* (Toranzo and Barja, 1993).

Photobacterium strains are widespread in the marine environment and have been isolated from seawater, sediment, the surface and intestines of diseased marine animals, and the specialized light organs from marine fish. Some strains are found as symbionts in specialized luminous organs of marine fish.

Strains of *P. leiognathi* and *P. phosphoreum* are able to emit light due to the presence of luciferase. The reaction catalyzed by luciferase involves the luminescent oxidation of reduced flavin mononucleotide ($FMNH_2$) and a long chain aliphatic aldehyde by molecular oxygen. The reaction can be expressed as $FMNH_2 + O_2 + RCHO \rightarrow hv + FMN + RCOOH$.

Enrichment and Isolation Procedures

Photobacterium species may be recovered from the marine environment and on the surfaces and the intestinal contents of marine animals using blood agar, brain–heart infusion agar, tryptic soy agar (supplemented with 1% (w/v) NaCl), thiosulfate citrate bile sucrose agar, and marine agar. Details of the isolation of *Photobacterium* in luminous organs of fish are given by Baumann and Baumann (1981b) and Hastings and Nealson (1979). Nutrient agents affecting the growth, luminescence intensity, and luciferase synthesis are described by Rodicheva et al. (1993).

Maintenance Procedures

Photobacterium strains may be maintained at room temperature on long-term preservation medium (West and Colwell, 1984) for several months and reactivated on brain–heart infusion agar (Difco) to which 1% (w/v) NaCl is added. For long-term storage, cultures should be frozen and maintained at −70°C. A method for long-term preservation of luminous bacteria, such as *P. leiognathi* and *P. phosphoreum*, is described by Janda and Opekarova (1989).

Procedures for Testing Special Characters

A somewhat unusual combination of properties of *Photobacterium* is the ability to accumulate PHB as an intracellular reserve product, coupled with the inability to utilize the exogenous monomer, β-hydroxybutyrate, as a sole or principal source of carbon and energy. Accumulation of refractile PHB granules can be readily detected by phase microscopy in early stationary-phase cultures grown in basal medium containing 0.2% (w/v) D-glucose. In the case of organisms requiring growth factors, the medium is supplemented with 0.05–0.1% (w/v) yeast extract.

Differentiation of the genus *Photobacterium* from other genera

Classical biochemical differentiation of the genus *Photobacterium* from related genera, such as *Vibrio*, *Aeromonas*, and *Plesiomonas*, is primarily achieved via the identification of the individual species. *Photobacterium* can be differentiated from *Vibrio*, *Aeromonas*, and *Plesiomonas* by its production of arginine dihydrolase, Voges–Proskauer reaction, inability to produce alginase, gelatinase, and indole, fermentation of sucrose, utilization of D-mannitol, and requirement of over 100 mM Na^+ for optimal growth. Moreover, *Photobacterium* can be distinguished from *Vibrio* by the presence of unsheathed polar flagella. Analysis of poly-β-hydroxybutyrate enables clear differentiation of *Photobacterium* strains from *Vibrio* strains, but is of limited value in a routine diagnostic laboratory.

The decay kinetics of light emission by luciferase in the presence of dodecanal subdivides luminous bacteria into two major groups having either "slow" or "fast" kinetics (Jensen et al., 1980; Hastings and Nealson, 1981). "Slow" decay kinetics are characteristic of the enzyme from *Vibrio harveyi*, *V. splendidus* biovar I, *V. cholerae*, and *Xenorhabdus luminescens*, while "fast" decay kinetics occur with the luciferases of *Photobacterium*, *V. fischeri*, *V. logei*, and *Alteromonas hanedai*. Although *Photobacterium* is not unique in having "fast" decay kinetics, this property still has diagnostic value, since the luminous species of *Vibrio* and *Alteromonas* are readily distinguished from *Photobacterium* by a few easily determined properties; *V. fischeri* and *V. logei* have a yellow-orange, cell-associated pigment, while *Photobacterium* does not, and *A. hanedai* is a strict aerobe, whereas *Photobacterium* is facultative anaerobe.

Taxonomic Comments

Since its creation in 1889, a variety of Gram-negative, facultatively anaerobic, PHB-producing bacteria have been included in the genus *Photobacterium*. Originally, the genus was composed of 3 species: *P. angustum*, *P. leiognathi*, and *P. phosphoreum*. Later phylogenetic work based on ribosomal RNA and DNA sequence analysis and/or hybridization experiments has revealed the presence of other species in this genus, such as *P. fischeri* (formerly *V. fischeri*) (Reichelt and Baumann, 1973b), *P. logei* (Harwood et al., 1980), *P. histaminum* (Okuzumi et al., 1994), *P. damselae* subsp. *piscicida* (formerly *Pasteurella piscicida*) (Gauthier et al., 1995b), *P. damselae* subsp. *damselae* (formerly *Vibrio damsela* or *Listonella damsela*) (Gauthier et al., 1995b), *P. profundum* (Nogi et al., 1998c), and *P. iliopiscarium* (formerly *V. iliopiscarius*) (Urakawa et al., 1999a). *P. logei*, however, has been removed from *Photobacterium* and classified in the genus *Vibrio*. The taxonomic position and classification of *P. fischeri* (*Vibrio fischeri*) remains uncertain. More details are given in the chapter on *Vibrionaceae*.

There are some taxonomic problems at the species level. Although the names *P. damselae* subsp. *piscicida* and *P. damselae* subsp. *damselae* have been validly published, some doubt exists whether or not these organisms should be classified as two separate species. They are phenotypically and genotypically dissimilar, develop different diseases and have different ecological niches (Thyssen et al., 1998; Thyssen et al., 2000). DNA–DNA hybridization and 16S rRNA sequence analysis, however, indicate that they are closely related (Gauthier et al., 1995b).

Another problem concerns the taxonomic position of *P. iliopiscarium* and *P. histaminum*. *P. iliopiscarium* was originally placed in the genus *Vibrio* (Onarheim et al., 1994), but has recently been reclassified as *P. iliopiscarium* based on 16S rRNA gene sequences (Urakawa et al., 1999a). *P. histaminum* (Okuzumi et al., 1994) is considered to be a later heterotypic synonym of *P. damselae* subsp. *damselae*, based on 16S rDNA sequencing and DNA–DNA hybridization (Kimura et al., 2000).

List of species of the genus Photobacterium

1. **Photobacterium phosphoreum** (Cohn 1878) Beijerinck 1889, 401[AL] (*Micrococcus phosphoreus* Cohn 1878, 126.)
phos.pho' re.um. Gr. v. *phosphoreo* bring light; M.L. neut. adj. *phosphoreum* light-bearing.

Straight rod. Motile by means of unsheathed polar flagella. Luminescent. Contains high concentrations of $C_{16:1}$, $C_{16:0}$, and $C_{14:0}$ fatty acids, as well as $C_{12:0}$ and $C_{12:0\ 3OH}$, and to a lesser extent $C_{14:1}$, $C_{14:0\ 3OH}$, $C_{18:0}$, and $C_{18:1}$ (Nogi et al., 1998c). Isoprenoid quinone Q-8 accounts for 100% of the total isoprenoid quinones (Nogi et al., 1998c). May require L-methionine, either alone or in combination with other amino acids. Able to grow at 4°C, but not at 35°C or 40°C. Optimum growth at 160–280 mM Na^+ and 20–25°C. The description is the same as that for the genus. Gas production. Oxidase, caseinase, and lipase are not produced. L-arabinose, cellobiose, *i*-inositol, D-mannitol, salicin, D-sorbitol, sucrose, trehalose, and D-xylose are not fermented. Acetate, alanine, arginine, citrate, ethanol, glycine, leucine, putrescine, proline, pyruvate, and threonine are not used as sole carbon source. See Table BXII.γ.178 for other characteristics.

DNA–DNA hybridization experiments have revealed a DNA relatedness of 20.5% between *P. phosphoreum* and *P. profundum* (Nogi et al., 1998c). Moreover, there was a DNA–rRNA relatedness of 98.7% to *P. leiognathi* (Baumann and Baumann, 1981b). Bacteriophages active against *P. phosphoreum* have been isolated from the marine environment (Spencer, 1963). Isolated from the light organs of five fish families (*Macrouridae*, *Merluccidae*, *Opisthoproctidae*, *Trachichthydae*, and *Moridae*) that are usually found in deep, cold waters. *P. phosphoreum* is a psychrophilic, deepwater species found at depths of 50–500 m.

The mol% G + C of the DNA is: 40.8 (HPLC).

Type strain: ATCC 11040, LMG 4233.

GenBank accession number (16S rRNA): D25310, X74687, Z19107.

2. **Photobacterium angustum** Reichelt, Baumann and Baumann 1979, 79[AL]

[a]For symbols, see standard definitions; nd, not determined.

an.gus' tum. L. neut. adj. *angustum* limited, with respect to nutritional versatility.

Rod. Motile by means of polar flagella. Not luminescent. The fatty acid profile has recently been determined by Nogi et al. (1998c), who have found that the bacterium contains high concentrations of $C_{16:1}$, $C_{16:0}$, and $C_{18:1}$ fatty acids. Moreover, $C_{12:0}$ and $C_{12:0\ 3OH}$, and to a lesser extent $C_{14:0}$, $C_{14:0\ 3OH}$, $C_{14:1}$, $C_{15:0}$, $C_{17:0}$, $C_{17:1}$, and $C_{18:0}$ fatty acid have been detected. The major isoprenoid quinone is Q-8 (Nogi et al., 1998c). Optimal growth at 20–25°C and 160–280 mM Na^+. No growth in absence of NaCl, or at NaCl concentration higher than 8%. Not able to grow at 42°C. No gas production from D-glucose. Oxidase and DNase positive. Urease, lysine decarboxylase, and phenylalanine deaminase are not produced. D-adonitol, L-arabinose, cellobiose, esculin, *i*-inositol, D-mannitol, L-rhamnose, salicin, and D-sorbitol are not fermented. Arginine, citrate, citrulline, ethanol, glycine, leucine, malate, methionine, proline, and putrescine are not used as sole carbon sources. Some strains are gelatinase positive. See Table BXII.γ.178 for other characteristics.

DNA–DNA hybridization experiments have indicated relatedness between *P. angustum* and *P. damselae* subsp. *piscicida*, *P. damselae* subsp. *damselae*, *P. leiognathi*, *P. phosphoreum*, and *P. profundum* of, respectively, 21%, 18.5%, 43.5%, 33.5%, and 24.5% (Nogi et al., 1998c; Thyssen et al., 2000). Susceptible to vibriostatic agent O/129 (2,4-diamino-6,7-diisopropyl pteridine) (10 μg and 150 μg). Resistant to penicillin G, oxacillin, streptomycin, and amoxicillin. Isolated from the open ocean and the light organs of several fish species.

The mol% G + C of the DNA is: 41.0 (HPLC).

Type strain: ATCC 25915.

GenBank accession number (16S rRNA): D25307, X74685.

3. **Photobacterium damselae** (Love, Teebken-Fisher, Hose, Farmer, Hickman and Fanning 1981) Smith, Sutton, Fuerst

and Reichelt 1991, 533[VP] (*Vibrio damsela* Love, Teebken-Fisher, Hose, Farmer, Hickman and Fanning 1981, 1140.)
dam.se′ la.e. L. *damselae* named after damselfish.

Not luminescent. Na^+ required for growth. Does not produce phenylalanine deaminase. D-Glucose and D-mannose are fermented. No fermentation of L-arabinose, lactose, D-mannitol, melibiose, or trehalose. Several molecular techniques, such as AFLP, ribotyping, and RFLP, have been used to characterize and differentiate between the two subspecies of *Photobacterium damselae*, *P. damselae* subsp. *piscicida* and *P. damselae* subsp. *damselae* (Magariños et al., 1992, 1997; Pedersen et al., 1997; Thyssen et al., 2000). Plasmids have been reported. Isolated from fish.

The mol% G + C of the DNA is: 40.6–41.4 (enzymatic hydrolysis + HPLC).

Type strain: ATCC 33539.

a. **Photobacterium damselae** *subsp.* **damselae** (Love, Teebken-Fisher, Hose, Farmer, Hickman and Fanning 1981) Gauthier, Lafay, Ruimy, Breittmayer, Nicolas, Gauthier and Christen 1995b, 142[VP] emend. Kimura, Hokimoto, Takahashi and Fujii 2000, 1341 (*Photobacterium damselae* Smith, Sutton, Fuerst and Reichelt 1991, 533; *Vibrio damsela* Love, Teebken-Fisher, Hose, Farmer, Hickman and Fanning 1981, 1140.)

Analyses of lipopolysaccharides and outer membranes have shown that different patterns can be seen, although some bands were common (Fouz et al., 1992). The fatty acid profile of the bacterium contains high concentrations of $C_{16:1}$, $C_{16:0}$, and $C_{18:1}$ fatty acids; $C_{12:0}$ and $C_{12:0\ 3OH}$, and, to a lesser extent, $C_{14:0}$, $C_{14:0\ 3OH}$, $C_{14:1}$, $C_{15:0}$, $C_{17:0}$, $C_{17:1}$, and $C_{18:0}$ fatty acids are also present (Nogi et al., 1998c) . The major isoprenoid quinone is Q-8, and a minor quinone is Q-7; these account for 90% and 10% of the total isoprenoid quinones, respectively (Nogi et al., 1998c). Round to slightly irregular, off-white, opaque, flat, shiny colonies. Able to grow at 1–6% NaCl, with an optimum of 3% NaCl. Produces urease, phosphatase, DNase, and arginine dihydrolase, but not gelatinase or ornithine decarboxylase. Production of amylase and lysine decarboxylase is variable. Some strains produce β-hemolysis. Able to grow on TCBS and MacConkey agar. Gas is produced during fermentation of carbohydrates. Citrate is not used as a sole source of carbon and energy. Maltose is fermented. No fermentation of D-adonitol, D-arabitol, dulcitol, erythritol, *i*-inositol, raffinose, L-rhamnose, salicin, D-sorbitol, or sucrose. See Table BXII.γ.178 for other characteristics.

DNA–DNA hybridization experiments show a DNA relatedness of 21%, 21%, and 19.5% between *P. damselae* subsp. *damselae* and *P. leiognathi*, *P. phosphoreum*, and *P. profundum*, respectively (Nogi et al., 1998c). Plasmids have been reported to be common in *P. damselae* subsp. *damselae* (Fouz et al., 1992). Plasmids can be heterogeneous in size, varying from very small (3.0 kb) to very large (~190 kb) (Pedersen et al., 1997). A high-molecular-weight plasmid band can be detected in most strains. Antigenic differences exist among different *P. damselae* subsp. *damselae* strains, and at least 4 distinct groups are recognized. The serological results are supported by lipopolysaccharide profiles and the outer membrane protein patterns (Fouz et al., 1992).

Resistant to penicillin G, ampicillin, erythromycin, streptomycin, and kanamycin. Susceptible to vibriostatic agent O/129 (150 μg). Virulence tests have shown that *P. damselae* subsp. *damselae* strains are pathogenic for turbot and rainbow trout (Fouz et al., 1992). Pathogenicity is due to production of toxins. *P. damselae* subsp. *damselae* strains have been shown to possess similar virulence determinants for poikilothermic and homeothermic hosts, secreting a potent, lethal phospholipase toxin with hemolytic and cytotoxic activities (Toranzo and Barja, 1993). Isolated from several marine fish (damselfish, yellowtail, seabream, brown shark, lemon shark, etc.), mammals (dolphin), reptiles (turtle), mollusks (octopus), and uninfected fish. Also associated with wound infections in humans.

The mol% G + C of the DNA is: 40.6–41.4 (enzymatic hydrolysis, HPLC).

Type strain: ATCC 33539, DSM 7482.

GenBank accession number (16S rRNA): X74700.

b. **Photobacterium damselae** *subsp.* **piscicida** (ex Janssen and Surgalla 1968) Gauthier, Lafay, Ruimy, Breittmayer, Nicolas, Gauthier and Christen 1995b, 142[VP]
pis.ci.ci′ da. L. n. *piscis* a fish; L. suff. *-cida* from L. v. *caedo* to cut or to kill; M.L. n. *piscicida* fish killer.

Nonflagellated, straight rods with bipolar staining, measuring 1.5 × 1.0 μm. Pleomorphic, changing from coccoidal to long rods under different culture conditions. The toxicity and chemistry of the lipopolysaccharides (LPS) has been studied by Salati et al. (1989). LPS structures are similar for different isolates (Nomura and Aoki, 1985), possessing O-side chains consisting of high-molecular-mass bands in a ladder-like pattern (Magariños et al., 1992). Outer membrane protein patterns (OMP) are similar for different strains (Magariños et al., 1992); when grown under iron-restricted conditions, strains are able to produce iron-regulated outer membrane proteins (IROMPs) (Bakopoulos et al., 1997). Capsular proteins (CP) are not produced by all strains, but production can be induced by growth under special conditions (Magariños et al., 1996). The chemical composition of the capsular polysaccharides has been studied by Bonet et al. (1994). Fatty acid analysis has revealed that saturated and unsaturated fatty acids of 16 carbon atoms are the predominant fatty acids (Romalde et al., 1995). Colonies are regular, uniformly round, 1–2 mm in diameter, glistening, convex, opaque, and viscid. Capsules may be produced. Cells are not able to grow at NaCl concentrations lower than 0.02 M. Optimal growth at 0.3 M NaCl; osmotic requirement of 0.5–3% NaCl. Cells are able to grow at 25°C, but not at 4°C. Growth at 37°C is variable. Cells are able to grow at pH 6–9; optimal growth is at pH 6.8. Oxidase and catalase variable. Lecithinase and lipase positive. Does not produce urease, elastinase, caseinase, phospholipase, and lysine decarboxylase. The following carbon compounds are utilized as sole carbon and energy sources: glutamate, adipate, and L-proline. Fructose, D-galactose, sucrose, and raffinose are fermented anaerobically. L-rhamnose, D-glucitol, D-xylose, maltose, glycerol, galactitol, and cellobiose are not fermented. Gas is not produced. See Table BXII.γ.178 for other characteristics.

By DNA–DNA hybridization, DNA relatedness between *P. damselae* subsp. *piscicida* and *P. damselae* subsp. *damselae* is 77%. DNA relatedness between *P. damselae* subsp. *piscicida* and both *P. leiognathi* and *P. angustum* is much lower, at 23% and 21%, respectively (Thyssen et al., 2000). Direct analysis of DNA sequences has revealed that the rRNA sequences of *P. damselae* subsp. *piscicida* and *P. damselae* subsp. *damselae* differ only by one nucleotide (Gauthier et al., 1995b). Considerable variation in the prevalence, number, and size of plasmids found in *P. damselae* subsp. *piscicida* has been described. R-plasmids encode resistance for chloramphenicol, tetracycline, sulfamonomethoxine, and kanamycin (Kim and Aoki, 1993). *P. damselae* subsp. *piscicida* was formerly thought to be serologically homogeneous (Magariños et al., 1992), but serological differences have been recently detected (Bakopoulos et al., 1997; Kawahara et al., 1998). The median values for minimum inhibitory concentrations of antibiotics are (μg/ml): oxytetracycline, 6.4; penicillin, 0.1; tetracycline, 0.8; amoxicillin, 0.1; ampicillin, 0.05; chloramphenicol, 1.6; flumequin, 0.2; gentamycin, 12.8; neomycin, 12.8; nitrofurantoin, 25.6; sulfonamide, 51.2; streptomycin, 25.6; and trimethoprim, 6.4. Can be extremely virulent for fish. The presence of capsules, the iron uptake system, and the phospholipase are thought to play an important role in the virulence (Romalde and Magariños, 1997). Isolated from diseased fish (mainly *Seriola quinqueradiata*, *Sparus aurata*, and *Dicentrarchus labrax*). Restricted to the East Coast of North America, Japan, and the Mediterranean area.

The mol% G + C of the DNA is: 41.1–41.3 (enzymatic hydrolysis and HPLC).

Type strain: NCMB 2058.

GenBank accession number (16S rRNA): X78105.

4. **Photobacterium iliopiscarium** (Onarheim, Wiik, Burghardt and Stackebrandt 1994) Urakawa, Kita-Tsukamoto and Ohwada 1999a, 260[VP] (*Vibrio iliopiscarius* Onarheim, Wiik, Burghardt and Stackebrandt 1994, 377.)
i.li.o.pis.ca' ri.um. L. n. pl. *ilia* intestines, guts; *ilio* pertaining to intestines; L. adj. *piscarius* belonging to fish *iliopiscarium*, belonging to intestines of fish.

Cells are highly pleomorphic. Morphology of both the colonies and the cells varies, even under apparently identical growth conditions. Bacteria growing in broth cultures at salt levels higher than 2% tend to aggregate. Other factors that influence the morphology are the presence of glucose, temperature, and age of the culture. In broth medium with 2% NaCl and lacking glucose, the dominant cell morphology is rods and curved rods. Motile. Not luminescent. The dominant colony morphology of young cultures comprises small, colorless to grayish, opaque colonies with entire edges. At least 0.5% NaCl is required for growth; this varies with the temperature. No growth occurs at NaCl concentrations of ≥5%. Optimum growth in media with 2% NaCl. The ability to grow at different temperatures varies with the medium composition. No growth is observed at 30°C; 20°C is the optimal temperature when grown in peptone water containing 2% salt. Bacteria are able to grow at 4°C. Growth is better under aerobic conditions rather than anaerobic conditions.

Produce gas from glucose. Cells possess lysine decarboxylase. Negative with respect to urease, and tryptophan deaminase. Citrate, *i*-inositol, D-sorbitol, L-rhamnose, sucrose, melibiose, amygdaline, erythritol, D-xylose, L-xylose, adonitol, β-methylxyloside, L-sorbose, dulcitol, α-methyl-D-mannoside, α-methyl-D-glucoside, arbutin, salicin, melibiose, inulin, melezitose, xylitol, D-turanose, D-lyxose, D-tagatose, D-fucose, L-fucose, L-arabitol, 2-cetogluconate and 5-cetogluconate are not utilized. See Table BXII.γ.178 for other characteristics. Maximum-likelihood, maximum-parsimony, and neighbor-joining methods of nearly complete 16S rRNA gene sequences have shown that the nearest phylogenetic neighbor is *P. phosphoreum* (Urakawa et al., 1999a). Susceptible to vibriostatic agent O/129 at 150 μg/disc, but only slightly sensitive at 10 μg/disc. Resistant to penicillin-G, but sensitive to novobiocin, chloramphenicol, sulfamethoxazole, tetracycline, nitrofurantoin, oxytetracycline, and trimethoprim. Slightly sensitive to ampicillin and streptomycin. Isolated from the intestines of fish (herring, coal fish, cod, and salmon) living in cold seawater.

The mol% G + C of the DNA is: 39 ± 1 (T_m).

Type strain: PS1, ATCC 51760, DSM 9896.

GenBank accession number (16S rRNA): AB000278.

5. **Photobacterium leiognathi** (Hendrie, Hodgkiss and Shewan 1970) Boisvert, Chatelain and Bassot 1967, 521[AL] (*Photobacterium mandapamensis* Hendrie, Hodgkiss and Shewan 1970, 165.)
lei.o.gna' thi. M.L. gen. n. *leiognathi* named after fish of the family *Leiognathidae*.

Coccobacillus, approximately 1.6 × 3.2 μm. Motile. Luminescent. The fatty acid profile of the bacterium contains high concentrations of $C_{16:1}$, $C_{16:0}$, and $C_{18:1}$ fatty acids; as well as $C_{12:0}$, $C_{12:0\ 3OH}$, $C_{14:0}$, and, to a lesser extent, $C_{14:1}$, $C_{14:0\ 3OH}$, $C_{15:0}$, $C_{17:0}$, $C_{17:1}$, and $C_{18:0}$ fatty acids (Makemson et al., 1997; Nogi et al., 1998c). The major isoprenoid quinone is Q-8, and a minor quinone is Q-7; these account for 90% and 10% of the total isoprenoid quinones, respectively (Nogi et al., 1998c). Colonies are 1 mm in diameter, regular, convex, smooth, transparent, and yellow. The optimal temperature is 30°C. Growth can be observed at 37°C, but not at 4°C. Cells can grow at a salt concentration of 0.5–6%. Optimal NaCl concentration is 1.5%. Negative for the production of oxidase and for tryptophan deaminase. No production of lysine decarboxylase. Esculin is not hydrolysed. Fermentation occurs without gas production from fructose, D-glucose, D-galactose, glycerin, D-mannose, *N*-acetylglucosamine, and ribose. Cells are not able to ferment L-arabinose, cellobiose, dulcitol, *i*-inositol, lactose, maltose, D-sorbitol, saccharose, trehalose, or D-xylose. Citrate, citruline, glucuronate, leucine, malonate, methionine, putrescine, and tartrate are not utilized. See Table BXII.γ.178 for other characteristics.

DNA relatedness of *P. leiognathi* to *P. phosphoreum* and *P. profundum* is 26% and 19%, respectively (Nogi et al., 1998c). DNA–rRNA hybridization experiments have shown a relatedness of >98% between *P. leiognathi* and *P. phosphoreum* (Baumann and Baumann, 1981b). Susceptible to vibriostatic agent O/129, chloramphenicol, kanamycin, thiam-

phenicol, tetracycline, erythromycin, novobiocin, nitrofurantoin, polymyxin, trimethoprim, ampicillin, flumequin, gentamycin, and neomycin. Resistant to penicillin G, oxacillin, and amoxicillin. Isolated from the light organs of Leiognathidae and Apogonidae, which are usually found in warm, shallow, tropical water.

The mol% G + C of the DNA is: 41.6 (enzymatic hydrolysis, HPLC).

Type strain: ATCC 25521.

GenBank accession number (16S rRNA): D25309, X74686.

6. **Photobacterium profundum** Nogi, Masui and Kato 1998d, 631^{VP} (Effective publication: Nogi, Masui and Kato 1998c, 6.)

pro.fun′dum. L. adj. n. *profundum* deep, living within the depth of the oceans.

Cells are rod shaped; 0.8–1.0 × 2–4 µm. Motile by means of single, unsheathed polar flagella. Nonluminescent. The fatty acid profile is very distinct from those of other *Photobacterium* species and is particularly characterized by substantial amounts of $C_{16:0\ iso}$ and $C_{20:5}$. The dominant cellular fatty acids are $C_{16:1}$, $C_{16:0\ iso}$, $C_{16:0}$, $C_{18:1}$, and $C_{20:5\ \omega 3c}$ (IPA). The major isoprenoid quinone is Q-8, and a minor quinone is Q-7; these account for 95% and 5% of the total isoprenoid quinones, respectively (Nogi et al., 1998c). Colonies are entire, smooth, semitranslucent, and ivory. They are 0.7–1.0 mm in diameter after 48 h of incubation at 10°C. Growth occurs between 4°C and 18°C at atmospheric pressure, with optimum growth displayed between 8°C and 12°C. No growth occurs at 0°C or 20°C. Growth occurs at pressures between 0.1 MPa and 70 MPa at 10°C, with optimum growth displayed at 10 MPa. Best growth occurs at a NaCl concentration of ~3%. No growth occurs in the absence of NaCl. Moderately barophilic and psychrophilic.

Acid is produced from D-glucose, but gas is not produced. Production of indole. D-Mannitol, but not *N*-acetyl-D-galactosamine, *N*-acetyl-D-glucosamine, or D-fructose, can be utilized as a sole carbon and energy source. See Table BXII.γ.178 for other characteristics. The level of DNA relatedness of *P. profundum* to *P. angustum*, *P. damselae* subsp. *damselae*, *P. leiognathi*, and *P. phosphoreum* is 24.5%, 19.5%, 19%, and 20.5% respectively (Nogi et al., 1998c). Resistant to vibriostatic agent O/129 (10 µg and 150 µg). Isolated from sediment at a depth of 5110 m.

The mol% G + C of the DNA is: 42 (reverse-phase HPLC).

Type strain: DSJ4, JCM 10084.

GenBank accession number (16S rRNA): D21226 for Strain DSJ4.

Genus III. **Salinivibrio** *Mellado, Moore, Nieto and Ventosa 1996, 820^{VP}*

ANTONIO VENTOSA

Sa.li.ni.vib′ri.o. L. adj. *salinus* saline; L. v. *vibrio* move rapidly to and from, vibrate; M.L. masc. n. *Salinivibrio* saline organism which vibrates.

Gram-negative curved rods (0.5–06 × 1.0–3.2 µm). Cells occur singly, in pairs, or occasionally united by S shapes or spirals. **Motile by one polar flagellum**. Spores are not formed.

Moderately halophilic. The optimum NaCl concentration for growth is between 2.5 and 10% at 37°C; grows between 0 and 20% NaCl. Temperature range for growth: 5–50°C; optimum temperature: 37°C. pH range for growth: 5–10; optimum pH: 7.3–7.5. No growth factors are required for growth.

Facultatively anaerobic. Chemoorganotrophic. Catalase and oxidase are produced. Acid is produced from D-glucose. Gelatin is hydrolyzed. Voges–Proskauer and arginine decarboxylase tests are positive. Indole, β-galactosidase, lysine, and ornithine decarboxylase tests are negative. Colonies are circular, convex, opaque, smooth, and cream colored. Broth cultures are uniformly turbid.

The mol% G + C of the DNA is: 49.4–50.5.

Type species: **Salinivibrio costicola** (Smith 1938) Mellado, Moore, Nieto and Ventosa 1996, 820 emend. Huang, Garcia, Patel, Cayol, Baresi and Mah 2000, 620 (*Vibrio costicola* Smith 1938, 29.)

FURTHER DESCRIPTIVE INFORMATION

The genus is currently represented by a single species, *S. costicola*, with two subspecies: *S. costicola* subsp. *costicola* and *S. costicola* subsp. *vallismortis*. The genus was established to separate *Vibrio costicola* from the other species of the genus *Vibrio*, based on their phenotypic features and the lack of a close phylogenetic relationship between *S. costicola* and other *Vibrio* species (Mellado et al., 1996). The species *S. costicola* was isolated from hypersaline environments (salterns, saline soils) and from salted food (Garcia et al., 1987b; Mellado et al., 1996). Recently, Huang et al. (2000) isolated a single strain from a hypersaline pond located in Death Valley, California, USA, with phenotypic and genotypic features typical of *S. costicola*. Based on 16S rRNA gene sequence comparison, it was closely related to *S. costicola* (mean sequence similarity 97.7%) and DNA–DNA hybridization studies showed a high degree of relatedness (93%). However, there were some phenotypic differences and it was proposed to place the new strain in a subspecies of *S. costicola*, designated *S. costicola* subsp. *vallismortis*, which automatically created *S. costicola* subsp. *costicola* (Huang et al., 2000).

The most peculiar feature of the species *S. costicola* is its ability to grow optimally at salt concentrations ranging from 2.5 to 10%, with an upper limit for growth at 20–25% salts. For that reason it is classified as a moderately halophilic bacterium (Ventosa et al., 1998) and especially with respect to its physiology and biochemistry, has been considered a model organism representative of that physiological group (Ventosa et al., 1998). Several studies have determined that *S. costicola* has a specific requirement for Na^+. Addition of high concentrations of compounds such as glucose or glycerol lowered the NaCl requirement from 0.5 M to 0.3 M NaCl (Adams et al., 1987). Temperature and medium composition affect the salt requirement (Kushner, 1978; Adams and Russell, 1992).

S. costicola strains have simple growth requirements. The minimum growth requirements have been determined, and two synthetic media have been described. One contained D-glucose, L-

cysteine or cystine, glutamate, L-arginine, L-valine, L-isoleucine, and salts (Flannery and Kennedy, 1962). Kamekura et al. (1985) reported a minimal medium based on D-glucose, glutamate, biotin, thiamine, choline, and salts. Complex media stimulate growth at high salt concentrations. The effect may be due to the presence in the medium of compatible solutes or their precursors, or to the fact that other growth factors may be synthesized more slowly under the high salt conditions (Ventosa et al., 1998).

Strains of *S. costicola* show a heterogeneous response to antibiotics; they are very sensitive to chloramphenicol and rifampin (Nieto et al., 1993). The salt concentration may influence the susceptibility of *S. costicola* to antimicrobial compounds. However, *S. costicola* shows a high sensitivity to rifampin and trimethoprim, regardless of the salt concentration (Coronado et al., 1995). The susceptibility of *S. costicola* to several heavy metals has also been studied (Garcia et al., 1987a). All 58 strains tested were susceptible to cadmium, copper, silver, zinc, and mercury, but showed tolerance to lead (Garcia et al., 1987a).

The genome organization of *S. costicola* has been investigated by pulsed field gel electrophoresis. The genome sizes of six strains ranged from 2100 to 2600 Kb. (Mellado et al., 1997). Several plasmids and one megaplasmid have also been reported (Fernandez-Castillo et al., 1992; Mellado et al., 1997). Conjugation is the only genetic transfer mechanism that has been described for this organism. A bacteriophage, phage UTAK, that infected and lysed *S. costicola* was isolated from salterns in Alicante (Spain), and propagated optimally at 1–2 M NaCl (Goel et al., 1996). However, genetic transfer by transduction has not been studied.

Besides its presence in salted foods, the natural environment of *S. costicola* is hypersaline habitats such as salt lakes and salterns. This organism is present in ponds of salterns with 10–25% salts, and is one of the predominant bacteria in ponds with less that 15% salts, as determined by isolation of *S. costicola* from these habitats in culture media (Rodriguez-Valera et al., 1985; Márquez et al., 1987). However, its presence in hypersaline soils is less evident (Quesada et al., 1982).

Since *S. costicola* has served as a model organism in different studies of moderately halophilic bacteria, there is much information concerning its ecology, physiology, and biochemistry (internal ions concentration and ion pumps, compatible solutes, cytoplasmic and membrane-bound enzymes, polar lipid and fatty acid composition, etc.). Further information can be found in a review on moderately halophilic bacteria (Ventosa et al., 1998).

Enrichment and Isolation Procedures

Selective procedures for the enrichment and isolation of *S. costicola* have not been reported. It can be isolated in complex media with the addition of a salt mixture and incubated at 37°C under aerobic or preferentially anaerobic (to avoid the growth of strictly aerobic species) conditions. The isolation medium described by Ventosa et al. (1982) can be used. Another isolation procedure has been described by Huang et al. (2000). Enrichments are prepared by inoculating samples into serum bottles containing 25 ml anaerobic enrichment medium (12% NaCl and 0.5% D-glucose) and incubation at 37°C without shaking.

Maintenance Procedures

Salinivibrio costicola may be maintained on complex medium containing 10% salts. An appropriate medium is described by Garcia et al. (1987b). Long-term storage of members of this genus can be carried out by freeze-drying, storage at −80°C, or by storing in liquid nitrogen.

Differentiation of the genus *Salinivibrio* from other genera

The genus *Salinivibrio* can be differentiated from other related genera, except *Vibrio*, based on morphology, since it contains curved rods. Typical features of *Salinivibrio costicola* are its optimal growth in media containing 10% salts, and its ability to produce arginine decarboxylase. The genus *Salinivibrio* can also be differentiated from *Vibrio* and other related genera of the family *Vibrionaceae* by comparative analysis of 16S rRNA gene sequences. Besides, in comparison with species of the genus *Vibrio*, *Salinivibrio costicola* has two unique helical sequences and secondary structures at positions 178–197 and 197–219 of the 16S rRNA (*E. coli* 16S rRNA gene sequence numbering) (Huang et al., 2000).

Taxonomic Comments

The single species of the genus *Salinivibrio* was isolated from rib bones in Australian bacon and described originally by Smith (1938), as *"Vibrio costicolus"*. In *Bergey's Manual of Determinative Bacteriology* (7th ed.), this species was included as a member of the genus *Vibrio* (Breed et al., 1957) and in the 8th edition it was named correctly as *Vibrio costicola* (Shewan and Véron, 1974). Very few taxonomic studies were performed on this species and they were carried out on isolates from cured meats (Gardner, 1980). Garcia et al. (1987b) amended the description of this species, including strains isolated from cured meats as well as 54 isolates from several salterns located in different areas of Spain. Further DNA–DNA hybridization studies determined that isolates from cured meats and salterns have a high level of DNA relatedness and should be considered members of the same species (Gutiérrez et al., 1989). The analysis of complete 16S rRNA gene sequences of six strains showed that phylogenetically they form a monophyletic branch that is distinct from other *Vibrio* species and related genera (Fig. BXII.γ.184). This evidence, together with several phenotypic differences, permitted the establishment of a different genus for this species, *Salinivibrio costicola* (Mellado et al., 1996).

Acknowledgments

I am grateful to J.T. Staley for the critical reading of this article and to D.R. Arahal for his help with the phylogenetic analysis.

Order XII. **Aeromonadales** *ord. nov.**

Amy Martin-Carnahan and Samuel W. Joseph

Ae.ro.mo.na.da'les. M.L. fem. n. *Aeromonas* type genus of the family and order; suff. *-ales* to denote an order; M.L. pl. n. *Aeromonadales* the *Aeromonas* order.

The order *Aeromonadales*, which contains a single family, *Aeromonadaceae*, with the *Aeromonas*, is herein proposed. Gram-negative, straight, rigid rods. Facultatively anaerobic; oxidase positive with rare exceptions and catalase positive. Includes motile (single, polar flagellum) and nonmotile species, as well as mesophilic and psychrophilic species. Primarily aquatic inhabitants of freshwater, marine, and especially estuarine environments, often associated with aquatic animals. Some species are either primary or opportunistic pathogens in humans, as well as a variety of other warm-blooded and cold-blooded animals and invertebrates.

The mol% G + C of the DNA is: 57–63.

Type genus: **Aeromonas** Stanier 1943, 213.

**Editorial Note:* The family *Succinivibrionaceae* has been placed in this chapter by the editors as *familia incertae sedis* based on a phylogenetic analysis that indicated distant relationships between the 16S rDNA sequences of the type species of the four genera included in the *Succinivibrionaceae* and the 16S rDNA sequences of some members of the genus *Aeromonas*. This placement should not be taken to imply that members of the *Succinivibrionaceae* are or should be included in the definition of the order *Aeromonadales* as proposed here by Martin-Carnahan and Joseph.

Family I. **Aeromonadaceae** Colwell, MacDonell and De Ley 1986, 474[VP]

Amy Martin-Carnahan and Samuel W. Joseph

Ae.ro.mo.na.da'ce.ae. M.L. fem. n. *Aeromonas* type genus of the family; suff. *-aceae* to denote a family; M.L. fem. pl. n. *Aeromonadaceae* the *Aeromonas* family.

Gram-negative, straight, rigid, nonsporeforming rods. Motility by means of polar flagella with some evidence of lateral flagella; some species are considered nonmotile. Occur singly, occasionally in pairs, or in short chains.

Facultatively anaerobic and chemoorganotrophic. Fermentative or respiratory with oxygen as a universal electron acceptor. Reduce nitrates, but do not denitrify. Ammonium salts utilized by most isolates as a sole source of nitrogen. Oxidase positive, except for *Tolumonas*. Catalase positive. Most species are mesophilic, but psychrophilic species do exist. *Oceanimonas* requires NaCl.

Primarily aquatic, most frequently isolated from fresh and estuarine waters and in association with aquatic animals; also found in sewage, surface waters, sediments, and biofilms; several species are pathogenic for humans, other warm-blooded animals, fish, eels, frogs, as well as other vertebrates and invertebrates, such as leeches.

The mol% G + C of the DNA is: 57–63.

Type genus: **Aeromonas** Stanier 1943, 213.

Taxonomic Comments

The analysis of rRNA–DNA hybridization studies of the members of the family *Vibrionaceae*, in which *Aeromonas* was then included, was summarized in the first edition of *Bergey's Manual of Systematic Bacteriology* (Baumann and Schubert, 1984). The evidence from those studies suggested that the genus *Aeromonas* was sufficiently different from other genera in *Vibrionaceae* to merit its placement in a new family.

Subsequent analyses by Colwell et al. (1986) using 16S rRNA cataloging, 5S rRNA gene sequence comparisons, and rRNA–DNA hybridization data revealed that aeromonads demonstrated an evolutionary divergence that was approximately equidistant from the *Enterobacteriaceae* and the *Vibrionaceae*, thereby justifying classification of the genus *Aeromonas* in its own family. These authors formally proposed the creation of the family *Aeromonadaceae* to incorporate the single genus, *Aeromonas*, which was later supported in 1992 by analyses using 16S rDNA sequencing and dendrograms showing that members of the genus *Aeromonas* form a distinct line within the *Gammaproteobacteria* (Martinez-Murcia et al., 1992a).

Additional evidence for the separation of the family *Aeromonadaceae* from the family *Vibrionaceae* soon followed with the analysis of 50 reference strains from 10 genera on the basis of 600 16S rRNA nucleotides by using reverse transcriptase sequencing (Kita-Tsukamoto et al., 1993). Shortly thereafter, the sequencing of nearly complete 16S rRNAs of 54 reference strains from the genera *Vibrio*, *Photobacterium*, *Aeromonas*, and *Plesiomonas* was added to all other known sequences for bacteria belonging to the *Gammaproteobacteria* to generate a database of 70 sequences for subsequent comparison (Ruimy et al., 1994). Their results showed that the family *Vibrionaceae* should include only *Vibrio* and *Photobacterium*, and that the genus *Aeromonas* should be moved to a separate family, *Aeromonadaceae*. The genus *Oceanimonas* has provisionally been placed in the family *Aeromonadaceae*.

Genus *Incertae Sedis* Although the genus *Tolumonas* is included as a member of the family *Aeromonadaceae* in this edition of *Bergey's Manual*, there is evidence to question the validity of this placement. In the genus description of *Tolumonas* in this edition, Fischer-Romero and Tindall have described the genus and single species, *Tolumonas auensis*, as either an anaerobic or aerobic Gram-negative rod that is oxidase negative, with a mol% G + C content of 49 (T_m). This description also differs from that given herein for the family *Aeromonadaceae*.

Genus I. **Aeromonas** *Stanier 1943, 213*[AL]

AMY MARTIN-CARNAHAN AND SAMUEL W. JOSEPH

Ae.ro.mo' nas. Gr. n. *aer* air, gas; Gr. n. *monas* unit, monad; M.L. fem. n. *Aeromonas* gas(-producing) monad.

Cells straight, coccobacillary to bacillary with rounded ends, 0.3–1.0 × 1.0–3.5 µm. Occur singly, in pairs, or rarely in short chains. Gram negative. **Most species are motile by a single, polar flagellum** of 1.7 µm wavelength; peritrichous flagella may be formed on solid media in young cultures and lateral flagella occur in some species. Facultatively anaerobic. Chemoorganotrophic, displaying oxidative and fermentative metabolism of D-glucose. Acid and often acid with gas produced from many carbohydrates, especially D-glucose. Nitrate is reduced to nitrite. A variety of exoenzymes such as arylamidases, amylase, DNase, esterases, peptidases, and other hydrolytic enzymes are produced. Main cellular fatty acids are hexadecanoic acid ($C_{16:0}$), hexadecenoic acid ($C_{16:1}$), and octadecenoic acid ($C_{18:1}$). **Usually oxidase positive and catalase positive.** Optimum growth temperature varies between 22°C and 37°C; growth temperature can range from 0 to 45°C, and some species do not grow at 35°C. **Generally resistant to 150 µg of the vibriostatic agent 2,4 diamino-6, 7-diisopropylpteridine (0/129).** Occur in fresh, brackish, tap, well, and chlorinated water, as well as biosolids and sewage. Some of the species have been associated with disease in a wide variety of warm-blooded and cold-blooded animals, including humans, domestic animals, frogs, fresh and salt water fish, and invertebrates. The phylogenetic position of *Aeromonas*, as determined by 16S rRNA gene sequence analysis, is in the *Gammaproteobacteria*, with its closest relatives in the families *Vibrionaceae* and *Enterobacteriaceae*. 16S rDNA sequences (signature sequences) have been determined for nearly all validly named species and are deposited in GenBank, EMBL, or RDP databases (Table BXII.γ.180).

The mol% G + C of the DNA is: 57–63.

Type species: **Aeromonas hydrophila** (Chester 1901) Stanier 1943, 213 (*Bacillus hydrophilus* Chester 1901, 235.)

FURTHER DESCRIPTIVE INFORMATION

The genus *Aeromonas* has traditionally been divided into two major groups of species, i.e., motile versus nonmotile species and mesophilic versus psychrophilic species. This general approach will be used here with the caveat that there are isolated instances where species considered to be nonmotile (*Aeromonas salmonicida*) do harbor flagellin genes (Umelo and Trust, 1997) and although *A. salmonicida* was generally considered not to grow above 30°C, it may actually be able to grow at 37°C (Austin, 1993).

The larger of these main categories includes the mesophilic, motile aeromonads which include 14 phenospecies that correspond to at least 17 genomospecies (DNA hybridization groups or HGs) (Table BXII.γ.181). The majority of human clinical isolates to date have been isolated from only six genomospecies, namely 1, 4, 8/10, 9, 12, and 14 (Holmberg et al., 1986a; Kuijper et al., 1989a; Altwegg, 1990; Altwegg et al., 1990; Abbott et al., 1992; Carnahan and Joseph, 1993). The category of psychrophilic, nonmotile aeromonads contains *A. salmonicida* (genomospecies 3), which includes four subspecies and is a major cause of fish disease worldwide (Austin et al., 1989a; Hänninen and Siitonen, 1995; Austin and Adams, 1996).

Phylogenetic treatment In the early 1980s, DNA relatedness studies of the motile aeromonads resulted in the establishment of three phenotypic species, namely *Aeromonas hydrophila*, *Aeromonas sobria*, and *Aeromonas caviae*, from among the eight reported genomospecies or DNA–DNA hybridization groups (Popoff et al., 1981). The number of aeromonad hybridization groups was subsequently expanded to 12 (Fanning et al., 1985; Farmer et al., 1986), and there are at present at least 17 hybridization groups, of which only two are unnamed: DNA hybridization Group 11 and *Aeromonas* Group 501 (HG 13) (Table BXII.γ.181).

Current recommendations define a genetic species as strains with approximately 70% or greater DNA–DNA relatedness and with 5°C or less ΔT_m to enable clear-cut differentiation of genomospecies (Wayne et al., 1987). 16S rDNA sequence analysis, which is routinely used to distinguish and establish relationships between genera, is often not as clear cut at the species level and has a lower discriminatory value when sequence analysis reveals a similarity of 97% or higher (Stackebrandt and Goebel, 1994).

[a]Numbers are homologous positions following the numbering system in *E. coli* (Brosius et al., 1978). Dashes indicate the same nucleotide as that of *A. hydrophila*. The two triplets characteristic of species from the "Schubertii" branch are underlined. Martínez-Murcia, unpublished.

The comparative analysis of the 16S rRNA gene sequences for *Aeromonas* species generally correlates with species designations derived from DNA–DNA hybridization studies (Martinez-Murcia et al., 1992a). While there is some lack of congruence between DNA–DNA hybridization studies and 16S rDNA sequencing results, the overall differentiation between groups is very similar. Table BXII.γ.180 provides the nucleotide composition at variable positions of the 16S rDNA sequences (signature sequences) determined from all currently recognized *Aeromonas* species. Fig. BXII.γ.186 is a phylogenetic tree showing the relationships between described *Aeromonas* species (type strains and reference strains) as determined by a continuous 1502-nucleotide 16S rDNA sequence comparison using the neighbor-joining method (Martinez-Murcia, 1999). Within the genus *Aeromonas*, the species are closely related and high levels of sequence similarity (~97.8–100%, which corresponds to 0–33 base differences) are observed. For example, the 16S rDNA of *A. hydrophila* ATCC 7966^T (HG 1) exhibits only three nucleotide differences with the sequence of *A. media* ATCC 33907^T (HG 5B). *A. jandaei* and *A. schubertii* represent quite separate lines, and together with *A. veronii*, seem to form a separate subbranch or affiliation within the genus (Fig. BXII.γ.187). Support for this loose association comes from the presence of paired signature triplets at the V2 region (positions 154–156 and 165–167) seen in Table BXII.γ.180 (Martinez-Murcia, unpublished), which distinguishes this "Schubertii" cluster from all other aeromonads. *A. schubertii* reveals the highest values of nucleotide differences (up to 33) within the genus and shows the highest number of sites with "unique" nucleotide composition.

Quite presciently, Sneath suggested that there was evidence for genetic crossing-over or recombination based on his analysis of the ribosomal sequences of Martinez-Murcia et al. (1992a) (Sneath, 1993). Although crossing-over may obliterate true phylogenetic relationships, Sneath reconstructed a speculative evolutionary phenogram from the right and left parts of the ribosomal sequence that seemed to suggest that *A. schubertii* might be the basal lineage species of the genus.

Further problems in using 16S rDNA for species identification of aeromonads were revealed when multiple strains from each species were sequenced. This subsequent research used Multilocus Sequence Typing (MLST) to examine a large collection of 94 well-characterized aeromonads, including type and reference strains, for four gene loci: 16S rDNA, *recA*, *chiA*, and *gyrB* (Carnahan, 2001). 16S rDNA exhibited less than 1% variable nucleotides within a species, which means that 16S rDNA sequencing can clearly define an isolate at the genus level only. In contrast, the other three loci were all more variable than 16S and could be more helpful in species identification. The phylogenetic analyses from these three loci arranged the aeromonads into their expected species clusters based on previous phenotypic and genotypic data. However, there were several instances where a single strain would cluster with its proper species designation for 2 of 3 loci, but for the other locus that strain would fall into an entirely different species cluster, again suggesting that recombination or lateral gene transfer is occurring within *Aeromonas*. For each locus examined, *A. schubertii* appeared to be the basal lineage species, consistent with Sneath's earlier assertion.

These observations of recombination across species boundaries and the recent touting of MLST as a "method of great promise" for the re-evaluation of the species definition in bacteriology (Stackebrandt et al., 2002) strongly suggest that the analysis of multiple gene loci should undoubtedly be pursued in future taxonomic studies of the genus *Aeromonas*.

Cell Morphology The members of the genus *Aeromonas* are Gram-negative, straight rods with rounded ends, but sometimes can appear as coccobacilli or with filamentous forms. Cells are 0.3–1.0 × 1.0–3.5 μm and can occur singly, in pairs, or even as short chains (Altwegg, 1999).

Cell Wall Composition Early studies of the composition of core oligosaccharides from motile aeromonads, with respect to combinations of hexose and heptose monosaccharide residues present in the core region of the cell wall lipopolysaccharides, revealed three general groups (Shaw and Hodder, 1978). These three groups generally matched later species designations of *A. hydrophila*, *A. caviae*, and *A. sobria* (Popoff et al., 1981). Analysis of the electrophoretic mobilities of purified or partially purified (proteinase K-treated) lipopolysaccharide (LPS) components by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) or either autoradiography or silver staining techniques indicated at least three major resolvable fractions (Chart et al., 1984; Dooley et al., 1985). Three major patterns among LPS O polysaccharide side chain profiles include a common heterogeneous profile that appears as a series of ladder-like bands ex-

[a]This includes nonmotile, psychrophilic strains.

[b]This includes motile, mesophilic strains.

[c]It has been proposed that *A. eucrenophila* Subgroup II may reside within *A. encheleia* (Huys et al., 1996a, 1997a).

[d]*A. ichthiosmia* appears to be synonymous with *A. veronii* biovar sobria (Martinez-Murcia et al., 1992a; Collins et al., 1993; Huys et al., 2001).

[e]It has been proposed that members of HG Group 11 may reside within *A. encheleia* (Huys et al., 1996a, 1997a).

[f]*A. enteropelogenes* appears to be synonymous with *A. trota* (Martinez-Murcia et al., 1992a; Collins et al., 1993).

[g]It has been proposed to emend the description of *A. encheleia* to include members of HG 11 and Subgroup II of *A. eucrenophila* (Huys et al., 1997a).

tending throughout the gel lane; a second homogeneous pattern that appears as a small number of prominent O side chain bands, sometimes arranged as a doublet; and a third pattern often associated with serologically rough strains and characterized by a lack of detectable side chains (Dooley et al., 1985; Kokka et al., 1990, 1991a).

The major fatty cellular fatty acids produced are hexadecanoic acid ($C_{16:0}$), hexadecenoic acid ($C_{16:1}$), and octadecenoic acid ($C_{18:1}$) (Lambert et al., 1983; Huys et al., 1994). Gas–liquid chromatographic analysis of cellular fatty acid methyl esters (FAMEs) can be used to separate the basic phenotypic clusters of *A. hydrophila*, *A. caviae,* and *A. sobria* (Canonica and Pisano, 1988; Huys et al., 1995). However, the growth medium used can affect the cellular fatty acid composition, and hence the chemotaxonomic differentiation ability of FAME analysis (Huys et al., 1997c). There is limited general information on *Aeromonas* outer membrane profiles (OMPs) other than studies of particular subsets of virulent aeromonads (Aoki and Holland, 1985; Kuijper et al., 1989b).

Fine structure *Aeromonas* species exhibit many fine structures outside the cell membrane and cell wall such as S-layer, flagella, pili, and capsule. A review of these features can be found in the chapter on "Pathogenic mechanisms" in *The Genus Aeromonas* (Gosling, 1996b). Further discussion of these individual features can be found in the pathogenicity section of this chapter *vide infra.*

Colonial or cultural characteristics On standard laboratory media, colonies of motile mesophilic aeromonads are 1–3 mm in diameter, smooth, circumscribed, circular, convex, translucent,

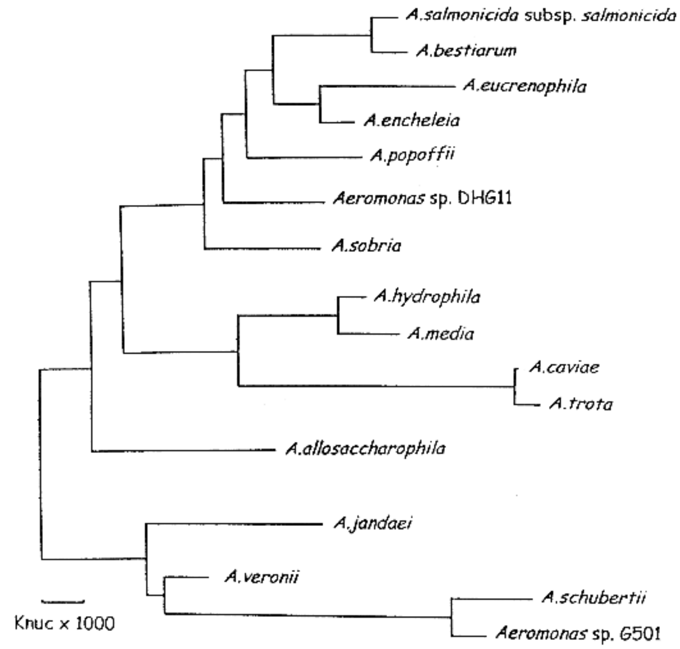

FIGURE BXII.γ.186. Phylogenetic relationships of described *Aeromonas* genomospecies as determined by a continuous 1502-nucleotide 16S rDNA sequence comparison using the neighbor-joining method (Saitou and Nei, 1987) and the MEGA Program version 1.01. Strain designations from different culture collections (in parentheses) and 16S rDNA sequence accession numbers [in brackets] are: *Aeromonas hydrophila* (HG 1) ATCC 7966^{T} [X60404]; *A. bestiarum* (HG 2) ATCC 51108^{T} (CIP 7430^{T}) [X60406]; *A. salmonicida* (HG 3) ATCC 33658^{T} (NCIMB 1102^{T}) [X60405]; *A. caviae* (HG 4) ATCC 15468^{T} (NCIMB 13016^{T}) [X60408]; *A. media* (HG 5) ATCC 33907^{T} [X60410]; *A. eucrenophila* (HG 6) NCIMB 74^{T} [X60411]; *A. sobria* (HG 7) CIP 7433^{T} (NCIMB 12065^{T}) [X60412]; *A. veronii* (HGs 8/10) ATCC 35624^{T} [X60414]; *A. jandaei* (HG 9) ATCC 49368^{T} [X60413]; *Aeromonas* sp. (HG 11) ATCC 35941 [X60417], *A. schubertii* (HG 12) ATCC 43700^{T} [X60416]; *Aeromonas* Group 501 (HG 13) ATCC 43946 (CECT 4254) [U88663]; *Aeromonas trota* (HG 14) ATCC 49657^{T} [X60415], *Aeromonas allosaccharophila* (HG 15) CECT 4199^{T} (S39232); *Aeromonas encheleia* (HG 16) CECT 4342^{T} [AJ224309]; and *Aeromonas popoffii* (HG 17) LMG 17541^{T} [AJ224308]. The sequences that start with the letter "X" are assigned with EMBL accession numbers and the other prefix letters, such as AJ, S, and U, can be found on the NCBI Website at http://www.ncbi.nlm.nih.gov (Reprinted with permission from A.J. Martinez-Murcia, International Journal of Systematic Bacteriology *49:* 1403–1408, 1999, ©International Union of Microbiological Societies.)

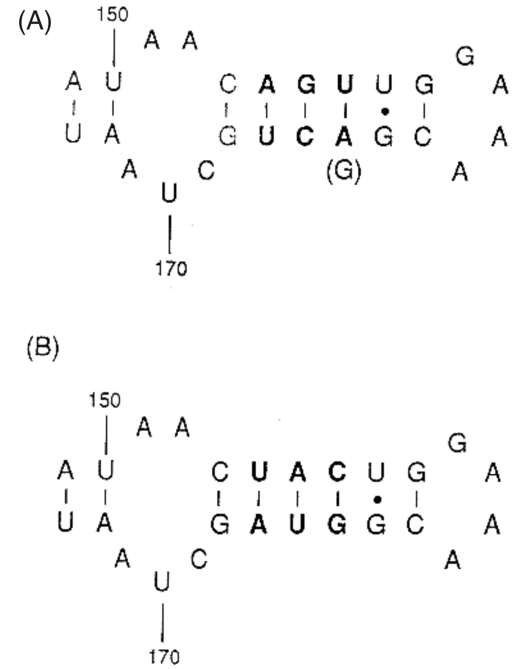

FIGURE BXII.γ.187. Primary structures of the diagnostic sequences at the V2 regions of the 16S rDNA (position ~160) which distinguish the *Aeromonas* "type" groups (*A*) from the "Schubertii" cluster (*B*). The nucleotide in parentheses occurs only in *Aeromonas eucrenophila.* (Reprinted with permission from A.J. Martinez-Murcia et al., International Journal of Systematic Bacteriology *42:* 412–421, 1992a, ©International Union of Microbiological Societies.)

and grayish-white to buff with a sometimes buttery consistency after 24–48 h of incubation at 35°C. Older colonies can develop a greenish hue, similar to that seen with certain *Vibrio* species, and a somewhat strong odor. There can be variation in colony size in some instances, either on original isolation or after subculture. *A. media* strains can produce a brown diffusible pigment on trypticase soy agar (TSA) (Allen et al., 1983). Colonies of the psychrophilic, nonmotile *A. salmonicida* subspecies are pinpoint in size after 18–24 h at 20–22°C, but after 4 d of incubation are circular, convex, entire, friable, and 1–2 mm in diameter (Griffin et al., 1953). Several of the *A. salmonicida* subspecies produce a brown, diffusible pigment after 5 d, especially on media containing tyrosine (Bernoth and Artzt, 1989). The presence of conspicuous encapsulation among several of the species results in the appearance of glistening to mucoid colonies.

There is variability in hemolysin production both within and between the species, as well as differences in the presence and/or type of hemolysis displayed depending on the type of red cells used. In one study, out of erythrocytes from nine animal species tested, the most sensitive blood agar medium contained mouse red cells, and sheep red cells were among the least sensitive for detection of β-hemolysis (Brenden and Janda, 1987). *A. hydrophila* and *A. veronii* are two of the more commonly isolated species that are strongly β-hemolytic on sheep blood agar, with less commonly isolated species often exhibiting β-hemolysis as well (Table BXII.γ.182). This β-hemolysis can be a broad zone, a double zone of partial hemolysis, or a narrow zone of β-hemolysis just under the colony edge. Many *A. caviae* isolates are partially hemolytic, displaying α-hemolysis, but can display narrow zones of β-hemolysis as well (Carnahan and Joseph, 1993).

On MacConkey agar, the majority of the mesophilic species grow as nonlactose fermenters, but a fair number of *A. caviae* isolates can ferment lactose. This can lead to confusion when testing water sources for coliforms, which are also lactose fermenters.

Nutrition and growth conditions The aeromonads grow over a wide temperature range (0–45°C), with the mesophilic strains growing between 10 and 42°C (Hänninen, 1994). The optimum temperature range is 22–37°C depending on the strain. While earlier studies have reported 28°C as the optimum temperature for motile aeromonads (Popoff, 1984a), at least one study on the effect of incubation temperature on growth and soluble protein profiles suggests that in some cases 37°C may be the optimum growth temperature (Statner et al., 1988). The psychrophilic

[a]Symbols: +, >90%; −, <10%; d, 11 89% positive with incubation at 35°C for 7 d except for *A. popoffii* and *A. sobria*, which were incubated at 25°C (data from Abbott et al., 2003); nd, not determined.

[b]The *A. salmonicida* results are for the motile, mesophilic strains residing in HG 3 that are a currently unnamed subspecies.

[c]For determination of gluconate oxidation, the culture was incubated for only 48 h.

[d]Hemolysis detected on TSA on 5% sheep blood agar.

[e]Ampicillin susceptibility performed with 10 μg/disk and the culture incubated for only 24 h.

[f]Cephalothin susceptibility performed with 30 μg/disk and the culture incubated for only 24 h.

[g]Pyrazinamidase activity slants were incubated for only 48 h.

[h]Utilization as a sole carbon source.

strains in the *A. salmonicida* subspecies grow at temperatures generally ranging from 2 to 30°C.

Clinical isolates are generally incubated at 37°C, and environmental isolates are quite often incubated at 22–30°C, so that interlaboratory comparisons of biochemical reactions are difficult to make. Some mesophilic strains appear to be biochemically more active at 22°C than at 37°C. There are even cases of some biochemical tests having quite different results at the two different temperatures for the same strain (Ali et al., 1996a). In brain heart infusion medium at 28°C, the growth range for *A. hydrophila* is between pH 4.5 and 9.0 and 0–4% NaCl (Palumbo et al., 1985b).

Metabolism Aeromonads are facultative anaerobes that ferment D-glucose to acid or acid with gas and are oxidase and catalase positive, reduce nitrates to nitrites, and are enzymatically very active. They have been reported to produce amylase, DNase, chitinase, elastase, esterases, peptidases, arylamidases, and other hydrolytic enzymes (Hsu et al., 1981; Waltman et al., 1982; Janda, 1985; Carnahan et al., 1988; Hänninen, 1994). Recently, an adenylyl cyclase 2 was isolated from *A. hydrophila* with thermophilic properties and sequence similarities to proteins from hyperthermophilic *Archaea* (Sismeiro et al., 1998). There is new evidence that *Aeromonas* may exhibit anaerobic respiration and dissimilatory metal reduction (Knight and Blakemore, 1998).

Numerous large-scale phenotypic biochemical studies on *Aeromonas* have been published (Eddy, 1960, 1962; Ewing and Johnson, 1960; Ewing et al., 1961; Eddy and Carpenter, 1964; Popoff, 1969; McCarthy, 1975; Popoff and Veron, 1976; Lee, 1987). Both motile and nonmotile aeromonads utilize a number of other carbohydrates in addition to glucose (Popoff, 1984a; Arduino et al., 1988; Renaud et al., 1988; Carnahan et al., 1989a; Kuijper et al., 1989a; Altwegg et al., 1990; Abbott et al., 1992; Kämpfer and Altwegg, 1992; Carnahan and Joseph, 1993; Hänninen and Siitonen, 1995; Noterdaeme et al., 1996; Oakey et al., 1996a). In two recent major biochemical studies examining representatives of all known hybridization groups, excluding *A. encheleia* (HG 16), *A. popoffii* (HG 17), and nonmotile psychrophilic *A. salmonicida* subspecies (HG 3), it was determined that members of HGs 1–15 (including motile, mesophilic HG 3 *A. hydrophila*-like strains) shared a number of common features other than the aforementioned production of acid from glucose, oxidase and catalase activity, and reduction of nitrate (Abbott et al., 1992, 2003). These included the production of acid from D-trehalose; failure to utilize malonate or mucate as the sole carbon source; inability to ferment adonitol, dulcitol, erythritol, inositol, and D-xylose; and growth in nutrient broth containing 0 and 3% NaCl. Test results for several other phenotypic properties were nearly always positive (98–99%) and included motility, β-galactosidase activity, and resistance to O/129; fewer than 2% of the strains tested hydrolyzed urea, degraded pectin, or produced acid from arabitol, D-raffinose, or D-amygdalin. Variable results were obtained for 36 tests which included production of acetyl methyl carbinol (Voges–Proskauer test), indole, phenylpyruvic acid, acetate, citrate, and ascorbate utilization; elaboration of elastase, hemolysin, stapholysin, deoxyribonuclease, and corn oil lipase; esculin and gelatin hydrolysis; growth in KCN (potassium cyanide) broth; ornithine and lysine decarboxylase, arginine dihydrolase, and pyrazinamidase activities; H_2S production in GCF (gelatin–cysteine–thiosulfate) medium, pigment production at 25°C, gluconate oxidation; susceptibility to cephalothin and ampicillin; and acid production from L-arabinose, cellobiose, glycerol, lactose, α-methylglucoside, maltose, D-mannitol, D-mannose, melibiose, L-rhamnose, salicin, and sorbitol fermentation (Abbott et al., 1992, 2003) (Table BXII.γ.182). Nine tests were determined by these authors as well as others to be discriminatory enough to use as an initial primary battery of tests to separate aeromonads from the more commonly isolated species in the clinical laboratory (Carnahan et al., 1991a; Abbott et al., 1992, 2003; Furuwatari et al., 1994). However, these test results may not be reliable for the identification of HG 3 nonmotile, psychrophilic *A. salmonicida* subspecies strains, since the most recent studies noted above were conducted at 35–37°C and generally evaluated only motile aeromonad isolates. Therefore, the HG 3 strains in the Abbott et al. (1992) study were members of the unnamed, motile subspecies within *A. salmonicida* (Hänninen, 1994), which are genetically identical with nonmotile, psychrophilic fish pathogens (HG 3), but phenotypically resemble HG 1 *A. hydrophila* strains (Table BXII.γ.183). It should be noted that rapid identification systems to date are not very accurate at identifying motile *Aeromonas* species other than *A. hydrophila*, *A. caviae*, and *A. veronii* biovar sobria (HG 8; formerly termed *A. sobria* HG 7) from clinical specimens. Often the rarer clinical species are misidentified by these systems (Hickman-Brenner et al., 1987; Carnahan et al., 1991a; Janda, 1991; Abbott et al., 1992, 1998; Janda and Abbott, 1998b; Altwegg, 1999).

Over the years, there have likewise been extensive biochemical studies of large numbers of nonmotile *A. salmonicida* strains (both typical and atypical) (Griffin et al., 1953; Smith, 1963; Schubert, 1974; Popoff, 1984a; Austin et al., 1989a, 1998a; Dalsgaard et al., 1994, 1998; Hänninen et al., 1995, 1997). A recent review and examination of the results from these studies revealed several discrepancies for key reactions previously published as useful for separating the various subspecies (Millership, 1996). This is most likely due to a combination of reasons, namely that only a limited number of strains were available in older studies, and that test methods and reagents varied, particularly incubation temperature and length of incubation. Recent extensive biochemical studies of the *A. salmonicida* subspecies, including the increasing numbers of "atypical" strains, are those by Hänninen et al. (1995) and Hänninen and Hirvelä-Koski (1997), who studied Scandinavian fish isolates (Table BXII.γ.183); Austin et al. (1998a); and a review article by Wiklund and Dalsgaard (1998). There is an urgent need for standardization of methods both within and between laboratories (Dalsgaard et al., 1998) (*vide infra* Taxonomic Issues).

Genetic classification of aeromonads has been accomplished by mol% G + C composition (Popoff, 1984a), DNA–DNA relatedness studies (Popoff et al., 1981; Fanning et al., 1985; Farmer et al., 1986), 16S rDNA sequence analysis (Martinez-Murcia et al., 1992a; Martinez-Murcia, 1999), and multilocus sequence typing (MLST) analysis (Carnahan, 2001). Popoff et al. (1981) originally designated eight DNA–DNA hybridization groups using the DNA S1 nuclease method. The number of HGs was expanded to 12 (Fanning et al., 1985; Farmer et al., 1986) using the hydroxyapatite method and the recommended specified values of >70% relatedness at the optimum temperature of 60°C, >55% relatedness at the stringent temperature of 75°C, and divergence of 5% or less.

A variety of other molecular methods has been employed for both taxonomic purposes and/or epidemiological typing of aeromonads. An excellent review of these can be found in the articles by Carnahan and Altwegg (1996) and Altwegg (1996), and include plasmid analysis, restriction enzyme analysis (REA), ribo-

[a]Data from Hirvelä-Koski et al. (1994) (deals with both typical *A. salmonicida* subsp. *salmonicida* strains (n 47), as well as atypical strains (n = 34), Hänninen and Hirvelä-Koski (1997) (atypical strains).

[b]β-Hemolysis detected on ox blood agar.

[c]Oxidase-negative strains have been isolated from turbots.

[d]Pigment production for all strains in this table were evaluated using the medium containing tyrosine (Bernoth and Artzt, 1989) (see text for medium formulation).

[e]Tested with API 50 CH.

typing, restriction fragment length polymorphism (RFLP), and amplified fragment length polymorphism (AFLP). In addition, the use of pulsed-field gel electrophoresis (PFGE) (Hänninen and Hirvelä-Koski, 1997), species-specific probes, polymerase chain reaction (PCR) tests, and RFLP-PCR of 16S rDNA has been proposed (Husslein et al., 1992; Ash et al., 1993a, 1993b; Dorsch et al., 1994; Cascon et al., 1996; Oakey et al., 1996b, 1998; Borrell et al., 1997; Hoie et al., 1997; Khan and Cerniglia, 1997; Graf, 1999a; Figueras et al., 2000). These findings reaffirm the opinion of some investigators that the separation of species and accurate identification requires a polyphasic approach (Altwegg, 1993; Carnahan and Joseph, 1993).

In addition, a variety of phenotypic methods outside of conventional or rapid identification kits have been used for subtyping of *Aeromonas* isolates. These include phage typing (DeMarta and Peduzzi, 1984); resistotyping (determining antimicrobial susceptibility patterns) (Motyl et al., 1985; Overman and Janda, 1999); protein analysis using SDS-PAGE protein profiles (Stephenson et al., 1987); SDS-PAGE of outer membrane proteins (OMPs) (Kuijper et al., 1989b); immunoblots of SDS-PAGE gels (Mulla and Millership, 1993); analysis of quinone, polyamine, and fatty acid patterns (Kämpfer et al., 1994); FAME (gas liquid chromatographic analysis of cellular fatty acid methyl esters) (Hansen et al., 1991; Huys et al., 1994, 1995); and enzyme analyses (Altwegg, 1996). Methods to detect the presence or absence of a particular enzyme using chromogenic substrates have already been discussed, but a second method of enzyme analysis involves the analysis of electrophoretic mobilities of enzymes using non-denaturing gel electrophoresis followed by staining for particular enzyme activities. Electrophoretic typing of esterases in an *Aeromonas* hospital outbreak (Picard and Goullet, 1985) was followed by the development of multilocus enzyme electrophoresis (MEE) based on the relative frequencies of four alleles at only four loci to separate HGs 1–12 (Altwegg et al., 1991).

Antigenic structure There are several serotyping schema for aeromonads that are based on the presence of unique heat-stable somatic (O) determinants (Sakazaki and Shimada, 1984; Fricker, 1987; Guinee and Jansen, 1987; Cheasty et al., 1989; Thomas et al., 1990). Only one comparison study of two of these schema has been published (Shimada and Kosako, 1991). The original Sakazaki and Shimada scheme recognizes 44 serogroups with an additional 52 provisional serogroups (Albert et al., 1995b). Using the Sakazaki and Shimada scheme on 268 strains, *Aeromonas* species were found to be serologically heterogeneous, with individual serogroups present in more than one species (Janda et al., 1996a). Most type and reference strains were not serologically representative of the genomospecies at large. Further, three particular serogroups—O:11 (24%), O:16 (14%), and O:34 (10%)—were predominant. They were not necessarily associated with any particular genomospecies, but did appear to be associated with clinical infections (48%). Following the report of Albert et al. (1995b) that some strains of *Aeromonas trota* cross-reacted with *Vibrio cholerae* O:139 antisera, it was determined that most of the *A. trota* strains examined by another investigator did not express the O139 antigen of *Vibrio cholerae* (Janda et al., 1996a).

Antimicrobial susceptibility Most motile *Aeromonas* species are generally resistant to penicillin, ampicillin, carbenicillin, and ticarcillin, but continue to be susceptible to second- and third-generation cephalosporins, aminoglycosides, carbapenems, chloramphenicol, tetracyclines, trimethoprim-sulfamethoxazole, and the quinolones (Koehler and Ashdown, 1993; Janda and Abbott, 1998b; Altwegg, 1999). In the three earliest studies on antimicrobial susceptibility, all clinical isolates were considered

to be *A. hydrophila*, so that species-related differences in susceptibility could not be inferred (Overman, 1980; Fass and Barnishan, 1981; Fainstein et al., 1982b). A study comparing the "*in vitro*" susceptibilities among *A. hydrophila*, *A. veronii*s biovar sobria (formerly considered to be *A. sobria*), and *A. caviae* found *A. hydrophila* generally more resistant than the other species (Motyl et al., 1985). Most aeromonad species produce "inducible" chromosomal β-lactamases, and at least three distinct types have been noted (Bakken et al., 1988; Iaconis and Sanders, 1990; Morita et al., 1994; Walsh et al., 1997b). There have been reports of rapid commercial susceptibility systems that were unable to accurately detect this inducible resistance factor (Schadow et al., 1993). It appears that cephalothin can be a potential marker for clinical strains of *A. veronii* biovar sobria from clinical sources (Janda and Motyl, 1985) and that a certain minimum inhibitory concentration (MIC) of colistin (4 μg/ml) could be a marker for *A. jandaei* (Carnahan et al., 1991c). *Aeromonas trota* has a unique susceptibility to ampicillin, with up to 30% of some *A. caviae* isolates being susceptible as well (Kilpatrick et al., 1987; Carnahan et al., 1991b). Therefore, the use of ampicillin in selective media may lead to underestimation of these species. Examination of the more rarely isolated clinical species for antimicrobial resistance patterns included 17 *A. jandaei*, 12 *A. schubertii*, 15 *A. trota*, and 12 *A. veronii* biovar veronii strains (Overman and Janda, 1999). All of the *A. trota* isolates were susceptible to all of the agents tested except for 20% resistance to cefazolin and 13% to cefoxitin. All of the *A. schubertii*, *A. veronii* biovar veronii, and 88% of the *A. jandaei* isolates were resistant to ampicillin. Overall, *A. veronii* biovar veronii and *A. schubertii* had markedly increased resistance to tobramycin; *A. veronii* biovar veronii and *A. jandaei* were generally resistant to imipenem; and *A. schubertii* and *A. trota* were less susceptible to cefoxitin, an expanded-spectrum cephalosporin, than to broad-spectrum cephalosporins. These species-related antibiograms may be useful adjuncts to species identification of clinical isolates.

Antimicrobial resistance to tetracycline, trimethoprim-sulfamethoxazole, some extended-spectrum cephalosporins, and aminoglycosides seems to be increasing among clinical aeromonad isolates in Taiwan, as compared to isolates from Australia and the United States (Ko et al., 1996). A study of the spectrum of extraintestinal disease due to *Aeromonas* species in Queensland, Australia found that in nine cases, the empirical antibiotic regimen prescribed did not adequately cover infection due to *Aeromonas* (Kelly et al., 1993). This suggests that identification to the species level may play a role in the selection of appropriate antimicrobial therapy for infection with motile *Aeromonas* species.

Reports from several countries indicate increasing resistance of *A. salmonicida* isolates from fish. As with the motile species, there is a report of at least three β-lactamases among isolates of *A. salmonicida* (Hayes et al., 1994). Farmed Atlantic salmon in Scotland were assessed for antimicrobial disk diffusion values and compared with MIC results for amoxycillin, oxolinic acid, oxytetracycline, and potentiated sulfonamide (Grant and Laidler, 1993). Of the 65 isolates tested, 23 were susceptible to all four antimicrobials, and 12, 13, and 16 isolates showed resistance to 1, 2, or 3 antimicrobials, respectively. Among 35 Finnish isolates, resistance was found only to oxytetracycline in strains from 9 of the 35 farms (Hirvelä-Koski et al., 1994). A total of 130 strains originating from farmed salmonid fish isolated in Denmark, Norway, Scotland, Canada, and the United States were tested for susceptibility to 22 antimicrobial agents (Dalsgaard et al., 1994). Antibiograms revealed increasing resistance to oxytetracycline and the quinolones, with multiresistant strains found in several countries.

Plasmids carrying resistance to streptomycin, chloramphenicol, tetracycline, and sulfathiazole as R factors have been isolated from *A. salmonicida* (Aoki et al., 1971; Toranzo et al., 1983). They have likewise been detected in motile aeromonads (Chang and Bolton, 1987). There is widespread plasmid-mediated resistance by means of 20–30 MDa plasmids in fish farms and eel ponds, and this most likely affects the potential benefit of antimicrobial compounds (Toranzo et al., 1983; Aoki, 1988). Broth conjugation experiments showed the transfer of the oxytetracycline (OT)-resistant phenotype from *A. salmonicida* to *Escherichia coli* and found this resistant phenotype to be encoded by high-molecular-weight R-plasmids that could be characterized by restriction digest profiles (Adams et al., 1998). One study of *Aeromonas* from clinical and environmental sources, representing seven species, found single or multiple resistance in 107/108 strains examined, with the highest incidence shown for β-lactam antibiotics other than cefotaxime. Thirty-five strains were found to contain transferable resistance plasmids, encoding resistance to ampicillin, cephalexin, cefoxitin, erythromycin, and furazolidone, either alone or in combination (Chaudhury et al., 1996).

Pathogenicity The early interest of von Graevenitz in *Aeromonas* stimulated others to begin to study this aquatic-borne organism, which seemed to be more common in clinical samples than previously realized (von Graevenitz and Mensch, 1968). While initially believed to be an opportunistic organism capable of infecting only immunocompromised individuals, a body of evidence now indicates that *Aeromonas* is a primary cause of extraintestinal illness and is strongly associated with gastrointestinal disease (Kelly et al., 1993; Janda and Abbott, 1996, 1998b; Joseph, 1996). Isolation rates have ranged from <1% to more than 60% in diarrheic populations in various geographic locations. The first well-documented extraintestinal infection was a case of septicemia in a menstruating woman who had been swimming in Jamaican waters. The organism was identified as *"Vibrio jamaicensis"* at the time but was later shown to be an *Aeromonas* sp. (Hill et al., 1954; Caselitz, 1955). The lack of final proof that *Aeromonas* is an etiologic agent of gastrointestinal disease lies in the absence of significantly large outbreaks and in one unsuccessful human volunteer study (Morgan et al., 1985). However, there is significant circumstantial evidence in the literature of sporadic cases and small outbreaks (Joseph, 1996; Janda and Abbott, 1998b).

Before the aeromonads were recognized as human pathogens, they were commonly isolated from poikilothermic animals, particularly amphibians, reptiles, and fish (Marcus, 1971, 1981; Shotts et al., 1972; Brackee et al., 1992; Burns et al., 1996; Gosling, 1996a; Schillinger, 1997). One of the first diseases attributed to *Aeromonas* was "red-leg" disease in frogs (Sanarelli, 1891). Aeromonads are also found with some frequency to cause various types of diseases in birds and domestic animals including pneumonia, peritonitis, and various localized infections (Gray, 1984; Shane et al., 1984; Shane and Gifford, 1985; Gosling, 1996a). Various species of fish develop hemorrhagic disease, ulcerative disease, furunculosis, red sore disease, and septicemia, resulting from infections with both motile and nonmotile *Aeromonas* species (Joseph and Carnahan, 1994; Austin and Adams, 1996). Humans can suffer from a variety of extraintestinal infections including wound infections, septicemia, meningitis, ophthalmitis, and infections associated with leech therapy, as well as gastroenteritis, especially in children <5 years (Altwegg, 1985; Janda

and Duffey, 1988; Altwegg and Geiss, 1989; Janda, 1991; Fedorko, 1993; Janda and Abbott, 1996, 1998b; Graf, 1999b). The species most frequently isolated from clinical specimens are *A. hydrophila* (HG 1), *A. veronii* biovar sobria (HG 8), *A. caviae* (HG 4), *A. jandaei* (HG 9), *A. schubertii* (HG 12), and *A. trota* (HG 14) (Altwegg, 1990; Altwegg et al., 1990; Carnahan et al., 1991a; Janda, 1991; Carnahan and Joseph, 1993; Janda and Abbott, 1998b). There is some indication from experimental mouse lethality studies that some species are more virulent than others (Janda and Kokka, 1991).

Current theory suggests that the virulence of *Aeromonas* species may be multifactorial. Possible virulence-associated substances and components described for *Aeromonas* spp. include toxins (cytotoxic and cytotonic), proteases, hemolysins, lipases, adhesins, agglutinins, pili, enterotoxins, various enzymes, and outer membrane arrays (Cahill, 1990; Janda and Abbott, 1996; Gosling, 1996a, b; Howard et al., 1996). Unfortunately, with some of the early work, the species identification of the organisms was not consistent with present day criteria, so it is difficult to determine to which and to how many aeromonads these results apply.

Filamentous structures on aeromonads are diverse. There are two broad morphological types of pili (short, rigid and long, wavy), as well as polar and lateral flagella. Short, rigid pili are the main pilus type expressed on heavily piliated aeromonads. Amino acid sequencing of their pilin showed they are homologous to *E. coli* type 1 and Pap pili (Ho et al., 1992). Long, wavy pili on fecal isolates belong predominantly to a family of a type IV pili which has been designated Bfp for "bundle-forming pilus" (Kirov and Sanderson, 1996). Their pilins have a molecular mass of 19–23 kDa. Despite the tendency to form bundles, the pilins of Bfp pili have closer N-terminal homology to the type IVA pilins, such as MSHA of *Vibrio cholerae*, than they do to the type IVB pilins of enteropathogenic *E. coli* and *V. cholerae*. There is compelling evidence that this pilus type mediates adherence to enterocytes as revealed by observations made with EM and immunoelectron microscopy, reduction of adhesion when pili are removed from the organism, adhesions to Henle 407 cells, and blocking experiments with purified pili or antibody to Bfp (Honma and Nakasone, 1990; Iwanaga and Hokama, 1992; Kirov et al., 1999). Bfp pili have not yet been genetically characterized. However, a type IV pilus gene cluster (*tapABCD*) has been identified in *Aeromonas* spp. It was originally cloned from a strain of *A. bestiarum* AH65 (previously published as *A. hydrophila*), and the product was designated Tap for type IV *Aeromonas* pilus (Pepe et al., 1996). *TapD* encodes a type IV leader peptidase/methyltransferase, which in addition to processing Tap pilin, is responsible for the extracellular secretion of aerolysin and other enzymes via the type II secretion pathway (Strom and Lory, 1993; Strom and Pepe, 1999). The *tap* cluster was subsequently cloned from a strain of *A. veronii* biovar sobria from which Bfp had been purified and it was clearly established that Tap pili was a second and distinct family of pili from the Bfp family (Barnett et al., 1997). Tap pili have a predicted molecular mass of approximately 17 kDa.

To date, there is little known regarding the function(s) of Tap pili. If assembled on the cell surface, they represent a minor pilus species on fecal isolates grown under standard laboratory conditions. Studies with Tap pilin mutants in *in vitro* adhesion assays and in animal models have found no evidence that Tap pili are important enterocyte adhesins or colonization factors. The widespread conservation of the *tap* gene cluster among all *Aeromonas* spp., however, suggests that the cluster does play an important function (Barnett and Kirov, 1999a, b).

Genetic characterization of the polar (Pof) and lateral (Laf) flagella of *Aeromonas* spp. has been described very recently (Shaw and Kirov, 1999). Evidence was presented that Pof are adhesins for *Aeromonas* spp. The Laf, when purified from a strain of *A. caviae*, showed considerable homology to the Laf of *Vibrio parahaemolyticus*. Laf genes are present in approximately 50% of *Aeromonas* isolates and lateral flagella are optimally expressed when bacteria are grown on solid media for <8 h at 37°C or 22°C. Preliminary evidence suggests that Laf serve as accessory colonization factors at the cell surface (Shaw and Kirov, 1999).

Enterotoxic (aerolysin), cytotoxic (Act), and two cytotonic toxins (Alt and Ast) have been detected in *A. hydrophila* (Chopra et al., 1996; Xu et al., 1998; Chopra and Houston, 1999). It appears that there may be a family of related hemolytic, cytotoxic enterotoxins. Because presumed "aerolysin" has been described in different species and/or strains, it is difficult to determine if these are all the same protein owing to some variance in the description of this toxin. Comparisons of Act of *A. hydrophila* SSU with the aerolysin of *A. trota* AH-2 (Chakraborty et al., 1987) and that of *A. bestiarum* (formerly *A. hydrophila*) AH-65 (Buckley et al., 1981) show differences in restriction maps, divergent flanking sequences, possibly different host cell receptors, and variability in the role of selected amino acid residues in biological function, e.g., in post-cleavage activity of the pro-toxin and eventual folding. Act appears to increase levels of tumor necrosis factor α (TNF-α) and interleukin (IL)-1 β in macrophage cell line RAW 264.7, as well as other pro-inflammatory cytokines, which could mediate inflammation and tissue damage during *Aeromonas* infections. There was also an increase in prostaglandin activity (PG_1 or PG_2). Use of PG inhibitors such as NS 398 and Celebrex eliminated activity or reduced the time of production of PG including INOS and $SsPLA_2$ (GrpV) levels in Chinese hamster ovary cells (Chopra and Houston, 1999).

Aerolysin from *A. trota* AH2 (formerly *A. hydrophila/A. sobria*) was first shown to be an important virulence feature by marker exchange mutagenesis, where the mutants were found to be much less toxic to mice (Chakraborty et al., 1987). It is first released as a proaerolysin, which is inactive until it is cleaved proteolytically and a C-terminal fragment of approximately 40 amino acids is removed.

A type II secretion pathway was described for a different "aerolysin" from *A. bestiarum* AH 65 that contained two operons, *exeAB* and *exeC–N*, forming the central components of this pathway in *Aeromonas*. The products of these genes form an apparatus that appears to culminate in an outer membrane secretion port. Phosphate bond hydrolysis and proton motive force are required for secretion through this port. The two operons appear to form an inner membrane complex, and *in vitro* mutagenesis of *exeA* suggests that this complex functions in the energy-dependent gating of the port (Howard et al., 1993, 1996; Howard, 1999). Their proaerolysin is a dimer in crystalline form and in solution (van der Goot et al., 1993). Murine erythrocytes, which have a glycoprotein receptor, are particularly susceptible to aerolysin activity and are easily lysed. The mode of action of this "aerolysin" involves channel formation in the target cell, and it functions in similar fashion to the action of membrane porins. The heptameric toxin inserts into the membrane of the cell and forms a 1–2 nm channel, causing the cell to lose its stability because of increased permeability and it is eventually destroyed (Howard, 1999).

Aeromonas also produces a lipase, named glycerophospholipid:cholesterol acyltransferase (GCAT), which can produce cholesteryl esters and can act as a phospholipase by digesting plasma membranes (Buckley, 1983). Two distinct types of proteases have been isolated from aeromonads including metallo- and serine proteases (Rodriguez et al., 1992). While considered accessory toxins in most instances, some studies with *A. salmonicida* suggest that they are primary virulence features. These enzymes probably function to protect the organism in its various environments, including humans, by inducing tissue destruction and assisting in the degradation of substrates for catabolic metabolism. Other miscellaneous toxins include amylase, chitinase, elastase, lecithinase, and nucleases (Gosling, 1996a).

The presence of a polysaccharide capsule has been reported for *A. salmonicida* and *A. hydrophila* serogroups O:11 and O:34 (Garrote et al., 1992; Martinez et al., 1995). Functionally, it is presumed that the capsule is a virulence factor that aids in complement resistance and/or in adherence to and invasion of fish cell lines (Merino et al., 1996, 1997).

S-layers of *Aeromonas* spp. are paracrystalline structures composed of identical protein subunits that are translocated across the cytoplasmic membrane, periplasm, and outer membrane to the cell surface, where they are assembled and tethered to the cell via an interaction with the O-polysaccharide side chains of the lipopolysaccharide. The S-Layer was originally referred to as an "A-Layer" first described in *A. salmonicida* (Udey and Fryer, 1978). It was considered a virulence feature because strains with this feature were more virulent than those without it. Specifically, strains with the S-layer could cause furunculosis in fish, while those without S-layers were avirulent. S-layer mutants have an altered ability to produce disease (Noonan and Trust, 1997). The significance of the S-layer in mesophilic aeromonads such as *A. hydrophila* and *A. veronii* biovar sobria appears to be less significant. Studies to correlate the presence of an S-layer on human isolates of *Aeromonas* through an autoagglutination phenomenon yielded inconclusive evidence for a direct involvement in mouse pathogenicity (Janda et al., 1987; Paula et al., 1988; Kokka et al., 1990, 1991a, b).

Aeromonads also possess more than one type of siderophore. In *A. salmonicida* there are at least two different mechanisms for iron acquisition (Chart and Trust, 1983). Mesophilic aeromonads usually produce either a unique siderophore, amonabactin (a four-peptide-based *bis*-catecholate siderophore), or an enterobactin-like siderophore (Telford and Raymond, 1997). Interestingly, *A. sobria* (HG 7), a species not isolated from humans thus far, does not produce siderophores (Zywno et al., 1992). *Aeromonas* spp. display significantly increased siderophore production under iron limiting conditions, and clinical strains are generally more productive than environmental strains (Naidu and Yadav, 1997).

Ecology Mesophilic aeromonads are indigenous to and have been isolated from various aquatic environments worldwide including fresh, estuarine (brackish), surface water (especially recreational), drinking water (including treated, well water, and bottled water), and polluted waters (Zimmermann, 1890; Hazen et al., 1978; Rippey and Cabelli, 1980, 1985; Seidler et al., 1980; Kaper et al., 1981; LeChevallier et al., 1982; Van der Kooj, 1988; Araujo et al., 1989; Alonso et al., 1994; Holmes and Nicolls, 1995; Holmes et al., 1996), as well as waste water effluent sludge (Schubert, 1975; Montfort and Baleux, 1991). They are not generally considered marine organisms, but can be found naturally in marine systems that interface with fresh waters, and found at all salinities, except the most extreme (Hazen et al., 1978). However, they are usually not a part of the autochthonous bacterial population of groundwater, which is normally poor in nutrients (Havelaar et al., 1990). However, in nutrient-rich waters, *Aeromonas* species can grow to large numbers, generally reaching a peak in the warmer temperatures of the summer months in both temperate freshwater lakes and chlorinated drinking water, showing a seasonal distribution (Burke et al., 1984a, b). While not considered to be of fecal origin, they seem to have a capacity to tolerate polluted environments including those of chemical origin (Seidler et al., 1980).

There is increasing interest in the incidence of *Aeromonas*, both during water treatment and distribution, particularly with regard to public health interest and to their role as indicators of chlorine resistance, disinfection efficacy, regrowth potential and biofilm development, even at 4°C (Holmes et al., 1996; Kuhn et al., 1997a, b; Sisti et al., 1998; Chamorey et al., 1999; Massa et al., 1999). Following the detection of increased numbers of aeromonads in the Netherlands in 1985, the public health authorities defined "maximum values" for *Aeromonas* densities in drinking water. These values are currently 20 CFU/100 ml of water for water leaving the production plant and 200 CFU/100 ml for drinking water in distribution (Van der Kooj, 1988). Examination of biofilms from exhumed pipe lengths revealed that 30% of the pipes examined contained an average population of aeromonads of 118 CFU/g dry weight (LeChevallier et al., 1987). After disinfection with 1 mg/l of chlorine, they could still isolate *Aeromonas* from 10% of the pipe lengths, with an average population of 51 CFU/g wet weight, suggesting that even though free cells of *Aeromonas* may be relatively susceptible to disinfection, populations may survive high chlorine dosing when associated with biofilms (LeChevallier et al., 1987; Holmes and Nicolls, 1995). Recent research revealed the apparent role of "quorum sensing" in biofilm formation on stainless steel by *A. hydrophila* (Lynch et al., 1999).

Aeromonas spp. have a capacity to infect fishes, reptiles, amphibians, humans, and other animals after exposure to such aquatic environments (Austin and Adams, 1996; Gosling, 1996a; Janda and Abbott, 1996, 1998b). There is good evidence that the species associated with clinical infections in humans are different hybridization groups than those isolated from drinking water and environmental sources, although putative virulence factors can be found in both categories (Holmberg et al., 1986a; Millership et al., 1986; Cahill, 1990; Havelaar et al., 1992; Hänninen, 1994; Kirov et al., 1994; Hänninen and Siitonen, 1995; Holmes and Nicolls, 1995; Kuhn et al., 1997a, b). Given the fact that the presence of aeromonads in water supplies may be connected with the increased incidence of *Aeromonas*-related gastroenteritis, the significance of which HGs are isolated from water as opposed to clinical isolates needs to be studied in greater detail (Holmes et al., 1996; Joseph, 1996).

Aeromonas species have been isolated from various food sources, including raw meats and fresh grocery produce, thereby establishing a possible source for *Aeromonas* human consumption (Kirov, 1993; Palumbo, 1996). These include raw chicken (Kirov et al., 1990; Akan et al., 1998); milk (Santos et al., 1994, 1996; Eneroth et al., 1998); cheese (Santos et al., 1994, 1996); ground meats (Okrend et al., 1987; Singh, 1997); seafood (Tsai and Chen, 1996; Lipp and Rose, 1997; Pianetti et al., 1997); poultry eggs (Yadav and Verma, 1998); fish, fish eggs, and shrimp (Hänninen et al., 1997); and a swine slaughter plant (Palumbo et al.,

1999). Produce sources include vegetables (Callister and Agger, 1987; Pedroso et al., 1997).

The presence of *Aeromonas* species in foods most likely reflects contact of these foods with water, as reflected in the name of the type species, *A. hydrophila*, which means "water-loving". The factors controlling the numbers of these organisms in these products include temperature, the trophic state of water, pH, NaCl, nitrite, atmosphere, and miscellaneous inhibitors such as essential oils of clove, coriander, nutmeg, and pepper (Palumbo et al., 1985b; Stecchini et al., 1993; Palumbo, 1996). However, a conclusive link between the consumption of *Aeromonas*-containing food and diarrheal disease has not yet been identified. As with the water isolates discussed above, putative virulence factors are found in both clinical and food isolates (Palumbo, 1996; Pedroso et al., 1997; Pin et al., 1997). It may be that temperature-related expression of virulence features, as yet undiscovered virulence features, and/or the existence of unique virulence "subsets" within several *Aeromonas* species can help to explain the absence of disease when *Aeromonas* is so ubiquitous (Daily et al., 1981; Palumbo, 1993; Joseph, 1996).

A. salmonicida is an inhabitant of natural waters and especially aquaculture ponds. It has been long considered a chief cause of furunculosis in various species of fishes (Shotts et al., 1972; Austin and Adams, 1996; Wiklund and Dalsgaard, 1998). Surprisingly, the organism has been difficult to isolate from the environment but is isolated from infected fish, particularly in the kidney. However, this organism was recently isolated in association with purple-pigmented bacteria in sediment from a Scottish loch (Austin et al., 1998b). Another possible reason for its cryptic character may be found in the recovery of cell wall deficient forms or L forms (McIntosh and Austin, 1990).

Enrichment and Isolation Procedures

The use of enrichments for the increased recovery of *Aeromonas* isolates from specimens is somewhat controversial. Ecological studies attempting to collect environmental samples should not use enrichments since the predominant strain(s) will quickly overgrow other strains that may be present. Enrichment broth can be useful as a presence–absence test for aeromonads in drinking water and food, or for monitoring marine populations in shellfish harvesting areas (Moyer, 1996). Among fish samples, both typical and atypical *A. salmonicida* have been recovered using an enrichment procedure with tryptone soy broth (TSB) (Austin and Adams, 1996). Food samples may be placed in enrichment broths when small numbers of aeromonads are expected and if there is the probability of cell injury from environmental pressures. The most frequently used broths are tryptic soy ampicillin (30 mg/l) broth (TSAB) and alkaline peptone water (APW). There are various formulations for these broths, as APW has been used with or without ampicillin for enrichment and enumeration of aeromonads from foods by the most probable number (MPN) technique.

The use of enrichment broths in clinical laboratories for the detection of low numbers of *Aeromonas* spp. has been exclusively used for the recovery from stool (fecal) samples. Early comparative studies found that nutrient broth gave the best recovery; but the authors contended that enrichment led to isolation of aeromonads in low concentrations that might be expected in convalescent patients, carriers, and those with subclinical infections. They further suggested that enrichment not be routinely used since it would interfere with interpretation of epidemiological studies trying to interpret the relationship between *Aeromonas* spp. and acute diarrhea (Robinson et al., 1984, 1986). The currently recommended broth for enrichment from fecal samples is APW adjusted to pH 8.6–9.8 (Shread et al., 1981; Millership et al., 1983; Moulsdale, 1983; von Graevenitz and Bucher, 1983; Moyer et al., 1991). The basic formulation contains 1% peptone in water at pH 8.6, but some investigators have increased the pH to 9.8 and added ampicillin (10–40 mg/l) and/or 0.5% desoxycholate to increase the selectivity of the medium (Khardori and Fainstein, 1988). The matter of the proper incubation temperature for APW enrichments is controversial as well, with some researchers finding better growth at 25°C than at 37°C (Millership and Chattopadhyay, 1984), but others finding no difference at all between these two temperatures (Price and Hunt, 1986). The use of GN (Gram-negative) broth for enrichment of aeromonads is only half as efficient as using APW (Millership et al., 1983), and Moyer et al. (1991) found that enrichment with APW increased the number of *A. caviae* isolates, suggesting that APW may be detecting not bona fide pathogens, but merely transient colonizers. The question of clinical relevance of aeromonads detected from enrichment broths only is clearly open to interpretation at this date and enrichment broths are generally not recommended for routine cultures.

Several studies have been conducted on the use of Cary–Blair transport medium for the transport of *Aeromonas* isolates from a variety of simulated clinical specimens (Siitonen and Mattila, 1990; Altwegg and Lüthy-Hottenstein, 1992; Koehler and Ashdown, 1993). Comparisons were made with other transport media, such as Amies medium, modified Stuart's medium, and glycerol-buffered saline. The consensus was that Cary–Blair transport medium was the best overall choice for transport of viable *Aeromonas*. Altwegg and Lüthy-Hottenstein (1992) also compared the behavior of *Aeromonas* species in Cary–Blair transport medium tubes incubated at 4°C, 25°C, and 37°C and found that the strains behaved similarly at both 25°C and 37°C, but very differently at 4°C with an initial drop in the colony count of all six strains examined during the first 24 h followed by a rapid increase for only the two *A. hydrophila* strains. The colony count of both *A. caviae* strains steadily dropped over the next few weeks, producing results consistent with those reported by Siitonen and Mattila (1990) in that storage at 4°C resulted in higher numbers of organisms only after several days.

Aeromonas species can be isolated from fish, food, water, and clinical specimens (most notably fecal) on a variety of primary plating media. They grow routinely on eugonic media such as blood and chocolate as well as on most enteric differential agar, although somewhat inhibited (Desmond and Janda, 1986). The following references include tables listing differential and selective media, their abbreviations, the application for which they are used, and the literature citation containing their formulation (von Graevenitz and Bucher, 1983; Joseph et al., 1988; Farmer et al., 1992; Moyer, 1996).

Aside from the enrichment above for *A. salmonicida* from fish, nearly all *A. salmonicida* strains can be isolated on trypticase soy agar (TSA). They require incubation at 22–25°C for 48 h and one should try to detect the presence of brown pigmentation, although furunculosis agar (recipe given below) seems superior (Bernoth and Artzt, 1989). There is only sparse growth of *A. salmonicida* on enteric agars and thiosulfate citrate bile salts sucrose (TCBS) medium, which is generally used for the isolation of *Vibrio* species. Rimler–Schotts (RM) medium (Shotts and Rimler, 1973) and a starch–glutamate–ampicillin–penicillin-based medium (SGAP-10C) (Jenkins and Taylor, 1995), both solid me-

dia, have been recommended for isolating *Aeromonas* species in general from piscine sources.

Methods for isolation of aeromonads from foods have been somewhat standardized (Palumbo et al., 1992). Some of the current recommended media used for the detection of motile aeromonads from food are starch–ampicillin agar (SA), blood ampicillin agar (BA, 30 mg/l), bile salts irgasan brilliant green agar (BIBG), Ryan Aeromonas agar (Oxoid, Basingstoke, England), and APW (Palumbo et al., 1985a; Moyer, 1996). Several comparison studies of media for food isolation resulted in slightly different recommendations for the preferred medium (Fricker and Tompsett, 1989; Ciufecu et al., 1990; Gobat and Jemmi, 1995). Trypticase soy ampicillin broth (TSBA, 30 mg/l) and MacConkey agar are currently considered the best combination for the isolation of *Aeromonas* from oysters (Abeyta et al., 1986).

An early recommendation for the detection of aeromonads from environmental samples was the use of dextrin fuchsin sulfite (DFS) in conjunction with membrane filtration for enumeration of aeromonads from clear waters (Schubert 1967a, 1987). This was followed by a selective and differential Rimler Shotts (RS) agar, which was subsequently modified into MRSM (Shotts and Rimler, 1973; Seidler et al., 1980). Rippey and Cabelli (1979) formulated mAeromonas medium or mA (a medium with trehalose, ampicillin, and ethanol) for use with a membrane filter. A comparison study of 11 media for recovery of aeromonads from polluted waters found mA to be the preferred medium followed by DNase–toluidine blue–ampicillin agar (DNTA), MacConkey Tween-80 (MACT), and starch bile (SB) agar (Arcos et al., 1988). A later study also found mA agar to be useful (Poffe and Op de Beeck, 1991). Analysis of surface waters using three media (mA, RS, and Ryan Aeromonas agar) found mA to be the most suitable (Bernagozzi et al., 1994). Ampicillin dextrin agar (ADA), mA, starch ampicillin (SA), Pril xylose ampicillin agar (PXA), and SGAP-10 appear to be the most widely used plating media (Moyer, 1996). However, there is no published comparison of these media nor does there appear to be a single optimal recovery medium.

Isolation of aeromonads from drinking water sources (chlorinated, unchlorinated, and well water) has been accomplished using a variety of media and methods, including anaerobic incubation (Burke et al., 1984a, b; Millership and Chattopadhyay, 1985; Cunliffe and Adcock, 1989; Havelaar et al., 1990; Moyer et al., 1992). In a study comparing ADA, xylose ampicillin agar (XAA), Ryan Aeromonas agar, and Aeromonas agar (Difco), Ryan's medium was found superior (Holmes and Sartory, 1993). The presence of lactose-fermenting aeromonad species, usually *A. caviae* phenotypes, has interfered with coliform determination by MF, MPN, and single tube coliform detection methods (Moyer, 1996; Landre et al., 1998). Aeromonads have been isolated from bottled waters by investigators in Canada, Saudi Arabia, Spain, and elsewhere (Gonzalez et al., 1987; Warburton et al., 1992; Hunter, 1993).

The recovery of *Aeromonas* from clinical specimens can be achieved with a number of media, many of which have already been discussed. Isolates from normally sterile sites should be easily detected on either blood or MacConkey agar. Blood agar has the advantage of allowing the simultaneous detection of hemolysis, oxidase, and indole production from a single primary medium, as well as the presence of more than one *Aeromonas* species (Janda et al., 1984). However, detecting fecal isolates of *Aeromonas*, particularly lactose-fermenting *A. caviae*-like strains on MacConkey, could be problematic as they would generally not be selected for further identification. Clinically significant *Aeromonas* species are also generally inhibited on TCBS, the selective medium for vibrios. Nearly all *Aeromonas* species can be detected on a modification of CIN (cefsulodin–irgasan–novobiocin) agar, which is normally used for the selection of *Yersinia enterocolitica* (Altorfer et al., 1985). This modified CIN, known as Yersinia selective agar (YSA, Difco), has a lower concentration of cefsulodin (4 mg/l) than the original CIN I formulation (15 mg/l) which tended to inhibit some species (Alonzo et al., 1996). This allows for simultaneous detection of both *Aeromonas* and *Yersinia* by streaking the plates with fecal matter and incubating at 25°C for 28 h. The incorporation of varying concentrations of ampicillin (10, 15, 20, and 30 mg/l) into blood agar for the purpose of inhibiting normal enteric flora has presented a few problems. Since several species of clinically significant *Aeromonas* are susceptible to ampicillin, most notably *A. trota* and a fair percentage of *A. caviae* (the most commonly isolated species from pediatric fecal samples), the incorporation of ampicillin in the media is controversial (Kilpatrick et al., 1987; Carnahan et al., 1991a; Singh and Sanyal, 1994). Most investigators use the lowest ampicillin concentration of 10 mg/l, if at all. A comparison of five selective media for detection of *Aeromonas* species from human and animal feces found that sheep blood agar with 30 mg/l of ampicillin (ASBA30) yielded a higher percentage of positive specimens, and that the addition of DNase–toluidine blue agar allowed them to detect 98% of all isolates (Mishra et al., 1987). Another comparison of five media included blood agar, blood agar with 20 mg/l of ampicillin, MacConkey, ampicillin Tween-80 agar (MAT), and YSA (modified CIN) for isolation of aeromonads from stools transported in Cary–Blair medium. Optimal recovery required the use of both BA20 and YSA (Kelly et al., 1988). An international multilaboratory study to establish the optimal culture media, incubation time, and incubation temperature found that APW enrichment streaked to blood agar with 10 mg/l of ampicillin gave the highest recovery of any single plate medium tested (Moyer et al., 1991). Ryan Aeromonas Medium Base with an ampicillin-selective supplement can also be used for clinical species isolation.

It should be noted that a modified MIO semisolid agar known as AH medium (Kaper's multitest medium) was proposed for screening presumptive *Aeromonas* colonies taken from selective medium (Kaper et al., 1979). It allowed for the determination of D-mannitol and *i*-inositol fermentation, ornithine decarboxylation, indole production, motility, H_2S, and gas production. It was evaluated by other investigators using an incubation temperature of 25°C for 24 h, rather than the originally described 30°C for 24 h (Toranzo et al., 1986). They detected false-negative indole reactions and the production of gas was difficult to determine. Furthermore, with species that are D-mannitol and indole negative (*A. schubertii*) and ornithine decarboxylase positive (*A. veronii* biovar veronii), the investigator would be better served to use one of several well-developed schema employing conventional biochemical tests (Carnahan et al., 1991a; Abbott et al., 1992; Altwegg, 1999).

Maintenance Procedures

The maintenance of stock cultures of *Aeromonas* can be accomplished by lyophilization, freezing in trypticase soy broth (TSB) with 15% glycerol at −20°C for short periods (months), TSB with 20% glycerol at −70°C for long periods (several years), or freezing in serum inositol broth (containing 25 g of *i*-inositol dissolved in 50 ml of distilled water, filter sterilized, and asepti-

cally added to 450 ml of sterile calf serum) at −70°C for long-term storage. For short-term storage, working cultures of *Aeromonas* spp. grown on nutrient media that do not contain fermentable carbohydrates can be placed at 5°C and subcultured every 2–3 weeks (Moyer, 1996). There is a medium for maintenance of marine strains that contains 0.5% peptone, 0.1% yeast extract, 2.4% NaCl, 0.7% Mg_2SO_4, 0.075% KCl, and 1.5% agar (Effendi and Austin, 1991). There is also a long-term room temperature maintenance medium (up to 15 years) from H.M. Atkinson that was originally developed for salmonellae, but has been adapted for use in storing aeromonads (Crowder, 1974).

Procedures for Testing Special Characters

H_2S from GCF (gelatin–cysteine–thiosulfate) (Véron and Gasser, 1963) Aeromonads were assayed for production of H_2S from cysteine using a medium containing Lab Lemco powder (Oxoid, 3 g), tryptone (Oxoid, 10 g), KCl (4 g), L-cysteine hydrochloride (0.1 g), sodium thiosulfate (0.1 g), ferric ammonium citrate (0.4 g), and agar (Difco Bacto, 12 g), w/v in 1000 ml of distilled water and steamed to dissolve all ingredients. The pH was adjusted to 7.4 and the media dispensed in 3-ml volumes (as broths). Special autoclave instructions included 10-lb pressure for 10 min and then the small agar butts were cooled and refrigerated until used. Inoculation involved stabbing the semisolid agar tubes with growth from an 18–24-h TSA culture and then incubating at 35–37°C. A positive reaction is indicated by a diffuse blackening of the medium radiating from the stab line after 72 h of incubation.

Pyrazinamidase Activity (Carnahan et al., 1990) Aeromonads were assayed using a medium obtained from Remel (Lenexa, KS) that contained tryptic soy agar (15 g), yeast extract (1.5 g), Tris-maleate (0.2 M, pH 6, 500 ml) buffer, and pyrazinamide (0.5 g), and was dispensed in 5-ml aliquots into screw-capped tubes (16 × 150 mm), autoclaved at 121°C for 15 min, and slanted. Slants were inoculated with 18–24 h bacterial growth taken from tryptic soy agar and incubated for 48 h at 36°C. One millimeter of 1% (w/v) freshly prepared ferrous ammonium sulfate (aqueous) solution was flooded over each slant, and a positive (pinkish rust color) or negative reaction (colorless) was recorded after 15 min. Positive pyrazinamidase activity indicated the presence of pyrazinoic acid resulting from the action of the enzyme pyrazinamidase.

DL-Lactate utilization (Altwegg et al., 1990; Janda et al., 1996a) Aeromonads were tested for utilization of DL-lactate as a carbon source using slants prepared according to the following formula, per liter: DL-lactic acid (60% w/v; Sigma, St. Louis, MO.), 2.5 ml; NaCl, 5 g; $NH_4H_2PO_4$, 1 g; K_2HPO_4, 1 g; $MgSO_4 \cdot 7H_2O$, 0.2 g; agar, 15 g; and 0.2% bromothymol blue, 40 ml, adjusted to a pH of 6.8. The medium was then autoclaved, dispensed in 5-ml slants, and inoculated with growth from an 18–24-h culture. Incubation was carried out at 25°C, 30°C, or 35°C for 48 h, 72 h, or 5 d with a positive reaction indicated by growth and blue color that begins to develop from the top of the slant.

Urocanic acid utilization (Hänninen, 1994) Aeromonads were tested for utilization of urocanic acid with a medium containing NaCl (5 g), $NH_4H_2PO_4$ (1 g), K_2HPO_4 (1 g), $MgSO_4 \cdot 7H_2O$ (0.2 g), agar (9 g), distilled water (1000 ml), and bromothymol blue (0.2% solution) 40 ml, adjusted to a pH of 6.8. The urocanic acid carbon source was added after the autoclaving of the basic medium as a filter-sterilized solution (2 g/l). The medium was dispensed in 5-ml amounts and slanted. Slants were inoculated and incubated as described above for DL-lactate testing and a positive reaction was recorded as growth and a bright blue color on the slant.

Furunculosis agar (Bernoth and Artzt, 1989 Hänninen and Hirvelä-Koski, 1997) The most sensitive method for brown pigment production among *A. salmonicida* isolates is furunculosis agar (tryptone, 10 g; yeast extract, 5 g; L-tyrosine, 1 g; NaCl, 2.5 g; agar, 15 g; 1000 ml water, pH 7.3). This medium was incubated at 22°C for 3, 7, and 18 d.

Differentiation of the genus *Aeromonas* from other genera

Aeromonas is most closely related to *Vibrio* and *Plesiomonas*. Key tests to differentiate these genera are given in Table BXII.γ.184. It should be noted that the classic test of resistance to 150 mg of O/129 bears the caveat that there are reports of increasing resistance to O/129 among isolates of *Vibrio cholerae* from India and Bangladesh (Ramamurthy et al., 1992).

Taxonomic Comments

Great strides have been made over the past 20 years in clarifying the taxonomic order of the aeromonads. Prior to 1985, only three species were recognized. Now there are at least 14 species and a new family, *Aeromonadaceae*, has been proposed. Though much of the earlier confusion has been dispelled, some concerns remain including the taxa HG 3 (motile, mesophilic subspecies of *A. salmonicida* only), HG 5A, and HG 5B; the biovars in *A. veronii*; the status of *A. ichthiosmia* and *A. enteropelogenes*; and whether to consider *A. trota* as HG 13 or HG 14. Several discrepancies can occur when trying to group isolates of *A. salmonicida* into one of four subspecies, subsp. *salmonicida*, subsp. *achromogenes*, subsp. *masoucida*, and subsp. *smithia*, thus creating a number of atypical groups caused by lack of congruence of phenotypic and molecular data (Table BXII.γ.183). These atypical groups require attention because members of these groups are increasingly being isolated, especially from marine fish (Hänninen et al., 1995; Hänninen and Hirvelä-Koski, 1997; Austin et al., 1998a; Wiklund and Dalsgaard, 1998).

In HG 3 (*A. salmonicida*) there is an orphan group that is motile, grows well at 37°C, and has been isolated from humans.

TABLE BXII.γ.184. Differential characteristics for the genera *Aeromonas*, *Plesiomonas*, and *Vibrio*[a]

Characteristic	*Aeromonas*	*Plesiomonas*	*Vibrio*
Resistance to O/129[b] (150 μg)	R	S	S[c]
String Test[d]	−	−	+
Growth in 6.5% NaCl	−	−	(+)
Ornithine decarboxylase	(−)	+	+
Fermentation of i-inositol	−	+	(−)
Fermentation of D-mannitol	(+)	−	+
Fermentation of sucrose	(+)	−	(+)
Gelatin liquefaction	+	−	+
Growth on TCBS[e]	(−)	−	(+)

[a]Symbols: +, positive for the majority of species within the genus; −, negative for the majority of species within the genus; (+), positive for most speices, but a few species may be negative; (−), negative for most species, but a few may be positive; R, resistant; S, susceptible.

[b]Vibriostatic agent (2,4-diamino-6,7-diisopropylpteridine) (150 μg/disk).

[c]Vibrios are generally susceptible to O/129 with increased reports of resistance in *V. cholerae* strains from India and Bangladesh (Ramamurthy et al., 1992).

[d]Performed using a 0.5% solution of sodium desoxycholate.

[e]Thiosulfate citrate bile salts sucrose agar.

TABLE BXII.γ.185. Identification of genomospecies within the phenospecies for *Aeromonas hydrophila*[a,b]

	HG 1		HG 2		HG 3[c]	
	A. hydrophila		*A. bestiarum*		Motile, mesophilic *A. salmonicida* subspecies	
Characteristic	25°C	35°C	25°C	35°C	25°C	35°C

Lysine decarboxylation	+	+	+	−	+	d
Maximum growth Temperature	41°C		38–39°C		38–39°C	

[a]Symbols: +, >75% of strains positive; −, <25% of strains positive; d, 26–74% of strains positive; nd, not determined.

[b]Data from Abbott et al. (1992); Hänninen (1994); Ali et al. (1996a); and Altwegg (1999); note that results for some tests vary in relation to the temperature of incubation.

[c]These are motile, nonpigmented, indole-positive strains that grow at 35°C.

It is unlike the other members of the group but exhibits subspecies level DNA relatedness to HG 3. See Tables BXII.γ.182 and BXII.γ.185 for differentiation of this motile *A. hydrophila*-like group from HG 1 (*A. hydrophila*) and HG 2 (*A. bestiarum*). It remains undesignated at present, but it is possible that a subspecies for this group could be proposed in the future.

For many years, the remaining subspecies members of the nonmotile *A. salmonicida* group were thought to be phenotypically distinct, but after additional taxonomic studies of the group by several researchers, it became evident that there are many more atypical strains in the environment than previously realized. An *Aeromonas* Taxonomy working group within the Subcommittee on the Taxonomy of *Vibrionaceae* has been established and is presently studying *A. salmonicida* in an attempt to clarify the position of atypical organisms and to reevaluate the presently accepted taxonomic designations for this group. It is questionable whether the currently recognized subspecies, as well as the possible incorporation of *Haemophilus piscium*, should be retained in the future (Austin et al., 1989a, 1998a; Thornton et al., 1999).

HG 5 is currently subdivided into HG 5A and HG 5B. HG 5A genetically resembles *A. media* but phenotypically resembles *A. caviae*. HG 5B genetically and phenotypically is *A. media*. It has been suggested that the two groups should be considered as either two subspecies of *A. media*, since HG 5B includes the type strain for *A. media* (Altwegg, 1990), or as biovars of the genomospecies *A. media* (Huys et al., 1996b).

HG 7, *A. sobria*, has not been isolated from human clinical specimens. However, there is a continuing use of this species name for clinical isolates, which resemble *A. sobria* but are actually *A. veronii* biovar sobria (HG 8) as opposed to *A. veronii* biovar veronii (HG 10). The terminology *A. veronii* biovar sobria for HG 8 and *A. veronii* biovar veronii HG 10 was suggested (Joseph et al., 1991) to clarify the situation and has been generally accepted based on usage in current literature and inclusion in the databases of most rapid identification systems. Although this suggestion to use the term " biovar sobria" for the biovar designation was to clarify that these HG 8 clinical isolates were genomically *A. veronii*, but phenotypically most similar to what we had heretofore called *A. sobria*, some concern has been expressed over the possibility that the term *sobria*, being used as both a species designation for HG 7 and the biovar designation for HG 8, might lead to confusion.

The proposed species *Aeromonas ichthiosmia* (Schubert et al., 1990b) has now been shown to actually be *A. veronii* biovar sobria (HG 8) by 16S ribosomal DNA sequencing (Collins et al., 1993), AFLP (Huys et al., 1996b, and DNA–DNA hybridization studies (Huys et al., 2001). Therefore, it is a junior synonym of *A. veronii* biovar sobria.

There is a proposal to divide *A. eucrenophila* into two groups, *A. eucrenophila* I and *A. eucrenophila* II based on ribotyping, AFLP fingerprinting, electrophoretic profiling of soluble cellular proteins, and cellular fatty acid methyl ester profiles (Huys et al., 1996a), with *A. encheleia* and HG 11 strains also residing in Group II. DNA hybridization studies (optical renaturation) (De Ley et al., 1970) of Group I and II *A. eucrenophila* and strains of *A. encheleia* and HG 11 grouped them into two distinct hybridization groups, with the first group composed only of *A. eucrenophila* I. The other group comprised *A. eucrenophila* subgroup II, *A. encheleia*, and HG 11 strains. DNA relatedness between strains in the *A. eucrenophila* I group versus strains in the second group, which included *A. encheleia*, *A. eucrenophila*, subgroup II, and HG 11, ranged from 42 to 52%. These findings suggest that members of this second group, which includes *A. encheleia*, *A. eucrenophila* subgroup II, and HG 11 strains, are genetically (DNA relatedness of values of 74–105%) and phenotypically very similar and should therefore all reside in *A. encheleia* (Huys et al., 1997a). However, a recent rebuttal to this suggestion was published with equally compelling arguments for their continued separation based on 16S rDNA sequence data and conflicting DNA relatedness values below the species level using the competitive nitrocellulose filter method (Martinez-Murcia, 1999). It appears that additional investigation is required to resolve this matter.

Aeromonas Group 501 was initially designated by Hickman-Brenner et al. (1988a) to identify three strains, that were phenotypically close to the newly proposed *Aeromonas schubertii*, and genotypically close to each other, but not related at the species level to any of the other HG groups, including *A. schubertii*. The group of unnamed organisms currently resides in HG 13 (Carnahan et al., 1991a) (Table BXII.γ.181). 16S rDNA sequencing of one Group 501 strain shows that there is a four-nucleotide difference between this strain and *A. schubertii* (Table BXII.γ.180).

Aeromonas trota (HG 14) and *A. enteropelogenes* are synonymous (Collins et al., 1993). While the frequency of terminology usage in the literature shows a marked preference for *A. trota*, the name

A. enteropelogenes was validated earlier (Schubert et al., 1990a). A request for a Judicial Opinion will eventually be made to decide which validated name will be accepted. Although they do not share the same type strain, phenotypic, typing, and molecular studies suggest they are the same organism (Carnahan, 1992; Collins et al., 1993; Huys et al., 2002a).

There is a discrepancy between Opinion 48 of the Judicial Commission in response to a request from Schubert (1971) and the Approved List of Bacterial Names (Amended Edition, 1989). Opinion 48 states that Kluyver and van Niel (1936) are no longer to be associated with the genus designation of *Aeromonas* (Editorial Board, 1973). In the future, Stanier (1943) should be associated with both the genus *Aeromonas* and the type species, *A. hydrophila*. A recent request for an Opinion from the Judicial Commission to correct the Kluyver and Van Niel citation in the 1980 Approved Lists for the genus *Aeromonas* has been submitted.

A. punctata and *A. caviae* have been considered objective synonyms and share the same type strain, ATCC 15468. This is because the type strain of *A. punctata* is incorrectly listed on the 1980 Approved List of Bacterial Names as ATCC 15468, when it should have been NCMB 74 (ATCC 23309). As part of the same request for an Opinion from the Judicial Commission on the Kluyver and van Niel issue mentioned above, it has also been registered to correct this *A. punctata*/*A. caviae* mistake and make *A. caviae* the single legitimate name for the type strain ATCC 15468. This would, however, cause *A. punctata* and *A. eucrenophila* to then become objective synonyms since both species would then share the same type strain of NCMB 74 (ATCC 23309). Although *A. punctata* is older and would have priority (it has a confusing history), it has been reported to have differing phenotypes and is not being used by the scientific community. Therefore, a second request for an Opinion from the Judicial Commission has been made to conserve the name *A. eucrenophila* Schubert and Hegazi, 1988a as the correct name for HG 6 with the type strain of NCMB 74 (ATCC 23309).

Acknowledgments

The authors wish to acknowledge the following persons for their invaluable support in supplying material for use in this chapter as well as their comments and suggestions: Martin A. Altwegg, Brian Austin, Geert Huys, Marja-Liisa Hänninen, J. Michael Janda, Sylvia M. Kirov, Antonio J. Martinez-Murcia, Hans G. Trüper, and Michael Waddington.

Differentiation of the species of the genus *Aeromonas*

Each validly named species *vide infra* has a particular HG (hybridization group) designation and can be found in either Tables BXII.γ.182 and BXII.γ.186 (motile aeromonad HGs) or in Table BXII.γ.183 (nonmotile aeromonad HGs).

List of species of the genus Aeromonas*

1. **Aeromonas hydrophila** (Chester 1901) Stanier 1943, 213[AL] (*Bacillus hydrophilus* Chester 1901, 235.)
hy.dro'phi.la. Gr. n. *hydro* water; Gr. adj. *philos* loving; M.L. adj. *hydrophila* water-loving.

Hybridization group 1 of 17 (Popoff et al., 1981; Farmer et al., 1986).

At 37°C hydrolyzes esculin; produces acetoin from D-glucose (positive Voges-Proskauer test); displays pyrazinamidase activity; produces acid from D-mannitol and sucrose and variably from arabinose; resistant to ampicillin and cephalothin. Decarboxylates lysine but not ornithine; produces indole, H_2S (from GCF medium), and gas from D-glucose; β-hemolysis on TSA with 5% sheep blood agar. Differential tests to aid in the identification of *A. hydrophila* from all validly named motile species are listed in Tables BXII.γ.185 and BXII.γ.186. Descriptive tests for all the validly named motile species are listed in Table BXII.γ.182. Isolated from fresh and marine waters, diseased fish and poikilothermic aquatic animals (e.g., frogs with red leg disease), and warm-blooded animals; associated with both extraintestinal and diarrheal disease in humans (Austin and Adams, 1996; Gosling, 1996a ; Holmes et al., 1996; Janda and Abbott, 1996; Joseph, 1996).

The mol% G + C of the DNA is: 58–62 (Bd, T_m).

Type strain: ATCC 7966, DSM 30187.

GenBank accession number (16S rRNA): X60404 (16S rDNA).

2. **Aeromonas allosaccharophila** Martinez-Murcia, Esteve, Garay and Collins 1992c, 511[VP] (Effective publication: Martinez-Murcia, Esteve, Garay and Collins 1992b, 203.)
al.lo.sa.ca.ro'phi.la. Gr. adj. *allos* different; Gr. n. *saccharo* sugar; Gr. adj. *philos* loving; M.L. adj. *allosaccharophila* different sugar loving.

Hybridization Group 15 of 17 (Martinez-Murcia et al., 1992b; Esteve et al., 1995b).

Motile. Diffusible brown pigment is not produced. Growth occurs in 0–3% (w/v) NaCl. Resistant to 2,4-diamino-6,7-diisopropylpteridine (vibriostatic agent 0/129). Acid and gas are produced from D-glucose. Lysine is decarboxylated (Moeller's medium); indole, and β-galactosidase are positive. H_2S production from thiosulfate and Voges–Proskauer test are negative. Growth occurs at 4–42°C and at pH 9.0, but not at pH 4.5. Acid is produced from sucrose, D-cellobiose, maltose, D-trehalose, D-galactose, D-mannose, glycerol, and D-mannitol, but not from adonitol, arbutin, D-xylose, lactose, *myo*-erythritol, dulcitol, *myo*-inositol, or D-sorbitol. Sole carbon and energy sources include L-arabinose, sucrose, D-cellobiose, maltose, D-trehalose, D-galactose, D-mannose, glycerol, D-mannitol, L-histidine, L-arginine, L-proline, L-glutamate, D-gluconate, fumarate, and

---

**Editorial Note:* Since the submission and review of this chapter, two new subspecies and one new species have been proposed and validly published. These are *Aeromonas hydrophila* subsp. *dhakensis* (Huys et al., 2002b), *Aeromonas hydrophila* subsp. *ranae* (Huys et al., 2003) and *Aeromonas culicicola* (Pidiyar et al., 2002).

[a]Symbols: +, ≥75% of the strains are positive; −, ≤25% of the strains are positive; d, 26–74% of the strains are positive; nd, not determined.

[b]Data from Carnahan et al. (1991a); all analyses were performed at 36°C ± 1°C for 3 d.

[c]Data from Martinez-Murcia et al. (1992b); analyses were performed at 35°C.

[d]Data from Ali et al. (1996a) and Carnahan and Joseph (1993); analyses were performed at 35°C for 7 d (see Table BXII.γ.185 for results at 25°C).

[e]Data from Esteve et al. (1995a) and Huys et al. (1996a, 1997a); analyses were performed at 28°C unless otherwise indicated.

[f]Data from Schubert and Hegazi (1988a); analyses were performed at 30°C and 20°C; Carnahan et al. (1991a) (36°C ± 1°C); and Abbott et al. (1992) (35°C for 7 d).

[g]Data from Allen et al. (1983); analyses were performed at 22°C for 7 d; Carnahan et al. (1991a) (36°C ± 1°C); and Abbott et al. (1992) (35°C for 7 d). Although originally described as nonmotile, later work by Austin and Austin (1990) reported on the motility of this species at 37°C; original description by Allen et al. (1983) also included production of a brown diffusible pigment on TSA (trypticase soy agar).

[h]Data from Huys et al. (1997b); analyses were performed at 28°C and 37°C for 7 d unless otherwise indicated.

[i]Data from Carnahan(unpublished data); analyses were performed at 25°C for 7 d incubation, unless otherwise indicated.

[j]Data from Carnahan et al. (1990); analysis performed at 35°C for 48 h.

[k]Antimicrobial susceptibility results were incubated at 35°C for 24 h; R, resistance; S, susceptibility; d, 26–74% susceptibility.

succinate. There is no growth on lactose, *myo*-erythritol, dulcitol, *myo*-inositol, ethanol, L-citrulline, L-leucine, L-alanine, glycine, L-serine, L-glutamine, DL-3-hydroxybutyrate, propionate, γ-aminobutyrate, D-glucuronate, α-ketoglutarate, or putrescine. Gelatin, casein, egg yolk, Tween 80, starch, and DNA are degraded but not urea, sodium dodecyl sulfate, or elastin (Martinez-Murcia et al., 1992b). Differential tests to aid in the identification of *A. allosaccharophila* from all motile species are listed in Table BXII.γ.186. Descriptive tests for all the motile species are listed in Table BXII.γ.182. Found in diseased elvers and diarrheic stools.

The mol% G + C of the DNA is: 59.5 (method unknown).

Type strain: ATCC 51208, CECT 4199, DSM 11576.

GenBank accession number (16S rRNA): S39232.

3. **Aeromonas bestiarum** Ali, Carnahan, Altwegg, Lüthy-Hottenstein, and Joseph 1996b, 1189[VP] (Effective publication: Ali, Carnahan, Altwegg, Lüthy-Hottenstein, and Joseph 1996a, 163.)

bes.ti.a′rum. L. n. *bestiarum* of beasts (whether wild or domestic).

Hybridization Group 2 of 17 (Popoff et al., 1981; Fanning et al., 1985; Farmer et al., 1986; Ali et al., 1996a).

At 25°C and 35°C it produces acid from L-rhamnose; does not usually produce acid from lactose or D-sorbitol; utilizes urocanic acid, but does not utilize DL-lactate. At 25°C it hydrolyzes elastin; utilizes phenylpyruvate and decarboxylates lysine. Differential tests to aid in the identification of *A. bestiarum* from all motile species are listed in Table BXII.γ.186 and tests for separation from closely related species are listed in Table BXII.γ.185. Descriptive tests for all the motile species are listed in Table BXII.γ.182. Primarily found in the environment in both wild and domestic animals and birds and fish. Isolated from human feces (Figueras et al., 1999).

The mol% G + C of the DNA is: not reported.

Type strain: ATCC 51108, CDC 9533-76.

GenBank accession number (16S rRNA): X60406 (16S rDNA).

Additional Remarks: X60406 is identical to *A. salmonicida* subsp. *achromogenes* X60407.

4. **Aeromonas caviae** (ex Eddy 1962) Popoff 1984b, 355[VP] (Effective publication: Popoff 1984a, 548.)
ca' vi.ae. M.L. fem. n. *cavia* generic name of a guinea pig; M.L. gen. n. *caviae* of a guinea pig

Hybridization Group 4 of 17 (Popoff et al., 1981; Farmer et al., 1986).

Does not produce gas during D-glucose fermentation, Voges–Proskauer (acetoin) negative, lysine decarboxylase negative, H_2S not produced from GCF media. Utilizes DL-lactate and citrate as sole source of carbon. Differential tests to aid in the identification of *A. caviae* from all motile species are listed in Table BXII.γ.186 with supplementary tests to separate *A. caviae* given in Table BXII.γ.187. Descriptive tests for all the motile species are in Table BXII.γ.182. Found in fresh water, sewage, and on domestic and wild animals, birds, and fish. May be associated with gastrointestinal disease in adults (Holmberg et al., 1986a; Kuijper et al., 1989a; Altwegg et al., 1990; Joseph, 1996). Etiological agent of gastroenteritis in young children (Altwegg, 1985; Namdari and Bottone, 1990). Causes extraintestinal disease primarily in immunocompromised humans (Janda and Duffey, 1988; Janda, 1991; Janda and Abbott, 1998b).

The mol% G + C of the DNA is: 61–63 (Bd, T_m).

Type strain: ATCC 15468, DSM 7323, NCIMB 13016.

GenBank accession number (16S rRNA): X74674.

5. **Aeromonas encheleia** Esteve, Gutiérrez and Ventosa 1995a, 464[VP] emend. Huys, Kämpfer, Altwegg, Coopman, Janssen, Gillis and Kersters 1997a, 1162.
en.che' le.ia. Gr. n. *encheyls* eel; M.L. adj. *encheleia* from eels.

Hybridization Group 16 of 17 (Martinez-Murcia et al., 1992b).

Motile. Colonies develop within 24 h at 28°C on TSA and are not pigmented. Old cultures (10–15 d) may have colonies with light brown pigmented colonies. No brown water-soluble pigment is produced. Growth occurs on MacConkey agar but not on thiosulfate–citrate–bile salts–sucrose agar. Acid is produced from D-glucose; gas production is variable. Resistant to vibriostatic agent 0/129. Growth in the presence of 0–3% NaCl at 4 and 37°C and under alkaline conditions (pH 9.0). Arginine dihydrolase variable; indole positive. H_2S variable, and lysine and ornithine decarboxylase negative. Voges–Proskauer reactions are usually negative. Acid is produced from D-mannose, D-trehalose, D-galactose, and D-mannitol, but not from L-arabinose, D-cellobiose, lactose, D-xylose, D-melibiose, D-raffinose, and *myo*-erythritol, dulcitol, *myo*-inositol, or D-sorbitol. Acid is sometimes produced from sucrose, salicin, maltose, L-rhamnose, and glycerol. Hydrolyzes esculin, arbutin, casein, collagen, chitin, Tween 80, egg yolk, and DNA, but not chondroitin sulfate, elastin, keratin, or urea. SDS-alkyl sulfatase negative. Fibrinogen and starch, but not mucin, are sometimes hydrolyzed. Human erythrocytes are hemolyzed. Sole carbon and energy sources include sucrose, salicin, maltose, D-mannose, D-trehalose, L-proline, L-serine, L-malate, fumarate, and D-mannitol. L-Histidine is sometimes utilized. The following are not used as sole carbon or energy sources: L-arabinose, D-cellobiose, L-rhamnose, lactose, D-raffinose, L-arginine, L-citrulline, L-leucine, L-alanine, glycine, L-glutamine, L-tyrosine, citrate, L-aspartate, DL-3-hydroxybutyrate, propionate, D-gluconate, D-glucuronate, α-ketoglutarate, *myo*-inositol, *myo*-erythritol, dulcitol, ethanol, and putrescine. L-Glutamate and D-galactose are sometimes utilized (Esteve et al., 1995a) See Table BXII.γ.182 for tests to differentiate *A. encheleia* from other *Aeromonas* spp. Differential tests to aid in the identification of *A. encheleia* from all motile species are listed in Table BXII.γ.186. Descriptive tests for all the motile species are listed in Table BXII.γ.182. Found in healthy European eels reared in a freshwater farm; not pathogenic for mice.

The mol% G + C of the DNA is: 59.4–60.8 (T_m).

Type strain: ATCC 51929, CECT 4342, DSM 11577.

6. **Aeromonas eucrenophila** Schubert and Hegazi 1988b, 449[VP] (Effective publication: Schubert and Hegazi 1988a, 34) emend. Huys, Kämpfer, Altwegg, Coopman, Janssen, Gillis and Kersters 1997a, 1162.
eu.cre.no.phi' la. Gr. fem. n. *eu* good; *krene* well; Gr. adj. *philos* loving; *eucrenophila* good well water.

Hybridization Group 6 of 17 (Popoff et al., 1981; Farmer et al., 1986).

Rod-shaped with rounded ends to coccoid 1.0–4.4 μm in diameter, occasionally forming filaments up to 8 μm long; occurs singly, in pairs, or chains. Motile by polar flagella, generally monotrichous. Voges–Proskauer negative. Facultatively anaerobic. Grows on a mineral medium with ammonia as the sole source of nitrogen and one of the following as the sole source of carbon: D-glucose, arginine, asparagine, or histidine. No growth at 40°C; maximum growth temperature is 37°C; minimum growth temperature is 0–5°C; optimal growth temperature 30°C, although incubation at 20°C is best for some tests; growth at pH range 5.5–9.0. Resistant to vibriostatic agent 0/129. Produces gas from D-glucose, but not from glycerol. Fructose, maltose, trehalose, and esculin are usually utilized; D-adonitol, dulcitol, i-inositol, inulin, melezitose, D-sorbose, and D-xylose are not fermented. Starch and dextrin are hydrolyzed; gelatin is liquefied; deoxyribonuclease, arginine dihydrolase, and phosphatase are usually produced; glutamic acid is not decarboxylated; urea is not hydrolyzed. Differential tests to aid in the identification of *A. eucrenophila* from all motile species are listed in Table BXII.γ.186. Descriptive tests for

TABLE BXII.γ.187. Identification of the genomospecies within the phenospecies *Aeromonas caviae*[a,b]

Characteristic	HG 4 *A. caviae*	HG 5A (unnamed)	HG 5B *A. media*[c]
Acid from:			
Lactose	d	+	+
Cellobiose	d	+	+
Utilization of:

Citrate	+	−	−

[a]Symbols: +, >75% strains positive; −, <25% strains positive; d, 25–75% strains positive.

[b]Results derived from API50 and API 32GN strips at an incubation temperature of 30°C for 48 hr incubation. (Reprinted with permission from M. Altwegg. *In* Murry, Baron, Pfaller, Tenover and Yolken (Editors), *Manual of Clinical Microbiology*, 7th. Ed., American Society for Microbiology, Washington D.C., pp. 507 516, 1999.)

[c]HGs 5A and 5B may constitute two subspecies with HG 5B consisting of two biovars.

all the motile species are listed in Table BXII.γ.182. Found in unpolluted surface and groundwater such as oligosaprobic (living in an environment rich in organic matter and relatively free of oxygen) streams and clean well waters.

The mol% G + C of the DNA is: 59.8–62.6 (Bd, T_m).

Type strain: ATCC 23309, NCMB 74.

GenBank accession number (16S rRNA): X74675.

7. **Aeromonas jandaei** Carnahan, Fanning and Joseph 1992b, 191[VP] (Effective publication: Carnahan, Fanning and Joseph 1991c, 562.)

jan.dae′i. M.L. gen. n. *jandaei* named after J. Michael Janda.

Hybridization Group 9 of 17 (Farmer et al., 1986).

Its unique biochemical profile includes negative reactions for esculin hydrolysis, fermentation of sucrose and cellobiose, and resistance to colistin (4 μg/ml). It differs from *A. schubertii* (HG 12), because *A. jandaei* is indole positive, ferments D-mannitol, and produces gas from D-glucose fermentation. A sucrose-negative reaction usually differentiates *A. jandaei* from other *Aeromonas* spp., although sucrose-negative strains that are not *A. jandaei* can occur. Differential tests to aid in the identification of *A. jandaei* from all motile species are listed in Table BXII.γ.186. Descriptive tests for all the motile species are listed in Table BXII.γ.182. Isolation has been from specimens of diverse geographic origin including wounds, blood, and feces of humans, aquatic sources, fish, and prawns (Carnahan et al., 1991c; Joseph et al., 1991; Janda and Abbott, 1996).

The mol% G + C of the DNA is: not determined.

Type strain: ATCC 49568, DSM 7311.

GenBank accession number (16S rRNA): X74678.

8. **Aeromonas media** Allen, Austin and Colwell 1983, 603[VP]

me′di.a. M.L. fem. gen. n. *media* in the middle.

Hybridization Group 5 of 17 (Popoff et al., 1981; Farmer et al., 1986).

Colonies on TSA are creamy, shiny, smooth, round, raised, entire, and 2 mm in diameter after incubation for 2 d at 22°C. Originally described as nonmotile, but motility can be expressed under certain laboratory conditions using appropriate media, temperature, and incubation periods (Austin and Austin, 1990). A diffusible, brown, nonfluorescent pigment is produced. Cultures in peptone broth are uniformly turbid. Chemoorganotrophic; metabolism is fermentative. Temperature range of 4–37°C; no growth at 42°C. Growth occurs in 0–3% NaCl. β-Galactosidase and arginine dihydrolase are usually produced. Phosphatase is not produced. Lysine and ornithine are not decarboxylated. Blood, gelatin, starch, ribonucleic acid, Tween 20, Tween 40, Tween 60, and Tween 80 are degraded, but cellulose, elastin, lecithin, xanthine, and urea are not. Methyl red test positive. Voges–Proskauer, gluconate oxidation, and H_2S production are negative. Utilizes DL-lactate, L-arabinose, glycerol, D-mannitol, L-proline, L-serine, sodium acetate, sodium glutamate, sodium pyruvate, and sodium succinate as sole carbon sources for energy and growth. Does not utilize either adonitol, D-cellobiose, *meso*-erythritol, ethanol, D-fructose, *meso*-inositol, inulin, L-leucine, D-melezitose, *p*-hydroxybenzoic acid, D-raffinose, sodium benzoate, sodium formate, sodium malonate, D-sorbitol, sucrose, D-trehalose, L-valine, or D-xylose (Allen et al., 1983). Differential tests to aid in the identification of *A. media* from all motile species are listed in Tables BXII.γ.186 and BXII.γ.187. Descriptive tests for all the motile species are listed in Table BXII.γ.182. Strains isolated from fishponds and other aquatic sources (Allen et al., 1983). One rare report of association with human diarrheal disease (Rautelin et al., 1995a).

The mol% G + C of the DNA is: 62.3 (Bd, T_m).

Type strain: ATCC 33907, DSM 4881.

GenBank accession number (16S rRNA): X74679.

9. **Aeromonas popoffii** Huys, Kämpfer, Altwegg, Kersters, Lamb, Coopman, Lüthy-Hottenstein, Vancanneyt, Janssen and Kersters 1997b, 1170[VP]

po.pof′fi.i. M.L. gen. n. *popoffii* of Popoff, named after Michel Popoff.

Hybridization Group 17 of 17 (Huys et al., 1997b).

Motile. Reduces nitrate to nitrite; resistant to vibriostatic agent 0/129. Optimal growth after 24 h at 28°C on TSA medium; acid and gas produced from D-glucose and glycerol. Growth in KCN broth but not in 3, 6, 8, and 10% NaCl; positive for arginine dihydrolase, DNase, and Voges–Proskauer test; variable production for indole; no production of urease, tryptophan deaminase, ornithine and lysine decarboxylase; H_2S is sometimes produced; citrate and malonate utilization is variable. Acid is uniformly produced from D-galactose, D-mannitol, D-mannose, methyl-D-glucoside, and D-trehalose, but not from adonitol, D-arabitol, D-cellobiose, dulcitol, erythritol, *myo*-inositol, lactose, α-D-melibiose, D-raffinose, L-rhamnose, salicin, D-sorbitol, D-sucrose, and D-xylose. The following substrates are used as carbon and energy sources: *N*-acetyl-D-glucosamine, L-aspartate, fumarate, D-galactose, D-gluconate, v-glucose, L-glutamate, L-glutamine, glycerol, L-histidine, L-malate, D-mannitol, D-mannose, D-maltose, putrescine, pyruvate, D-ribose, succinate, L-serine, D-trehalose, and L-tyrosine. The following are not utilized: acetate, *cis*-aconitate, *trans*-aconitate, adipate, adonitol, β-alanine, 4-aminobutyrate, arbutin, azelate, D-cellobiose, citrullin, dulcitol, ethanol, erythritol, D-glucuronate, DL-3-hydroxybutyrate, *myo*-inositol, itaconate, L-leucine, maltitol, α-D-melibiose, mesaconate, L-ornithine, oxoglutarate, phenylacetate, L-phenylalanine, L-proline, propionate, D-raffinose, L-rhamnose, salicin, D-sorbitol, suberate, D-sucrose, L-tryptophan, and D-xylose.

It hydrolyzes the following substrates: L-alanine-*p*NA, casein, 2-deoxythymidine-5′-*p*NP-phosphate, gelatin, lecithin, *bis*-*p*NP-phenylphosphonate, *p*NP-phosphoryl choline, L-proline-*p*NA, starch, and Tween 80. It does not hydrolyze chitin, esculin, L-glutamate-γ-3-carboxy-*p*NA, *p*NP-α-D-glucopyranoside, *p*NP-β-D-glucuronide, and *p*NP-β-D-xyloside (Huys et al., 1997b). Differential tests to aid in the identification of *A. popoffii* from all motile species are listed in Table BXII.γ.186. Descriptive tests for all the motile species are listed in Table BXII.γ.182. Found in drinking water production plants and reservoirs.

The mol% G + C of the DNA is: 57.7–59.6 (T_m).

Type strain: LMG 17541.

GenBank accession number (16S rRNA): AJ224308.

10. **Aeromonas salmonicida** (Lehmann and Neumann 1896) Griffin, Snieszko and Friddle 1953, 138[AL] (*Bacterium salmonicida* Lehmann and Neumann 1896, 240.)

sal.mon.ic′i.da. L. n. *salmo, salmonis* salmon; L. suff. *-cida* from L. v. *caedo* cut or kill; M.L. n. *salmonicida* salmon-killer.

Hybridization group 3 of 17 (Popoff et al., 1981; Fanning et al., 1985; Farmer et al., 1986).

Short Gram-negative rods, some pleomorphism and coccobacillary forms. In nutrient broth, pairs, chains, and clumps are usually observed in phase-contrast preparations. Nonencapsulated (Popoff, 1984a). Rarely motile. Usually possesses an S-layer (Noonan and Trust, 1997). Optimum growth temperature is 22–25°C. Maximum growth temperature in nutrient broth is 34.5°C (Griffin et al., 1953). Colonies on agar after 24 h are pinpoint. After 48–72 h colonies are circular, raised, convex, translucent, entire, and friable. On blood agar there is similar morphology and some subspecies produce β-hemolysis after 2–4 d (Millership, 1996). Colony pigmentation, when present, is usually yellowish; absence is indicated by grayish white colony. A brown, diffusible pigment appears after 24 h and reaches maximum color within 48–72 h. Differential and descriptive tests to aid in the identification of all nonmotile *A. salmonicida* subspecies, as well as atypical strains, are listed in Table BXII.γ.183. Differential and descriptive tests for the motile *A. salmonicida* strains within HG 3, which may be either a new subspecies or a biovar, are listed in Tables BXII.γ.182 and BXII.γ.185. Various diseases, including swelling at the vent and in the kidney, external and internal hemorrhages, ascitic fluid, and especially furunculosis are caused in a variety of fish. Interestingly, though not usually isolated from related aquatic locations, *A. salmonicida* was recently recovered in co-culture with purple-pigmented bacteria from fresh water lake sediment (Austin et al., 1998b).

The mol% G + C of the DNA is: 57–59 (Bd, T_m).

Type strain: ATCC 33658, NCMB 1102.

Additional Remarks: Neotype proposed Schubert, 1967b.

a. **Aeromonas salmonicida** *subsp.* **salmonicida** (Lehmann and Neumann 1896) Griffin, Snieszko and Friddle 1953, 138[AL] (*Bacterium salmonicida* Lehmann and Neumann 1896, 240.)

RBrown water-soluble pigment production on agar containing 0.1% tyrosine or phenylalanine. β-Hemolytic on ox blood agar, hydrolyzes esculin, indole negative, gas produced during D-glucose fermentation, ferments salicin and L-arabinose. Differential and descriptive tests to aid in the identification of this nonmotile *A. salmonicida* subspecies, as well as atypical strains, are listed in Table BXII.γ.183.

The mol% G + C of the DNA is: 57–59 (Bd, T_m).

Type strain: ATCC 33658, NCMB 1102.

GenBank accession number (16S rRNA): X60405.

Additional Remarks: Neotype proposed Schubert, 1967b.

b. **Aeromonas salmonicida** *subsp.* **achromogenes** (Smith 1963) Schubert 1967c, 278[AL] (*Necromonas achromogenes* Smith 1963, 273.)

a.chro.mo.ge′ nes. Gr. adj. *achromos* colorless; Gr. v. *gennaio* produce; M.L. adj. *achromogenes* not producing color.

Generally do not produce brown, water-soluble pigment unless grown on specific media such as furunculosis agar. May produce indole, arginine dihydrolase, ferment D-mannitol, and assimilate *N*-acetyl glucosamine. Gas is not produced during glucose fermentation; esculin is not hydrolyzed; no β-hemolysis on ox blood agar. Differential and descriptive tests to aid in the identification of all nonmotile *A. salmonicida* subspecies, as well as atypical strains, are listed in Table BXII.γ.183.

The mol% G + C of the DNA is: 57–59 (Bd, T_m).

Type strain: ATCC 33659, NCMB 1110.

GenBank accession number (16S rRNA): X60407.

c. **Aeromonas salmonicida** *subsp.* **masoucida** Kimura 1969, 52[AL]

ma.sou.ci′ da. Japan. n. *masou* specific epithet of *Onchorhynchus masou*, (fish); L. v. suff. *-cida* from L. v. *caedo* cut or kill; M.L. fem. n. *masoucida Onchorhyncus masou*-killer.

Does not produce brown, water-soluble pigment on agar; β-hemolytic on ox blood agar; may hydrolyze esculin; arginine dihydrolase positive; gas produced during glucose fermentation; L-arabinose fermented; *N*-acetyl glucosamine not assimilated. Differential and descriptive tests to aid in the identification of this nonmotile *A. salmonicida* subspecies, as well as atypical strains, are listed in Table BXII.γ.183.

The mol% G + C of the DNA is: not available.

Type strain: ATCC 27013.

GenBank accession number (16S rRNA): X74680.

d. **Aeromonas salmonicida** *subsp.* **pectinolytica** Pavan, Abbott, Zorzópulos and Janda 2000, 1123[VP]

Isolated from heavily polluted river.

The mol% G + C of the DNA is: not known.

Type strain: 34mel, DSM 12609.

GenBank accession number (16S rRNA): AF134065.

e. **Aeromonas salmonicida** *subsp.* **smithia** Austin, McIntosh and Austin 1989b, 495[VP] (Effective publication: Austin, McIntosh and Austin 1989a, 288.)

smi′ thi.a. M.L. fem. gen. n. *smithia* of Smith, named after Isabel W. Smith.

Nonmotile, approximately 1–2 μm in size, with rounded ends. Cultures on trypticase soy agar (TSA) dissociate into “rough”, “smooth”, and “G-phase” colonies (Duff, 1937). Does not readily produce brown diffusible pigment. In peptone broth, cultures are uniformly turbid. Metabolism is fermentative. Growth occurs at 4–25°C but not at 30°C and in 0–2%, but not 3% NaCl. No growth on MacConkey agar. Catalase, β-galactosidase, H_2S, oxidase, phosphatase, and phosphoamidase are produced, but not indole, arginine dihydrolase, lysine or ornithine decarboxylase, or phenylalanine deaminase. DNA, gelatin, RNA, and starch are degraded, but not aesculin, blood, chitin, elastins, guanine, hypoxanthine, lecithin, Tween 20, 40, 60, 80, or xanthine. Carbon-containing compounds are not readily utilized (Austin et al., 1989a). Differential and descriptive tests to aid in the identification of this nonmotile *A. salmonicida* subspecies, as well as atypical strains, are listed in Table BXII.γ.183. Pathogenic for fish, with mortality within 24–72 h. External hemorrhages are evident in the vent and on the fins, as is tail rot. Accumulation of ascitic fluid occurs in the peritoneal cavity, along with extensive muscle hemorrhaging, liquefaction, and gastroenteritis.

The mol% G + C of the DNA is: 55.9 (T_m).

Type strain: 138, ATCC 49393, CCM 4103.

GenBank accession number (16S rRNA): AJ009859.

11. **Aeromonas schubertii** Hickman-Brenner, Fanning, Arduino, Brenner and Farmer 1989, 205[VP] (Effective publication: Hickman-Brenner, Fanning, Arduino, Brenner and Farmer 1988a, 1563.)
schu.ber′ ti.i. M.L. masc. gen. n.*schubertii,* named after Ralph H.W. Schubert.

Hybridization Group 12 of 17 (Farmer et al., 1986).

At 36°C, positive reactions for methyl red, lysine decarboxylase, arginine dihydrolase, motility, lipase, DNase, reduction of nitrate to nitrite, oxidase, and growth in nutrient broth with 0 and 1% NaCl. No growth in 6% NaCl. Fermentation of D-glucose, D-galactose, maltose, D-mannose, and trehalose. No fermentation of adonitol. L-arabinose, D-arabitol, cellobiose, dulcitol, erythritol, *myo*-inositol, lactose, D-mannitol, melibiose, α-methyl-D-glucoside, raffinose, L-rhamnose, salicin, D-sorbitol, sucrose, and D-xylose. Esculin is not hydrolyzed. String test negative. Differential reactions include failure to ferment D-mannitol, sucrose, L-arabinose, and salicin; failure to produce indole, or hydrolyze esculin, and lack of gas production from glucose (Hickman-Brenner et al., 1988a; Carnahan et al., 1991a). A D-mannitol negative reaction usually differentiates *A. schubertii* from other *Aeromonas* spp. although mannitol-negative strains that are not *A. schubertii* can occur. Extracellular amylase, protease, and DNases produced. High cell surface charge but low hydrophobicity. Major cell wall fatty acids are hexadecenoic ($C_{16:1}$), hexadecanoic ($C_{16:0}$), and octadecanoic acid ($C_{18:1}$) (Kokka et al., 1992). Differential tests to aid in the identification of *A. schubertii* from all motile species are listed in Table BXII.γ.186. Descriptive tests for all the motile species are listed in Table BXII.γ.182. Strains isolated from wounds, abscesses, pleural fluid, and blood. There have been no isolates from human stools (Hickman-Brenner et al., 1988a; Carnahan et al., 1989b).

The mol% G + C of the DNA is: undetermined.
Type strain: ATCC 43700, DSM 4882.
GenBank accession number (16S rRNA): X74682.

12. **Aeromonas sobria** Popoff and Véron 1981, 215[VP] (Effective publication: Popoff and Véron 1976, 20.)
so.bri′ a. M.L. fem. adj. *sobria* moderate.

Hybridization Group 7 of 17 (Popoff et al., 1981; Farmer et al., 1986).

Biochemical results obtained at 25°C after 7 d of incubation. Produces acid and gas from glucose, acid from mannitol and sucrose, and is weakly positive Voges–Proskauer reaction. Lysine decarboxylase is weakly positive after 7 d; arginine dihydrolase and ornithine decarboxylase are not produced. Does not produce acid from L-arabinose. Does not hydrolyze esculin. Does not produce β-hemolysis on sheep blood agar (SBA) (5%). There is no growth at 42°C. Produces gas from glucose at 25°C and no gas at 37°C after 48 h. This species closely resembles *A. veronii* biovar sobria (HG 8) biochemically, although they differ in their arginine dihydrolase and hemolytic reaction (SBA) (Table BXII.γ.186) and their ability to grow at 42°C. Other differences include the ability of *A. sobria* to produce a positive string test (with 0.5% sodium desoxycholate) and susceptibility to O129 (150 μg). Differential tests to aid in the identification of *A. sobria* from all motile species are listed in Table BXII.γ.186. Descriptive tests for all the motile species are listed in Table BXII.γ.182.

The few known strains were isolated from fish, sewage, and water. These strains generally grow optimally at 25–30°C with few exceptions. Thus far, there are no reported human or animal clinical isolates. (There is frequent incorrect reference to this species as a human clinical isolate; see Taxonomic Comments.)

The mol% G + C of the DNA is: 58–60 (T_m).
Type strain: ATCC 43979, CIP 7433, NCIMB 12065.
GenBank accession number (16S rRNA): X74683.

13. **Aeromonas trota** Carnahan, Chakraborty, Fanning, Verma, Ali, Janda and Joseph 1992a, 191[VP] (Effective publication: Carnahan, Chakraborty, Fanning, Verma, Ali, Janda and Joseph 1991b, 1207.)
tro′ ta. Gr. adj. *trotos* vulnerable; M.L. fem. adj. *trota* vulnerable.

Hybridization Group 14 of 17 (Carnahan et al., 1991b).

Its unique biochemical profile includes negative reactions for esculin hydrolysis, L-arabinose fermentation, Voges–Proskauer test, and gluconate oxidation. Positive for cellobiose fermentation, lysine decarboxylase, and citrate utilization. Susceptible to ampicillin (in contrast to almost all other aeromonads) and carbenicillin (Tables BXII.γ.182 and BXII.γ.183). Differential tests to aid in the identification of *A. trota* from all motile species are listed in Table BXII.γ.186. Descriptive tests for all the motile species are listed in Table BXII.γ.182. Strains isolated from human stools, aquatic sources, and extraintestinal human infections. First thought to be found primarily in Southern Asia. Now considered to have worldwide distribution (Carnahan and Joseph, 1993). Documented case of pediatric diarrhea (Reina and Lopez, 1996b).

The mol% G + C of the DNA is: undetermined.
Type strain: AH2, ATCC 49657, DSM 7312.

The species name *Aeromonas enteropelogenes* has been validly published (Schubert et al., 1990a). It appears to be identical to *A. trota*, a more frequently used name (Carnahan et al., 1991b; Collins et al., 1993; Huys et al., 2002a) (see Taxonomic Comments).

14. **Aeromonas veronii** Hickman-Brenner, MacDonald, Steigerwalt, Fanning, Brenner and Farmer 1988b, 220[VP] (Effective publication: Hickman-Brenner, MacDonald, Steigerwalt, Fanning, Brenner and Farmer 1987, 901.)
ve.ro′ ni.i. M.L. gen. n. *veronii* of Véron, named after M.M. Véron.

Hybridization Groups 8/10 of 17 (Popoff et al., 1981; Farmer et al., 1986).

Subsequent to the proposal for this species (formerly termed Enteric Group 77 and HG 10), it was learned that although they had different biochemical reactions, HG 8 was genetically identical to HG 10. Thus, *A. veronii* contained two biogroups (Kuijper et al., 1989a; Altwegg et al., 1990). The first was the originally proposed ornithine decarboxylase positive species, *A. veronii* (HG 10) (Hickman-Brenner et al., 1987). The second group was lysine decarboxylase positive, arginine dihydrolase positive, and ornithine decarboxylase negative, and contained the so-called "clinical" *A. sobria* (HG 8). While the HG 7 environmental strains of *A. sobria* and the former HG 8 *A. sobria* are phenotypically very similar, they are genetically and clinically quite different. For this reason, it was decided to place the

two biogroups of *A. veronii* into two separate biovars, namely biovar veronii and biovar sobria (Joseph et al., 1991).

The mol% G + C of the DNA is: undetermined.

Type strain: ATCC 35624, DSM 7386.

GenBank accession number (16S rRNA): X74684.

Note that the species name *Aeromonas ichthiosmia* (Schubert et al., 1990b) has been validly published, but has been unarguably shown to be identical to *A. veronii* (Carnahan, 1992; Collins et al., 1993, Huys et al., 2001) (see Taxonomic Comments).

a. **Aeromonas veronii** *biovar* **veronii**

String test negative, produces gas from D-glucose, is resistant to O/129, and grows in the absence of added NaCl. This biovar is resistant to ampicillin (10 μg) and carbenicillin (30 μg), and sensitive to cephalothin (30 μg) and colistin (4 μg/ml). Indole positive and Voges–Proskauer positive, produces acid from D-mannitol and sucrose, does not produce acid from L-arabinose, and is pyrazinamidase negative. β-Hemolytic on sheep blood agar (5%).

Aeromonas veronii biovar veronii is characteristically ornithine decarboxylase positive, arginine dihydrolase negative, and esculin and arbutin hydrolysis positive. This biovar can be misidentified as *Vibrio cholerae* in some rapid identification systems (Hickman-Brenner et al., 1987). Differential tests to aid in the identification of *Aeromonas veronii* biovar veronii from all motile species are listed in Table BXII.γ.186. Descriptive tests for all the motile species are listed in Table BXII.γ.182. Isolated from aquatic environments, including leeches (Graf, 1999b) and specimens from human clinical disease including diarrhea, wounds, pulmonary complications, sinusitis (Hickman-Brenner et al., 1987), wounds (Joseph et al., 1991), and bacteremia (Abbott et al., 1994; Janda and Abbott, 1996).

The mol% G + C of the DNA is: 57.6–58.2 (Bd, T_m).

Type strain: ATCC 35624, DSM 7386.

GenBank accession number (16S rRNA): X74684.

b. **Aeromonas veronii** *biovar* **sobria**

String test negative, produces gas from D-glucose, is resistant to O/129, and grows in the absence of added NaCl. This biovar is resistant to ampicillin (10 μg) and carbenicillin (30 μg), and sensitive to cephalothin (30 μg) and colistin (4 μg/ml). Indole positive and Voges–Proskauer positive, produces acid from D-mannitol and sucrose, does not produce acid from L-arabinose, and is pyrazinamidase negative. β-Hemolytic on sheep blood agar (5%).

Aeromonas veronii biovar sobria is characteristically ornithine decarboxylase negative; lysine decarboxylase and arginine dihydrolase positive, and esculin and arbutin hydrolysis negative; β-hemolytic on 5% sheep blood agar and able to grow at 42°C. Differential tests to aid in the identification of *Aeromonas veronii* biovar sobria from all motile species are listed in Table BXII.γ.186. Descriptive tests for all the motile species are listed in Table BXII.γ.182. Associated with gastrointestinal disease and a wide array of extraintestinal and systemic disease including septicemia, wound infections, meningitis, peritonitis, septic arthritis, and hepatobiliary disease (Steinfeld et al., 1998; Janda and Abbott, 1996, 1998b). The reference strain for these clinical isolates, which were formerly considered to be HG 7 *A. sobria*, but in actuality are HG 8 *Aeromonas veronii* biovar sobria, is ATCC 9071.

The mol% G + C of the DNA is: undetermined.

Type strain: ATCC 9071.

Other Organisms

1. *"Aeromonas arequipensis"*

Isolated from a lake in the Arequipa region of Peru; may have diarrheagenic potential for humans (Matte et al., 1999).

2. *"Aeromonas dechromatica"*

This organism was proposed by Kvasnikov et al. (1985). Isolated from chromium-containing industrial wastewater; has basic characteristics of *Aeromonas* spp. Exceptions are requirement for sodium chloride (optimal 3%), mixed flagellation, Gram variable, absence of catalase activity, presence of a crystalline microcapsule; so named because it reduces highly toxic hexavalent chromium ions.

3. *"Aeromonas guangheii"*

This organism was isolated from eels. Unpublished; only one strain.

Deposited strain: 95-173.

GenBank accession number (16S rRNA): AB028881.

4. *"Aeromonas pastoria"*

This organism was proposed (Torres, 1990; Torres et al., 1991) and later included in a large phenotypic study of *Aeromonas* isolates (Noterdaeme et al., 1996). Two strains of *"Aeromonas pastoria"* were examined, one of which fell into their Cluster 2A, which was characterized by nonfermentation of L-arabinose and α-methyl-D-glucoside and by assimilation of citrate. Another strain of *"A. pastoria"*, which was received separately, fell into Cluster 7, which was characterized by the following reactions: negative for production of ornithine decarboxylase; hydrolysis of esculin; assimilation and fermentation of L-arabinose; fermentation of α-methyl-D-glucoside, arbutin, salicin, and lactose; and positive for the assimilation of citrate.

5. "*Aeromonas* Group 501" (formerly Enteric Group 501).

A designation given to two strains in the CDC collection by Hickman-Brenner et al. (1988a), which closely resembled *A. schubertii* but were genotypically and phenotypically different and currently reside in HG 13; see Taxonomic Comments above for further discussion.

Deposited strain: ATCC 43946.

GenBank accession number (16S rRNA): U88663.

6. "*Aeromonas* species ornithine positive" (formerly Enteric Group 77)

Currently resides in HG 11 (Fanning et al., 1985; Farmer et al., 1986; Hickman-Brenner et al., 1987); see Taxonomic Comments above for further discussion about these strains.

Deposited strain: ATCC 35941.

GenBank accession number (16S rRNA): X60417.

7. "Halophilic *Aeromonas* species"

There is a report of a strictly halophilic *Aeromonas* sp. from Atlantic salmon in association skin lesions leading to severe widespread lesions elsewhere, a condition that sug-

gested production of a potent toxin(s). On primary culture, the organism was slow growing (best in the presence of horse blood, 10% w/v) and had a strict requirement for at least 1.0% NaCl. Optimum growth temperature is between 15 and 20°C. No growth at 37°C. Growth at 30°C after 72 h yielded small (1–2 mm), round, low, convex, mucoid, translucent, β-hemolytic colonies. Individual cells were motile, straight, Gram-negative rods. Resistant to vibriostatic agent 0/129 (10 and 150 μg) and susceptible to oxytetracycline, oxalinic acid, furazolidone, and penicillin. Oxidase positive, reduced nitrates, and used D-glucose fermentatively. Majority of biochemical tests were negative, except for gelatinase and D-glucose. Voges–Proskauer test was variable. The organism (NCIMB 2263) was at and was deposited in the National Collection of Industrial and Marine Bacteria Ltd., Aberdeen (Cox et al., 1986).

Species Incertae Sedis

1. **Haemophilus piscium** Snieszko, Griffin and Friddle 1950, 699[AL]

   pis.ci′ um. L. n. *piscis* a fish; L. gen. pl. *piscium* of fishes.

   This microorganism was removed from the genus *Haemophilus* in the first edition of *Bergey's Manual of Systematic Bacteriology* (Kilian and Biberstein, 1984). This exclusion was made on the basis of its DNA base composition, growth factor requirements, cell wall structure, respiratory requirements, respiratory quinones, antigenic composition, and phage susceptibility. It was later concluded that it represents an atypical form of *Aeromonas salmonicida* (Paterson et al., 1980; Austin et al., 1989a). 16S rRNA encoding genes for the reference strains of *A. salmonicida* subsp. *smithia* and *H. piscium*, when amplified by PCR, revealed that these organisms showed 99.4 and 99.6% 16S rRNA gene sequence identity, respectively, with *A. salmonicida* subsp. *salmonicida* (Thornton et al., 1999).

   It should be noted that an authentic type strain of *Haemophilus piscium* was not available in any culture collection, so the *H. piscium* strain (NCIMB 1952) was obtained for use from the National Collection of Industrial and Marine Bacteria, Aberdeen, Scotland (Thornton et al., 1999).

   The mol% G + C of the DNA is: 55.1 (T_m).

   Type strain: ATCC 10801.

   GenBank accession number (16S rRNA): AJ009860.

Genus II. **Oceanimonas** *Brown, Sutcliffe and Cummings 2001, 71*[VP]

THE EDITORIAL BOARD

O.ce.a.ni.mo′ nas. Gr. n. *okeanus* ocean; Gr. fem. n. *monas* monad unit; M.L. fem. n. *Oceanimonas* ocean monad.

Gram-negative motile rods (0.7–1.2 × 2.0–2.5 mm). Up to four polar flagella. **Respiratory metabolism** using O_2. Phosphatidylethanolamine, phosphatidylglyerol, and diphosphatidylglycerol are the main phospholipids. **Require Na^+ for growth**

The mol% G + C of the DNA is: 54 (HPLC).

Type species: **Oceanimonas doudoroffii** (Baumann, Bowditch, Baumann and Beamann 1983b) Brown, Sutcliffe and Cummings 2001, 71 (*Pseudomonas doudoroffii* Baumann, Bowditch, Baumann and Beamann 1983b, 863.)

Further descriptive information

These organisms are chemoorganotrophs found in marine environments.

Enrichment and Isolation Procedures

O. doudoroffii strains were first isolated from Pacific Ocean surface water by enrichment in liquid medium containing allantoin, benzoate, creatine, caprylate, or D-aminovalerate followed by streaking on the same medium (Baumann et al., 1972). *O. baumannii* was isolated from estuary mud by enrichment in liquid minimal salts medium containing phenol as a carbon source and 5% NaCl, followed by streaking onto the same medium solidified with agar (Brown et al., 2001).

Maintenance Procedures

O. doudoroffii strains were maintained on Marine Agar (Difco) slopes with monthly transfer (Baumann et al., 1972).

Differentiation of the genus *Oceanimonas* from other genera

O. doudoroffii DSM 7028^T and *O. baumannii* GB6^T can be distinguished from the type strains of both *Aeromonas hydrophila* and *Tolumonas auensis* by the inability of the former two strains to utilize arabinose, gluconate, glucose, maltose, mannitol, mannose, and sucrose, and by the inability of the latter two strains to utilize malate. *O. doudoroffii* DSM 7028^T and *O. baumannii* GB6^T can be further distinguished from *Tolumonas auensis* by the inability of the latter to grow above 25°C and from *A. hydrophila* by the inability of the latter to utilize citrate and by its ability to produce indole, to produce acid from glucose, to produce arginine hydrolase, to hydrolyze esculin, and to utilize *N*-acetylglucosamine.

Taxonomic Comments

The major reevaluation of the taxonomy of the genus *Pseudomonas* and the reassignment of species in RNA groups II–V to other genera are discussed elsewhere in this volume. In the first edition of the *Manual*, Palleroni (1984) placed *Pseudomonas doudoroffii* in a separate section devoted to organisms whose relationships to those in the *Pseudomonas* RNA groups I–V were not known. Subsequent studies (De Vos et al., 1989; Kersters et al., 1996; Anzai et al., 2000) did not clarify the taxonomic relationships of *Pseudomonas doudoroffii.* Brown et al. (2001) place the genus *Oceanimonas* in the *Gammaproteobacteria* but do not assign it to a family.

List of species of the genus Oceanimonas

1. **Oceanimonas doudoroffii** (Baumann, Bowditch, Baumann and Beamann 1983b) Brown, Sutcliffe and Cummings 2001, 71[VP] (*Pseudomonas doudoroffii* Baumann, Bowditch, Baumann and Beamann 1983b, 863.)

   dou.do.rof′ fi.i. M.L. gen. n. *doudoroffii* of Doudoroff; named after M. Doudoroff.

Gram-negative rods (0.7–1.2 × 2.0–2.5 μm). One to three bipolar flagella. Utilizes acetate, aconitate, D-α-alanine, L-α-alanine, β-alanine, allantoin, γ-aminobutyrate, δ-aminovalerate, L-arginine, L-aspartate, benzoate, betaine, butylamine, caprate, citrate, creatine, ethanol, D-fructose, fumarate, L-glutamate, glutarate, DL-glycerate, glycine, glycolate, histamine, L-histidine, DL-β-hydroxybutyrate, α-ketoglutarate, DL-lactate, DL-malate, L-ornithine, phenol, L-proline, putrescine, pyruvate, L-serine, sarcosine, spermine, and succinate. Does not utilize galactose or glycerol. Oxidase positive. Accumulates poly-β-hydroxybutyrate. Fatty acids include dodecanoic, hexdecanoic, *cis*-hexadecenoic, and *cis*-octadecenoic.

The mol% G + C of the DNA is: 54 (HPLC).

Type strain: ATCC 27123, DSM 7028.

GenBank accession number (16S rRNA): AB019390.

2. **Oceanimonas baumannii** Brown, Sutcliffe and Cummings 2001, 71[VP]

bau.man' ni.i. M.L. gen. n. *baumannii* of Baumann; named after Paul and Linda Baumann, who first studied these organisms.

Gram-negative rods (1 × 2 μm). Aerobic growth on L-alanine, betaine, caprate, citrate, ethanol, L-glutamate, malate, L-proline, phenol, sarcosine, and succinate. Grows in NaCl up to 7% (w/v). Growth temperatures 10–30°C. Utilizes galactose and glycerol. Fatty acids include dodecanoic, hexdecanoic, *cis*-hexadecenoic, and *cis*-octadecenoic.

The mol% G + C of the DNA is: 54 (HPLC).

Type strain: GB6, ATCC 700832, NICMB 13685.

GenBank accession number (16S rRNA): AF168367.

Genus incertae sedis III. **Tolumonas** *Fischer-Romero, Tindall and Jüttner 1996, 187[VP]*

Carmen Fischer-Romero and Brian J. Tindall

To.lu.mo' nas. L. n. *toluolum* toluol (German for toluene); Gr. n. *monas* unit; M.L. fem. n. *Tolumonas* toluene-producing unit.

Cells are **nonmotile**, Gram-negative rods (2.5–3.2 × 0.9–1.2 μm) that occur singly or in pairs. **Growth** occurs under **aerobic and anaerobic** conditions. Anaerobic cultures are catalase and oxidase negative; aerobic cultures are **catalase positive** and **oxidase negative**. **Toluene is produced from phenylalanine, phenylacetate, phenyllactate, and phenylpyruvate** only in the presence of an additional carbon source. Phenol is produced when phenylalanine is replaced by tyrosine. The optimum conditions for anaerobic growth are **22°C** and pH 7.2. The major fermentation products in peptone–yeast extract–glucose cultures are ethanol, acetic acid, and formic acid. Under anaerobic conditions D-arabinose, D-cellobiose, D-fructose, D-glucose, glycogen, inulin, maltose, D-mannose, D-melecitose, melibiose, D-raffinose, L-rhamnose, D-ribose, salicin, sucrose, D-trehalose, D-mannitol, and D-sorbitol are used as carbon sources. In the presence of air the following organic substances are used: Tween 40, Tween 80, L-arabinose, D-fructose, D-galactose, D-glucose, methyl-pyruvate, monomethyl succinate, acetic acid, *cis*-aconitic acid, D-galacturonic acid, D-gluconic acid, D-glucuronic acid, β-hydroxybutyric acid, α-ketoglutaric acid, DL-lactic acid, malonic acid, quinic acid, sebacic acid, succinic acid, glucuronamide, L-alanine, L-asparagine, L-aspartic acid, L-glutamic acid, L-histidine, L-threonine, urocanic acid, and inosine. The enzymes lipase, lecithinase, urease, and exoprotease are not produced. Indole, lipase, and H_2S are not formed. According to the results of 16S rDNA sequence analysis this genus belongs to the *Gammaproteobacteria*.

The mol% G + C of the DNA is: 49.

Type species: **Tolumonas auensis** Fischer-Romero, Tindall and Jüttner 1996, 187.

Further descriptive information

Ecological studies (Fischer-Romero, unpublished results) on the distribution of *Tolumonas auensis* in different lakes and streams of central Europe suggest that this bacterium is not ubiquitously distributed. Cells were not found in surface samples, whereas in the water column the number of *Tolumonas auensis* increased with the depth and reached a maximum in the sediment and the overlying water. In the course of one year the maximum number of *Tolumonas auensis* cells was counted in samples taken in autumn, before the autumnal circulation, concurring with the highest seasonal toluene concentration in the hypolimnion.

Enrichment and Isolation Procedures

Members of the genus *Tolumonas* can be enriched in TP medium inoculated with anoxic freshwater sediment and isolated by agar deep dilutions (Fischer-Romero et al., 1996).

Maintenance Procedures

Strains of the genus *Tolumonas* can be maintained in TP medium at 4°C, after incubation to allow good growth, with monthly transfers or preserved by lyophilization or by storage in liquid nitrogen.

Procedures for Testing Special Characters

To determine the concentration of toluene in the culture media, the method described by Jüttner (1988) may be used. The medium (0.1–75 ml) was supplied with perdeutero-toluene (1 μl perdeutero-toluene/ethanol; 1:1000 v/v) as internal standard and stripped for 30 min in a closed-loop stripping apparatus. Toluene was adsorbed on a Tenax-filled cartridge (150 g Tenax TA) and transferred from these by thermodesorption into a combined GC–MS. Toluene was separated by gas–liquid chromatography on a DB 1301 fused silica capillary column (30 m × 0.32 mm, J & W Scientific) and detected by single ion monitoring (*m/z* 91 and *m/z* 98) on a Hewlett Packard 5970A mass spectrometer.

Differentiation of the genus *Tolumonas* from other genera

Tolumonas transforms phenylalanine and other phenyl precursors into toluene. A few bacteria that are able to transform amino acids into aromatic hydrocarbons have been described. *"Clostridium aerofoetidum"* transforms phenylalanine in a Stickland reaction with methionine into toluene (Pons et al., 1984). *Lacto-*

TABLE BXII.γ.188. Differentiation of the genus *Tolumonas* from the closest phylogenetic relatives[a]

Characteristics	*Tolumonas*	*Aeromonas*	*Citrobacter*	*Escherichia*	*Hafnia*	*Plesiomonas*	*Serratia*	*Vibrio*

[a]For symbols see standard definitions; nd, not determined.

bacillus sp. (Yokoyama and Carlson, 1981) and *Clostridium* sp. strains (Elsden et al., 1976) liberate *p*-cresol and phenol from tyrosine. These organisms differ from *Tolumonas* in their cytophysiological features and in the biochemistry of toluene production.

Other characteristics that differentiate members of the genus *Tolumonas* from their closest phylogenetic relatives, *Escherichia*, *Citrobacter*, *Hafnia*, *Plesiomonas*, *Serratia*, *Vibrio*, and *Aeromonas* (Holt et al., 1994) are shown in Table BXII.γ.188.

Based on the 16S rDNA sequence analysis *Tolumonas auensis* shows about 10% sequence divergence from its nearest neighbors. These include members of the genera *Escherichia*, *Serratia*, *Enterobacter* (i.e., members of the family *Enterobacteriaceae*), *Vibrio*, *Aeromonas*, *Shewanella*, *Alteromonas*, and *Pseudoalteromonas*. A greater degree of dissimilarity is observed between *Tolumonas* and members of the genera *Haemophilus*, *Actinobacillus*, *Pasteurella* (i.e., members of the family *Pasteurellaceae*) *Succinivibrio*, *Succinimonas*, *Anaerobiospirillum*, and *Ruminobacter* (Hippe et al., 1999).

T. auensis produces both ubiquinone 8 and menaquinone 8 (Fischer-Romero et al., 1996). Ubiquinone 8 is found in all members of the genera *Escherichia*, *Serratia*, *Enterobacter* (i.e., members of the family *Enterobacteriaceae*), *Vibrio*, *Aeromonas*, *Shewanella*, *Alteromonas*, and *Pseudoalteromonas* (Wilkinson, 1988; Akagawa-Matsushita et al., 1992a). In some cases, menaquinones with the same isoprenoid chain length are also found, and may comprise both menaquinones and demethyl menaquinones. Members of the genera *Alteromonas* and *Pseudoalteromonas* do not produce menaquinones, while those members of the genus *Shewanella* examined to date produce ubiquinone 7 and 8, but menaquinone 7, and usually, but not always, methylated menaquinone 7 (Akagawa-Matsushita et al., 1992a). Menaquinones are absent from *Ruminobacter amylophilus* (Stackebrandt and Hippe, 1986), while members of the family *Pasteurellaceae* produce either menaquinones and/or demethylnaphthoquinones with seven or eight isoprene units; ubiquinones with the corresponding isoprenoid side chain length may be found, although they apparently are not always present (Kroppenstedt and Mannheim, 1989; Engelhard et al., 1991).

The fatty acid composition of *T. auensis* is dominated by $C_{16:0}$ and $C_{16:1}$ fatty acids (Fischer-Romero et al., 1996), as are the fatty acids of members of the majority of genera listed above. The most notable exceptions are members of the genus *Shewanella* where *iso-* and *anteiso-*branched fatty acids are present in significant quantities. A $C_{14:0\ 3OH}$ fatty acid is also present in *Tolumonas auensis*, approximately half of which appears to be amide linked, probably to the lipopolysaccharide. In members of the family *Enterobacteriaceae* it is well documented that the lipopolysaccharides contain 3-hydroxy fatty acids, in which $C_{14:0\ 3OH}$ predominates, and is present in both an ester- and an amide-linked form (Wilkinson, 1988). It is interesting to note that, in addition to members of the genera *Vibrio*, *Aeromonas*, *Haemophilus*, *Actinobacillus*, *Pasteurella*, *Succinivibrio*, *Succinimonas*, *Anaerobiospirillum*, and *Ruminobacter* also contain a $C_{14:0\ 3OH}$ fatty acid (Miyagawa et al., 1979; Moore et al., 1994a; Urdaci et al., 1990; Engelhard et al., 1991; Huys et al., 1994; Weyant et al., 1996). Depending upon the genus, additional hydroxylated and nonhydroxylated fatty acids may be present, allowing some degree of differentiation between the genera; 2-hydroxy fatty acids are absent in *T. auensis*, and all of the genera listed above.

Phosphatidylethanolamine and phosphatidylglycerol are the major phospholipids present in *T. auensis* (Fischer-Romero et al., 1996). Based on the scant data currently available it appears the same phospholipids predominate in the closest evolutionary relatives, although differentiation between the genera may also be possible based on the presence of additional polar lipids (Wilkinson, 1988; Engelhard et al., 1991).

List of species of the genus Tolumonas

1. **Tolumonas auensis** Fischer-Romero, Tindall and Jüttner 1996, 187[VP]

au.en'sis. M.L. gen. n. *auensis* of Lake Au, the location of the first isolation of this organism.

The characteristics are those of the genus, as described in the text and in Table BXII.γ.189. The major lipoquinones present are ubiquinone 8 and menaquinone 8 under both oxic and anoxic growth conditions. The fatty acid profile of the cells is: $C_{12:0}$, $C_{14:0}$, $C_{14:0\ 3OH}$, $C_{16:1\ \omega7c}$, $C_{16:0}$, and $C_{18:1\ \omega7c}$. Isolated from the anoxic sediment of a freshwater lake.

The mol% G + C of the DNA is: 49 (T_m).

Type strain: TA 4, DSM 9187.

GenBank accession number (16S rRNA): X92889.

Family *incertae sedis* II. **Succinivibrionaceae** Hippe, Hagelstein, Kramer, Swiderski and Stackebrandt 1999, 782[VP]*

George M. Garrity, Julia A. Bell and Timothy Lilburn

Suc.ci.ni.vib.ri.o.na' ce.ae M. L. masc. n. *Succinivibrio* type genus of the family; *-aceae* ending to denote a family; M. L. fem. pl. n. *Succinivibrionaceae* the *Succinivibrio* family.

Gram-negative, short to long, **straight, curved, or helical rods.** Nonsporeforming. **Strict anaerobes.** Catalase negative. **Ferment carbohydrates to succinate and acetate.** No production of gas or reduction of nitrate. Take up CO_2.

The mol% G + C of the DNA is: 39–44.

Type genus: **Succinivibrio** Bryant and Small 1956, 22.

Editorial Note: This family was proposed based on 16S rDNA sequence analysis (Hippe et al., 1999).

Genus I. **Succinivibrio** *Bryant and Small 1956, 22*[AL]*

Marvin P. Bryant

Suc.ci.ni.vib' ri.o. M.L. n. *acidum succinicum* succinic acid; M.L. masc. n. *vibrio* that which vibrates, a generic name; M.L. masc. n. *Succinivibrio* the succinic acid vibrio.

Curved rods, 0.4–0.6 × 1.0–7.0 µm, with pointed ends. The cells are helically twisted with less than one coil to three or more coils per cell. The cells may become straight or only slightly curved after maintenance on artificial media. Gram negative. **Possess a progressive vibrating type of motility by means of a single polar flagellum.** Strictly anaerobic. Chemoorganotrophic, having a fermentative type of metabolism with carbohydrates being the main fermentable substrates. **The major products of glucose fermentation are succinate, acetate, formate, and sometimes lactate.** Butyrate and H_2 are not formed. A large net uptake of CO_2 may occur. Occur in the rumen of cattle and sheep.

The mol% G + C of the DNA is: unknown.

Type species: **Succinivibrio dextrinosolvens** Bryant and Small 1956, 22.

Further descriptive information

Cells from young cultures on RGCA slants[1] are short with one or less than one complete coil, but longer cells containing two or three coils are commonly present also. Cells are mainly single but a few short chains may occur. In aging cultures swollen, giant spirillar forms and round bodies may be present.

Surface colonies on RGCA agar in roll tubes are 1–2 mm in diameter, entire, translucent, slightly convex, and light tan in color after 3 d incubation at 37°C. Deep colonies are lenticular. In liquid media with glucose as the energy source growth occurs as a heavy, flocculent sediment that is easily dispersed; light turbidity also occurs.

Good growth of *S. dextrinosolvens* occurs in a chemically defined medium containing glucose, minerals, *p*-aminobenzoic acid, 1,4-naphthoquinone, ammonium ions, cysteine, methionine, leucine, and serine. The use of a CO_2/HCO_3^- buffer system (pH 6.7) is necessary for good growth (Gomez-Alarcon et al., 1982). Growth occurs at 30–39°C but not at 22° or 45°C.

The final pH in lightly buffered glucose medium is 4.8–5.2. *S. dextrinosolvens* requires a fermentable carbohydrate for growth and does not ferment amino acids. Succinic and acetic acids, and often formic and lactic acids, are produced from fermentation of glucose. Gas is not produced. Xylose, galactose, glucose, maltose, and dextrin can serve as fermentable substrates. Arabinose, fructose, cellobiose, sucrose, esculin, salicin, and mannitol are fermented by some strains. No fermentation of lactose, trehalose, cellulose, xylan, inulin, glycerol, or inositol occurs. Starch is partially fermented but not completely hydrolyzed. Nitrate is not reduced. Gelatin is not hydrolyzed. Acetoin, indole, and H_2S are not produced. The catalase test is negative.

Urease is produced by many strains but is strongly repressed in media containing large amounts of ammonia or other utilizable nitrogen sources (Wozny et al., 1977).

S. dextrinosolvens is not pathogenic for animals as far as is known. Isolates corresponding to the description of the organism have been isolated from a few cases of human bacteremia (Southern, 1975; Porschen and Chan, 1977).

S. dextrinosolvens is found in the rumen of cattle and sheep, especially when high-grain diets containing large amounts of starch are fed (Bryant and Small, 1956; Bryant et al., 1961; Wozny et al., 1977). The organism appears to be a major fermenter of dextrins under these conditions.

Enrichment and Isolation Procedures

S. dextrinosolvens is sometimes a predominant organism from the rumen of cattle fed high-grain diets, and can be isolated nonselectively in anaerobic roll tubes of RGCA medium incubated for 3 d or longer at 37°C.

Maintenance Procedures

S. dextrinosolvens can be maintained on stab-inoculated RGCA slants at −70°C for 1 year or longer. The organisms can also be preserved indefinitely by lyophilization.

Differentiation of the genus *Succinivibrio* from other genera

Succinivibrio differs from *Anaerobiospirillum* by having monotrichous rather than lophotrichous flagella. It differs from the genus *Anaerovibrio* by not producing a large amount of propionate, by not fermenting glycerol, and by its ability to ferment dextrin.

Editorial Note: The chapter on *Succinivibrio* is reprinted from the 1st edition of *Bergey's Manual of Systematic Bacteriology*.

1. RGCA slants (g/l): K_2HPO_4, 0.23 g; KH_2PO_4, 0.45; $(NH_4)_2SO_4$, 0.45; NaCl, 0.45; $MgSO_4$, 0.023; $CaCl_2$, 0.023; resazurin, 0.001; glucose, 0.5, cellobiose, 0.5; soluble starch, 0.5; rumen fluid (centrifuged), 400; cysteine·HCl, 0.25; $Na_2S{\cdot}9H_2O$, 0.25; Na_2CO_3, 4.0, agar (Difco), 10.0; pH 6.7; gas phase, 100% CO_2. Prepared and used with the Hungate technique (Bryant, 1972).

List of species of the genus Succinivibrio

1. **Succinivibrio dextrinosolvens** Bryant and Small 1956, 22.[AL]
dex.tri.no.sol′vens. M.L. n. *dextrinosum* dextrin; L. part. adj. *solvens* dissolving; M.L. part. adj. *dextrinosolvens* dextrin-dissolving.

The characteristics are as described for the genus.

Found in the bovine and ovine rumen.

The mol% G + C of the DNA is: unknown.

Type strain: 554, 24 of Bryant and Small (1956), ATCC 19716, DSM 3072.

GenBank accession number (16S rRNA): Y17600.

Genus II. **Anaerobiospirillum** *Davis, Cleven, Brown and Balish 1976, 503[AL] emend. Malnick 1997, 383*

Henry Malnick

An.ae.ro.bi.o.spi.ril′lum. Gr. prefix *an* not; Gr. n. *aer* air; Gr. n. *bios* life; M.L. dim. neut. n. *spirillum* a small spiral; M.L. neut. n. *Anaerobiospirillum* anaerobic small spiral.

Helical rods 0.6–0.8 × 3–15 μm, usually occurring singly. Some cells are up to 32 μm in length. **Motile by bipolar tufts of flagella**. Do not form endospores. Gram negative. **Anaerobic, having a strictly fermentative type of metabolism**. Catalase negative or weakly positive. Oxidase negative. Do not hydrolyze esculin, gelatin, hippurate, or urea. Do not reduce nitrate. Lipase activity does not occur. Indole is not produced and meat is not digested. **Ferment carbohydrates; produce succinic and acetic acids from glucose**. May also produce traces of lactic and formic acids. Optimal temperature 37–44°C. **Isolated from feces of dogs and cats. Pathogenic for humans, causing septicemia and/or diarrhea**. Belongs to the class *Gammaproteobacteria*, order *Aeromonadales*, and family *Succinivibrionaceae*.

The mol% G + C of the DNA is: 39–44.

Type species: **Anaerobiospirillum succiniciproducens** Davis, Cleven, Brown and Balish 1976, 503.

Further descriptive information

The diameter of the cell helix is 0.9–1.1 μm. Straight rods and spherical forms may occur, especially in liquid cultures. Some strains of *Anaerobiospirillum succiniciproducens*, including the type strain, can be pleomorphic, often producing bizarre forms. This feature seems to be rare in *A. thomasii.* The cells have a corkscrew-like motility. The flagella are 14 nm in diameter and are arranged as bipolar tufts of ~16 flagella.

Ultrastructural examination of *A. succiniciproducens* has shown that the cells possess fibrils arranged along the longitudinal axis within the cell. So far, this has not been described in any other organism. The flagellar base within the cell is disc shaped (Wecke and Horbach, 1999).

Surface colonies on most types of blood agar are 0.5–1.0 mm in diameter, circular, convex, and translucent after 2–3 days anaerobic incubation at 37°C. Colonies may have raised centers. Spreading or feathery edges from heavily inoculated areas is not uncommon on some media. Growth is most rapid at 37–40°C and does not occur below 33°C or above 44°C. Cells do not survive 80°C for 10 min.

Although requiring an anaerobic atmosphere for growth, *Anaerobiospirillum* spp. will survive in an atmosphere of reduced oxygen within a jar until other bacteria present have reduced the atmosphere. It is in this way that fecal isolates of *A. thomasii* were isolated on Skirrow's *Campylobacter* isolation medium.

At usual therapeutic levels, isolates of *Anaerobiospirillum* spp. are susceptible to amoxicillin-clavulanate, azithromycin, cefoxitin, ciprofloxacin, chloramphenicol, and trovafloxacin, and are resistant to cephalexin, clarithromycin, clindamycin, lincomycin, nalidixic acid, polymyxin B, sulfamethoxazole, and vancomycin. Susceptibility to ampicillin, erythromycin, penicillin G, and metronidazole is variable. *A. succiniciproducens* is mezlocillin resistant and gemifloxacin variable, and has an MIC for trimethoprim of 4 μg/ml, whereas *A. thomasii* is mezlocillin and gemifloxacin sensitive and has an MIC for trimethoprim of >256 μg/ml (McNeil et al., 1987b; Goldstein et al., 1999, Malnick, unpublished results).

Under favorable conditions of pH 6.2 and high CO_2 concentrations, *A. succiniciproducens* can produce industrially significant levels of succinate (up to 35 g/l) (Datta, 1989). The phosphoenolpyruvate-carboxykinase-encoding gene (*pckA*) involved has been sequenced, and the amino acid sequence—deduced from the data—encodes a 532-residue polypeptide. Phosphoenolpyruvate carboxykinase is a CO_2-fixing enzyme (Laivenieks et al., 1997).

Anaerobiospirillum species have been reported as causing septicemia and diarrhea in man. There appears to be a difference in pathogenicity between the two species. *A. succiniciproducens* has been isolated from blood cultures of patients suffering from septicemia, and in a number of cases it was reported either as the cause of death or as a contributory factor. Most of the patients involved had underlying disorders. So far, the isolation of *A. thomasii* has only been reported from cases of diarrhea (McNeil et al., 1987b; Malnick et al., 1990).

Of three isolates of *A. succiniciproducens* described by Davis et al. (1976), one came from the throat and two from cecal homogenate of dogs. Further studies have shown both species are found as part of the fecal flora in cats and dogs. Although the organisms seem to be part of the normal intestinal flora of these animals, no definite ecological function is known (Malnick et al., 1990).

Enrichment and Isolation Procedures

An enrichment and serial dilution method for obtaining isolates from throat and cecal contents of dogs was used without the aid of a selective medium by Davis et al. (1976). A selective medium for the isolation of *Anaerobiospirillum* spp. has been described (Malnick et al., 1990). It consists of a suitable anaerobic agar medium supplemented with (per liter): polymyxin, 2500 IU; vancomycin, 20 mg; sulfamethoxazole, 100 mg; Victoria blue B (Cl 44045 Sigma), 250 mg; and horse blood lysed with saponin, 50 ml. The Victoria blue was initially dissolved in 4 ml of ethanol. After 48–72 h of anaerobic incubation, *Anaerobiospirillum* species produce dark blue colonies, depending on the basal medium. Other organisms produce white or pale blue colonies.

Maintenance Procedures

Anaerobiospirillum spp. can be maintained at −70°C or in liquid nitrogen on beads, with any of a variety of cryoprotectants. The organisms can also be preserved by lyophilization.

Differentiation of the genus *Anaerobiospirillum* from other genera

The genus is distinguished from *Succinivibrio* and *Campylobacter* by its lophotrichous flagellar arrangement. In clinical situations, *Anaerobiospirillum* species have most often been confused with *Campylobacter*, however, *Campylobacter* species are oxidase positive and do not ferment carbohydrates. Production of succinic and acetic acids from glucose may help differentiate *Anaerobiospirillum* from other curved and spiral anaerobic bacteria.

Taxonomic Comments

The phylogenetic relationship between *Anaerobiospirillum* and other Gram-negative, strictly anaerobic bacteria has been determined by 16S rDNA sequence analysis, placing these organisms in the family *Succinivibrionaceae* (Hippe et al., 1999).

The DNA–DNA hybridization values between the type strain of *A. succiniciproducens* and the type strain of *A. thomasii* are less than 6% (Malnick, 1997).

Differentiation of the species of the genus *Anaerobiospirillum*

Characteristics useful in differentiating the two species of the genus are listed in Table BXII.γ.190.

List of species of the genus Anaerobiospirillum

1. **Anaerobiospirillum succiniciproducens** Davis, Cleven, Brown and Balish 1976, 503[AL]
suc.ci.ni.ci.pro.du'cens. M.L. n. *acidum succinicum* succinic acid; L. pres. part. *producens* producing; M.L. part. adj. *succiniciproducens* producing succinic acid.

The characteristics are as described for the genus and in Table BXII.γ.190, with the following additional information. Helical rods 0.6–0.8 × 3–15 μm. Produces weak β-hemolysis. Fixes CO_2.

The mol% G + C of the DNA is: 42–44 (T_m).
Type strain: S411, ATCC 29305, NCTC 11536.
GenBank accession number (16S rRNA): U96412.

2. **Anaerobiospirillum thomasii** Malnick 1997, 383[VP]
thom'as.i.i. N.L. gen. n. *thomasii* of Thomas, named after M.E.M. Thomas (Public Health Laboratory Service, 1947–1984), whose interest in and enthusiasm for uncommon medical bacterial infections led to the initiation of this study.

The characteristics are as described for the genus and in Table BXII.γ.190, with the following additional information. Helical rods, 0.5–0.7× 5–32 μm. Optimum temperature 37°C; range, 33–43°C. Colonies are flat with even, spreading edges, 1–2 mm in diameter after 24–48 h on horse blood agar. Hemolysis does not occur. Isolated from cat and dog feces and as a pathogen in human diarrheal feces.

The mol% G + C of the DNA is: 39–41 (T_m).
Type strain: NCTC 12467.
GenBank accession number (16S rRNA): AJ420985.

Genus III. **Ruminobacter** *Stackebrandt and Hippe 1987, 179[VP] (Effective publication: Stackebrandt and Hippe 1986, 205)*

Erko S. Stackebrandt

Ru.mi.no.bac′ter. L. adj. *ruminalis* of the rumen; M.L. masc. n. *bacter* equivalent of bacterium, a small rod; M.L. masc. n. *Ruminobacter* small rod of the rumen.

Oval to long rods. Gram negative. Nonsporeforming. Nonmotile. Chemoorganotroph. **Metabolize carbohydrates; fermentation products include succinate, acetate, and formate; trace amounts of lactate and ethanol may be formed. No rumen fluid requirement for growth. Obligately anaerobic.** CO_2 required, which is incorporated into succinic acid. NH_3 is essential as a nitrogen source. No cytochromes. Peptidoglycan contains *meso*-diaminopimelic acid. Sphingophospholipids absent. Straight chain saturated $C_{16:0}$ fatty acid predominates, while $C_{14:0}$ acid and the monounsaturated $C_{16:1}$ and $C_{18:1}$ acids occur in smaller amount. Low levels of iso- and anteiso-methyl branched fatty acids. Analysis of 16S rDNA places the genus into the family *Succinivibrionaceae* of the *Gammaproteobacteria*.

The mol% G + C of the DNA is: 40–42.

Type species: **Ruminobacter amylophilus** (Hamlin and Hungate 1956) Stackebrandt and Hippe 1987, 179 (Effective publication: Stackebrandt and Hippe 1986, 205) (*Bacteroides amylophilus* Hamlin and Hungate 1956, 552.)

Further descriptive information

As the genus currently contains a single species, the description of the genus is that of the species. The presence of an A–U base pair at positions 19 and 916 indicates that *R. amylophilus* belongs to a broad phylogenetic cluster of organisms within the *Gammaproteobacteria*, all of which are defined by the presence of this signature, such as members of the *Succinivibrionaceae*, *Aeromonadaceae*, *Enterobacteriaceae*, *Vibrionaceae*, *Pasteurellaceae*, *Methylococcaceae*, *Halomonadaceae*, and *Oceanospirillaceae*.

The colonial and cultural properties are based on the descriptions of Hamlin and Hungate (1956), Holdeman and Moore (1974), Cato et al. (1978), and Holdeman et al. (1984b). Cells of the type strain of *R. amylophilus* are pleomorphic after incubation for 2 d in peptone–yeast extract-maltose broth. Gram-negative, oval to long rods with tapered or round ends, and include some swollen forms and irregularly curved cells, 0.9–1.2 × 1.1–8.0 µm (Cato et al., 1978). Surface colonies on rumen fluid-glucose-cellobiose agar roll tubes are 1 mm in diameter, circular, entire, slightly convex, translucent, smooth, glistening, white to tan. Colonies on blood roll streak tubes are pinpoint to 2 mm in diameter, circular, entire to slightly erose, convex to slightly erose, convex to umbonate, translucent, colorless, shiny, and smooth after incubation for 4 d. Growth is sparse on freshly prepared blood agar plates incubated anaerobically. Surface colonies on rumen fluid–glucose–cellobiose agar roll tubes are 1 mm in diameter, circular, entire, slightly convex, translucent, smooth, glistening, white to tan. Colonies in deep agar are 0.8–1 mm in diameter, lenticular, entire or irregular, white, and soft butyrous. Growth is not stimulated by amino acids, volatile fatty acids (Miura et al., 1980), vitamins, or hemin (Macy and Probst, 1979). No colonies appear on egg yolk agar plates and on the surface of plates incubated in an aerobic jar.

The organism is strictly anaerobic. Only bicarbonate and/or CO_2, a fermentable carbohydrate, and minerals are required for growth. Rumen fluid is not required (Bryant and Robinson, 1962). Ammonia is essential as a nitrogen source. CO_2 is fixed and ammonia is assimilated. In the presence of CO_2 maltose is fermented to succinate: 2 maltose + $2CO_2 \rightarrow$ 2 succinate + 2 acetate + 2 formate (Kühn, 1979). Production of succinic acid has been patented (U.S. Pat. 5,143,833). The organism is able to grow well in basal medium supplemented with starch. Starch broth cultures are turbid and have a final pH of 5.3–5.5. Amylase production is stimulated by Tween 80 (McWethy and Hartman, 1977). Autolysis occurs after growth ceases and the degradation of bacterial protein is accompanied by the production of branched-chain amino acids (Miura et al., 1980). The organism is strongly proteolytic (Abou-Akkada and Blackburn, 1963), and protease is produced in the exponential growth phase (Blackburn and Hallah, 1974).

Optimum temperature for growth is near 37°C. Hydrogen is not produced; no growth in 20% bile; esculin not digested; milk and meat reaction negative. Cellulose is not digested. Casein is not utilized but is digested when cells are grown in ammonia-containing media (Caldwell et al., 1973). Protease is produced in the exponential growth phase (Blackburn, 1968; Blackburn and Hallah, 1974). Acid is produced from dextrin, glycogen, maltose, and starch. No acid is produced from amygdalin, arabinose, cellobiose, esculin, fructose, D-galactose, D-glucose, glycerol, inositol, inulin, lactose, D-mannitol, raffinose, L-rhamnose, ribose, salicin, sucrose, trehalose, and D-xylose. Strains are very sensitive to inhibition by heavy metals and trace elements (Forsberg, 1978).

An almost complete *rrn* operon, consisting of the 5′ upstream promoter region, the 16S rDNA gene of 1539 nucleotides (accession number Y15992), the intergenic spacer, including a tRNA (*gln*) gene (Martens et al., 1987), and the 23S rDNA (Spiegl et al., 1988) (accession number X06765) has been sequenced from a BgII-Kpn1 fragment of strain DSM 1361[T] (plasmid number DSM 4825). A partial 16S rDNA sequence, consisting of 1429 nucleotides, of a *R. amylophilus* strain with no assigned strain number has recently been released under the accession number AB004908. The similarity of the common stretch of the two 16S rDNA sequences is 99.7%.

Cytochromes (Reddy and Bryant, 1977) and sphingolipids have not been detected (Kunsman and Caldwell, 1974; Miyagawa et al., 1978). Menaquinones (R. Kroppenstedt, personal communication) are absent. Peptidoglycan contains *meso*-diaminopimelic acid (Miyagawa et al., 1981).

Ruminobacter amylophilus is one of the predominant anaerobic bacteria obtained in pure culture from ruminal contents of a Holstein cow. The bacterium thrives on basal medium supplemented with maltose and ammonia. A casein hydrolysate plus volatile fatty acids is only slightly stimulatory and glucose and cellobiose cannot substitute for maltose (Bryant and Robinson, 1962). *R. amylophilus* occurs sporadically in the rumen contents of cattle but, when present, may be the predominant starch digester and may constitute as much as 10% of the bacterial population of the rumen. It also occurs also in the ovine rumen (Blackburn and Hobson, 1962; Bryant and Robinson, 1962).

Enrichment and Isolation Procedures

None of the media described in the literature on the isolation of *Ruminobacter (Bacteroides) amylophilus* was designed to specifically enrich this organism. The media used are those to survey proteolytic bacteria present in the rumen of sheep (Blackburn and Hobson, 1962) and cows (Hamlin and Hungate, 1956; Bryant and Robinson, 1962). In some of these studies, the animals were fed different diets. As *R. amylophilus* does not require rumen fluid, a nonrumen fluid medium is described that has been used to isolate *R. amylophilus* (Bryant and Robinson, 1962). The basal medium contains 0.3% maltose, 0.0001% resazurin, 0.4% Na_2CO_3, 0.025% (each) cysteine-HCl·H_2O and $Na_2S{\cdot}9H_2O$, 0.09% (each) KH_2PO_4 and NaCl, 0.002% (each) $CaCl_2$ and $MgCl_2{\cdot}6H_2O$, 0.001% $MnCl_2{\cdot}H_2O$, 0.001% $CoCl_2{\cdot}6H_2O$, 0.2 mg per 100 ml (each) of thiamine-HCl, Ca-D-pantothenate, nicotinamide, riboflavine, and pyridoxal, 0.01 mg per 100 ml of *p*-aminobenzoic acid, 0.05 mg per 100 ml (each) of biotin, folic acid, and DL-thioctic acid, 0.02 mg per 100 ml of cobalamin, and is equilibrated with oxygen-free CO_2. All ingredients except cysteine, Na_2S, and Na_2CO_3 were mixed, adjusted to pH 6.5 with H_2SO_4, and autoclaved at 15 psi for 15 min. Sterile, CO_2-equilibrated Na_2CO_3 solution is added and the medium is added to tubes (13 × 100 mm) in 2.8 ml amounts, using anaerobic methods and CO_2 (Bryant and Robinson, 1961). Two milliliters each of 0.09% $(NH_4)_2SO_4$, and 2 mg/100 ml hemin plus 0.2 ml of a solution of cysteine, and Na_2S brings the medium constituents to final concentration.

According to Blackburn and Hobson (1962), samples are taken via a rumen cannula and rapidly strained to remove coarse debris. Tenfold dilutions of rumen fluid are made under CO_2 in a solution prepared exactly like the medium. Bacteria are cultured in 50-ml flasks each containing 25 ml of medium. For dilutions, the role tube method can be used as described by Bryant and Burkey (1953).

Maintenance Procedures

R. amylophilus is routinely maintained in the DSM-German Collection of Microorganisms and Cell Cultures in medium DSM 147 (DSM catalog of strains, 2001), containing (per 1000 ml distilled water): KH_2PO_4, 0.45 g; K_2HPO_4, 0.45 g; $(NH_4)_2SO_4$, 0.9g; NaCl, 0.9g; $MgSO_4{\cdot}7H_2O$, 0.18g; soluble starch, 5.0 g; casitone (Difco), 10.0 g; resazurin, 1.0 mg; cysteine hydrochloride, 0.5 g; $NaHCO_3$, 6.0 g; pH 7.0, at a gas atmosphere of 100 CO_2. For short-term storage, stab cultures in a modified medium DSM 147 is recommended, in which the starch content is reduced to 0.1%. For long-term conservation, freezing in liquid nitrogen is recommended.

Differentiation of the genus *Ruminobacter* from other genera

Recent phylogenetic analyses on some Gram-negative strictly anaerobic, nonsporeforming bacteria indicated *Ruminobacter amylophilus* to be a member of a separate line of descent that includes *Succinimonas amylolytica*, *Succinivibrio dextrinosolvens*, and members of the genus *Anaerobiospirillum*. This phylogenetic group has been described as *Succinivibrionaceae* (Hippe et al., 1999) (Fig. BXII.γ.188).

Taxonomic Comments

The first culture of *Bacteroides amylophilus*, isolated and described by Hamlin and Hungate (1956), was lost. Since then, organisms conforming to the original description of *B. amylophilus* have been isolated frequently from the rumen (Blackburn and Hobson, 1962; Bryant and Robinson, 1962; Caldwell et al., 1969; Holdeman et al., 1977). Cato et al. (1978) designated strain H 18 isolated by Blackburn and Hobson (1962), as the neotype strain of *B. amylophilus*. This species differs from the majority of *Bacteroides* species in a number of chemotaxonomic properties, e.g., fatty acid composition (Miyagawa et al., 1979) and the lack of sphingophospholipids (Kunsman and Caldwell, 1974; Miyagawa et al., 1978). These differences led Miyagawa et al. (1979) and Shah and Collins (1983) to the conclusion that *B. amylophilus* should be removed from *Bacteroides sensu stricto*. These conclusions were supported by the finding that *B. amylophilus* and authentic members of *Bacteroides* belong to different main phylogenetic lines of descent. The results of 16S ribosomal RNA cataloging (Woese et al., 1985) and later by 16S rDNA analysis (Martens et al., 1987) revealed that *B. amylophilus* groups loosely with the "core" organisms (e.g., enterobacteria, vibrios, oceanospirilla, alteromonads) of the *Gammaproteobacteria*, while authentic *Bacteroides* species (e.g., *B. fragilis*, *B. asaccharolyticus*, *B. distasonis*, *B. melaninogenicus*, *B. ovatus*, *B. ruminicola*, *B. thetaiotaomicron*, *B. uniformis*, and *B. vulgatus*) form a coherent cluster within the *Bacteroides-Cytophaga-Flavobacterium* line of descent (Paster et al., 1985). Consequently, *Bacteroides amylophilus* was reclassified as *Ruminobacter amylophilus* (Stackebrandt and Hippe, 1986). The generic name "*Ruminobacter*" was originally used to describe Gram-negative, nonmotile, anaerobic chemoheterotrophic cellulose fermenting bacteria (Kaars Sijpesteijn, 1949). Prévot (1966) considered this genus as *incertae sedis*, but at the same time transferred the *Bacteroides* species "*Bacteroides amylogenes*", *B. ruminicola*, *B. succinogenes*, and the noncellulolytic species *B. amylophilus* into this genus. The taxon *Ruminobacter* was not included in the Approved Lists of Bacterial Names (Skerman et al., 1980); hence, it had no standing in nomenclature and could be proposed to accommodate the former *B. amylophilus*.

Analysis of 16S rDNA sequence is to date the most reliable method by which isolates can be affiliated to *Ruminobacter amylophilus*. Without sequence information and placement, this species can be misclassified as *Prevotella ruminicola* (Shah and Collins, 1990) or *Fibrobacter succinogenes* (Montgomery et al., 1988), organisms that were previously classified as nonmotile members of *Bacteroides*. *Ruminobacter amylophilus* differs considerably from these organisms in a combination of properties, e.g., the pattern of carbohydrates utilized, fermentation products, mol% G + C of their DNA, and fatty acid composition. *Ruminobacter* differs phenotypically from other genera previously grouped in the family *Bacteroidaceae* as defined by Holdeman et al. (1984a). *Ruminobacter* can be distinguished from *Fusobacterium* and *Leptotrichia* by the end-products of carbohydrate fermentation (Holdeman et al., 1984a). On the basis of metabolic properties *Ruminobacter* can also be distinguished unambiguously from several other genera containing Gram-negative obligate-anaerobes that have been described recently, viz. *Acidaminobacter* (Stams and Hansen, 1984), *Ilyobacter* (Stieb and Schink, 1985), *Pelobacter* (Schink and Pfennig, 1982a), *Propionigenium* (Schink and Pfennig, 1982b), and *Propionispira* (Schink et al., 1982), all of which are phylogenetically related to members of the *Clostridium-Bacillus* line of descent.

List of species of the genus Ruminobacter

1. **Ruminobacter amylophilus** (Hamlin and Hungate 1956) Stackebrandt and Hippe 1987, 179[VP] (Effective publication: Stackebrandt and Hippe 1986, 205) (*Bacteroides amylophilus* Hamlin and Hungate 1956, 552.)
   am.y.lo' phi.lus. Gr. n. *amylo* starch; Gr. part. *philo* loving; M.L. adj. *amylophilus* starch loving.

   The characteristics are described for the genus.

   Occurs sporadically in the rumen of the bovine and sheep.

   The mol% G + C of the DNA is: 40-42 (Bd).

   Type strain: H 18, ATCC 29744, DSM 1361, VIP 2502B.

   GenBank accession number (16S rRNA): Y15992.

   Additional Remarks: GenBank accession number for 23S rRNA gene is X06765.

Genus IV. Succinimonas *Bryant, Small, Bouma and Chu 1958, 21*[AL]*

Marvin P. Bryant

Suc.ci.ni.mo' nas. M.L. n. *acidum succinicum* succinic acid; Gr. n. *monas* a unit, monad; M.L. fem. n. *Succinimonas* succinic acid monad.

Short, straight rods to coccobacilli, 1.0–1.5 µm × 1.0–3.0 µm, with rounded ends. No spores or resting stages are produced. Gram negative. **Motile by a single polar flagellum.**

Strictly anaerobic. Chemoorganotrophic, having a fermentative type of metabolism. **Glucose, maltose, dextrin, or starch can serve as the energy source. Succinate and acetate are the main products of glucose fermentation.** No butyrate or gas is formed. Catalase negative. Occur in the bovine rumen.

The mol% G + C of the DNA is: unknown.

Type species: **Succinimonas amylolytica** Bryant, Small, Bouma and Chu 1958, 21.

Editorial Note: The chapter on *Succinimonas* is reprinted from the 1st edition of *Bergey's Manual of Systematic Bacteriology.*

Further descriptive information

In the water of syneresis of RGCA slants[1] incubated overnight at 37°C, the cells are arranged as singles, pairs, and clumps. No capsules are evident. Motility is relatively slow and progressive and is rapidly lost upon exposure to air.

Surface colonies on RGCA agar in roll tubes are smooth, convex, translucent, light tan, and 0.7–1.5 mm in diameter after 3 d incubation at 37°C. Deep colonies are lenticular and 0.7–1.0

1. RGCA slants (g/l): K_2HPO_4, 0.23 g; KH_2PO_4, 0.45; $(NH_4)_2SO_4$, 0.45; NaCl, 0.45; $MgSO_4$, 0.023; $CaCl_2$, 0.023; resazurin, 0.001; glucose, 0.5; cellobiose, 0.5; soluble starch, 0.5; rumen fluid (centrifuged), 400; cysteine·HCl, 0.25; $Na_2S \cdot 9H_2O$, 0.25; Na_2CO_3, 4.0; agar (Difco), 10.0; pH 6.7; gas phase, 100% CO_2. Prepared and used with the Hungate technique (Bryant, 1972).

mm in diameter. In liquid media with glucose as the energy source growth occurs as light, uniform turbidity.

The type strain of *S. amylolytica* grows well in a glucose medium with rumen fluid replaced by trypticase and yeast extract. It also grows in a chemically defined medium containing glucose, CO_2/HCO_3 buffer, minerals, B vitamins, and acetate. Ammonium ions serve as the nitrogen source and cannot be replaced by amino acids or peptides. Sulfide serves as both the reducing agent and the sulfur source. Acetate (30 mM) is a highly stimulatory supplement even though the organisms produce acetate from glucose (Bryant and Robinson, 1962; Roberton and Bryant, unpublished data). During fermentation of glucose to succinate and acetate, a net uptake of CO_2 occurs. Of the substrates tested, only glucose, maltose, dextrin, and starch are fermented. Arabinose, xylose, fructose, cellobiose, lactose, sucrose, cellulose, inulin, xylan, glycerol, esculin, mannitol, lactate, amino acids, and peptides are not fermented. H_2S and indole are not produced. Gelatin is not liquefied. The Voges–Proskauer test is variable. Nitrate is not reduced.

Growth occurs at 30° and 37°C but not at 22° or 45°C. The final pH in poorly buffered, liquid glucose medium is 5.2–5.8. Good growth occurs at pH 6.5–7.0. The upper pH limit has not been determined.

S. amylolytica appears to be nonpathogenic for humans or animals. It occurs in the rumen of cattle fed diets containing roughage and some grain, where it is involved in fermentation of starch and its hydrolytic products. It is usually present as only a small proportion of the total viable bacteria in the bovine rumen (less than 6% of total). Whether *S. amylolytica* occurs in the rumen of ruminants other than cattle or in nonruminal ecosystems is not known.

Enrichment and Isolation Procedures

Succinimonas is isolated nonselectively in anaerobic roll tubes of RGCA medium from the rumen of cattle fed hay-grain diets. It constitutes only a small proportion of the colonies that develop after 3 d or longer of incubation at 37°C.

Maintenance Procedures

S. amylolytica strains can be maintained on stab-inoculated RGCA slants at −70°C for a year or more. They can also be preserved indefinitely by lyophilization.

Type genus: **Escherichia** Castellani and Chalmers 1919, 941. Designated type genus Nom. Fam. Cons. Opin. 15, Jud. Comm. 1958a, 73.

Further descriptive information

The definition of the family circumscribes a large biochemically and genetically related group that shows substantial heterogeneity in its ecology, host range, and pathogenic potential for man, animals, insects and plants. The phylogenetic position of the family *Enterobacteriaceae* lies within the *Gammaproteobacteria*. Its nearest neighbors are the families *Alteromonadaceae*, *Vibrionaceae*, *Aeromonadaceae*, and *Pasteurellaceae*. Phylogenetic relationships of genera within the *Enterobacteriaceae* based on analysis of the 16S rRNA sequences of the type strains of the type species are shown in Fig. BXII.γ.189. Phenotypic characteristics useful in differentiating *Enterobacteriaceae* from its nearest phenotypic neighbors are shown in Table BXII.γ.191. The genera *Vibrio*, *Photobacterium*, and *Aeromonas* are oxidase positive, have polar flagella when grown in liquid media, and do not contain the enterobacterial common antigen—characteristics which distinguish them from *Enterobacteriaceae*. However, at least two *Vibrio* species (*V. metschnikovii* and *V. gazogenes*) are oxidase negative; strains of other species are oxidase negative or weakly positive; and, under certain conditions (often on solid media), members of these genera produce peritrichous flagella. Some *Aeromonas* species show higher DNA relatedness to *E. coli*, the type species of the type genus of *Enterobacteriaceae*, than that seen between several genera within the family. 16S rRNA gene sequence comparisons do not reveal any overlap between these families.

Biochemical variability and fastidiousness of a growing number of new species added to *Enterobacteriaceae*, the proposed inclusion in the family of the genus *Plesiomonas*, and the inclusion of *Calymmatobacterium* and a number of genera that are endosymbionts of insects has made a literal description of this family difficult. *Calymmatobacterium* is very fastidious, and cultivation is rarely successful—no strains are available in culture collections. The insect symbionts in the genera *Arsenophonus* (Gherna et al., 1991; Hypsa and Dale, 1997), *Buchnera* (Munson et al., 1991b; Clark et al., 1992), and *Wigglesworthia* (Aksoy, 1995b) have not been cultivated on bacteriological media, and therefore no biochemical profiles are available. These species can only be identified by their 16S rRNA gene sequences and perhaps by their host specificity. The description of the family therefore includes many traits for which there are exceptions. For example, *Plesiomonas*, a biochemically well-defined genus with a single species, is oxidase positive genus in an extremely large, oxidase negative family. Similarly, all cultivated species except *Erwinia chrysanthemi* contain enterobacterial common antigen, a trait that is specific for the family *Enterobacteriaceae*; two members of the family *Pasteurellaceae*, *Actinobacillus equuli* and *Actinobacillus suis*, also possess this antigen (Le Minor et al., 1972; Ramia et al., 1982; Böttger et al., 1987).

The relationships of many members of *Enterobacteriaceae* have been defined based on DNA relatedness (Wayne et al., 1987; Fox et al., 1992; Stackebrandt and Goebel, 1994). DNAs from species within most genera are at least 20% related to one another and to *Escherichia coli*, the type species of the type genus of the family. Notable exceptions are species of *Plesiomonas*, *Yersinia*, *Proteus*, *Providencia*, *Hafnia*, *Edwardsiella*, *Xenorhabdus*, and *Photorhabdus*, whose DNAs are usually 5–20% related to those of species from other genera. Most species have been analyzed by their 16S rDNA sequence. 16S rDNA sequence analysis is the method of choice for determining genera and higher taxa (Stackebrandt and Goebel, 1994); however, DNA relatedness can also be used to approximate evolutionary divergence within genera (Fig. BXII.γ.190).

The numbers of genera and species in the family have markedly increased during the past 25 years. There were 12 genera and 36 species in 1974 when the 8th edition of *Bergey's Manual of Determinative Bacteriology* was published (Buchanan and Gibbons, 1974). By 1984, when the 1st edition of *Bergey's Manual of Systematic Bacteriology* was published, the family contained 20 genera and 76 species (Krieg and Holt, 1984). The total rose to 30 genera and 107 species by the 9th edition of *Bergey's Manual of Determinative Bacteriology* in 1994 (Holt et al., 1994). In the classification used in this chapter, the family contains 44 genera and 176 named species. Unnamed published and unpublished genomospecies and presently undescribed groups undoubtedly include a number of new genera and species. A prediction of 225 or more species contained in 60 or more genera by the next edition of this *Manual* may be conservative.

Compared with the 1st edition of *Bergey's Manual of Systematic Bacteriology* and the 9th edition of *Bergey's Manual of Determinative Bacteriology*, the present volume contains proposed changes in classification, new genera, and new species. Taxonomic proposals since the last edition of the *Manual* are shown in Table BXII.γ.192 and discussed below and in the chapters describing individual genera. If there is any certainty with respect to the *Enterobacteriaceae*, it is that the family will continue to change and to pose a challenge to microbiologists in all specialties.

Plant, animal, and human disease *Enterobacteriaceae* are distributed worldwide. They are found in soil, water, fruits, meats, eggs, vegetables, grains, flowering plants and trees, and in animals from insects to man. Their pathogenicity for man and animals and economic importance, as well as their rapid generation time, ability to grow on defined media, and ease of genetic manipulation have made them the objects of intense laboratory study.

Many species are of considerable economic importance. Erwiniae and pectobacteria cause blight, wilt and soft-rot disease in corn, potatoes, apples, sugar cane, pineapples, and many other crops, often destroying substantial amounts of these crops (Starr and Chatterjee, 1972). For example, it has been estimated that plant pathogenic species causing soft rot diseases have caused at least $50 million of damage annually (Pérombelon and Kelman, 1980). The commercial and tropical fish industries are severely affected by the diseases caused by *Yersinia ruckeri* and species of *Edwardsiella* (Ewing et al., 1978; Shotts and Snieszko, 1976).

Salmonellosis in poultry and in eggs is a worldwide problem, both for poultry farmers and as a vehicle for human disease (Williams, 1965; Von Rockel, 1965; Hall, 1965; Mishu et al., 1994). Salmonellosis is also common in pigs, cows, horses, dogs, and cats (Barnes and Sorensen, 1975; Ewing, 1969). Stillbirths and wool damage in sheep are usually caused by salmonellae (Jensen,

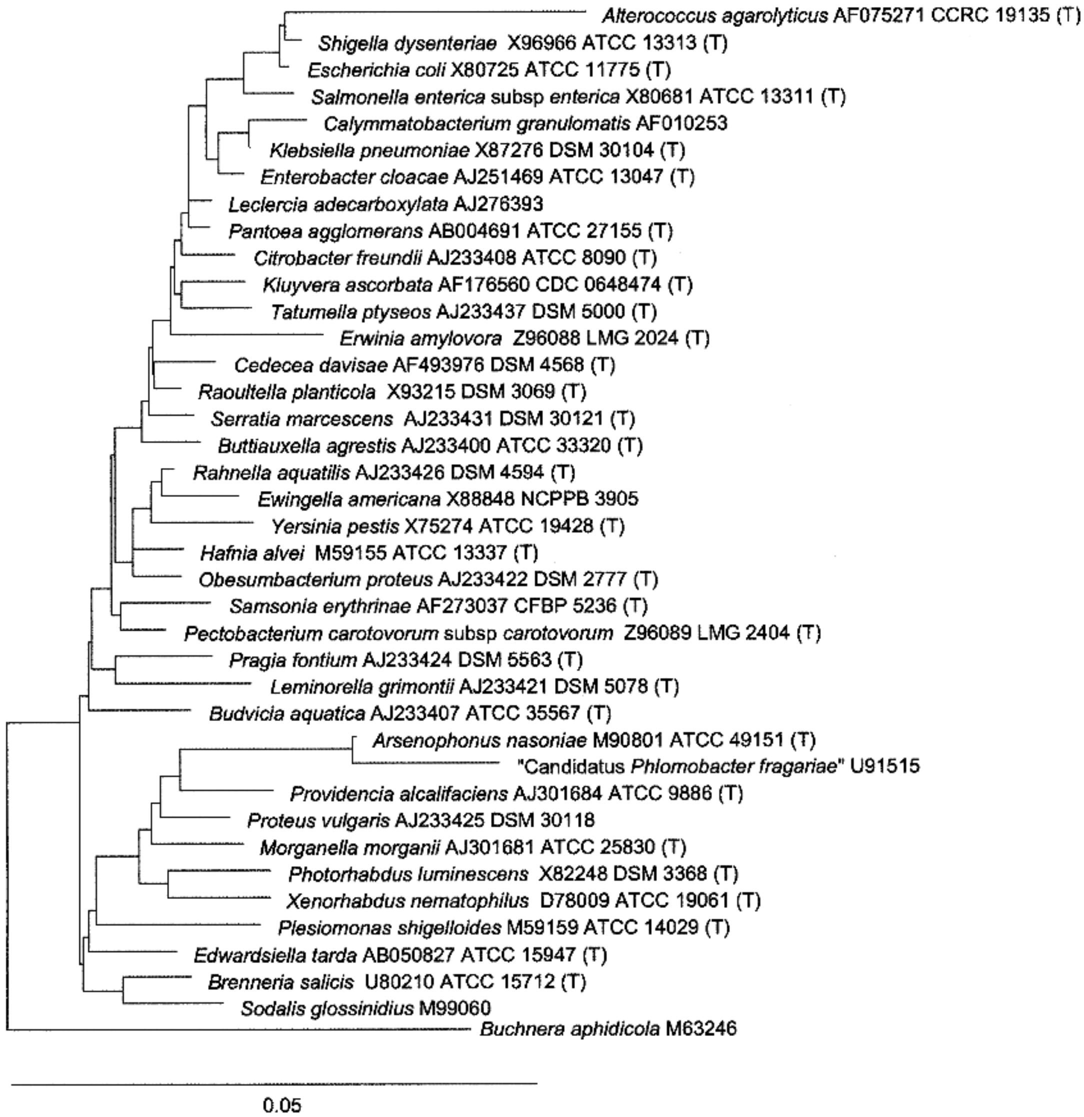

FIGURE BXII.γ.189. Phylogenetic relationships of the genera of the family *Enterobacteriaceae*. The distances in the tree were calculated using 1101 positions (the least-squares method, Jukes-Cantor model). (Courtesy T. Lilburn of the Ribosomal Database Project.)

1974). Enterotoxigenic *E. coli* strains are primarily responsible for diarrhea in lambs, piglets, and calves (Bruner and Gillespie, 1973). Klebsiellae and *Citrobacter freundii* are causes of bovine mastitis. Species of *Enterobacteriaceae* are responsible for numerous other animal infections. Examples include sexually transmitted uterine infections in horses caused by *Klebsiella pneumoniae*; infections in snakes, turtles and lizards caused by salmonellae; diarrheal and septicemic infection in rabbits, mink, and other rodents caused by yersiniae; and shigellosis in monkeys.

Salmonella serotype Typhi (*Salmonella typhi*) is the cause of typhoid fever, and *Yersinia pestis* causes bubonic and pneumonic plague. Many other *Enterobacteriaceae* are pathogenic for humans, causing a wide variety of diseases. These include diarrheal disease, usually transmitted by contaminated food or water; septicemia; respiratory disease; wound and burn infections; urinary tract infections; and meningitis. The causative agents of these diseases can be loosely divided into species that are normally pathogenic (*Salmonella*, *Shigella*, *K. pneumoniae*, *Y. pestis*, various serotypes of *E. coli*, and *Y. enterocolitica*) and species that cause disease under certain circumstances. Members of this second group are often referred to as opportunistic pathogens. The compromised host (for example, the malnourished, diabetic, immunosuppressed, catheterized, burn, cancer, respiratory, AIDS, or elderly patient) is vulnerable to nosocomial infections caused by opportunistic pathogens. *Enterobacteriaceae* have long been responsible for a substantial percentage of nosocomial infections in the United States (Jarvis et al., 1984), including urinary tract infections, surgical wound infections, lower respiratory infections, and bacteremias.

Salmonellae, *E. coli*, and shigellae are frequent causes of foodborne disease outbreaks (Beane et al., 1990), and *Yersinia enterocolitica* also causes foodborne disease. More recently, *E. coli* O157:H7, *Salmonella* serotype Typhimurium phage type 104 (definitive type 104, resistant to at least 5 antimicrobials), and *Salmonella* serotype Enteritidis phage type 4, have emerged as major foodborne pathogens (Boyce et al., 1995; Altekruse et al., 1997). *Salmonella* serotypes Typhimurium and Enteritidis are the two most prevalent causes of human salmonellosis in the United

Cells contain menaquinones[h]	D	D	−	D
Parasitic on mammals and birds	D	−[c]	+	−[c]
Heme and/or nicotinamide adenine dinucleotide required for growth	−	−	D	−
Plant pathogenicity	D	−	−	−
Organic nitrogen sources required	−[c]	−	+	−[c]

[a]Symbols: see standard definitions.

[b]Except *Ruminobacter*, *Tolumonas*, and certain biogroups of *Aeromonas salmonicida*.

[c]A few exceptions may occur.

[d]Except *Plesiomonas*, which has lateral polar flagella, and *Tatumella*, which may have polar, subpolar or lateral flagella.

[e]Except *Plesiomonas*.

[f]Except *Vibrio metschnikovii* and *Vibrio gazogenes* in *Vibrionaceae* and the genus *Tolumonas* in *Aeromonadaceae*.

[g]*Erwinia chrysanthemi* does not contain the antigen; *Actinobacillus equuli* and *Actinobacillus suis* contain the antigen.

[h]*Pasteurellaceae* do contain demethylmenaquinones but not menaquinones; ubiquinones may or may not be produced. *Enterobacteriaceae*, *Vibrionaceae*, and *Aeromonadaceae* may contain menaquinones, demethylmenaquinones, and ubiquinones.

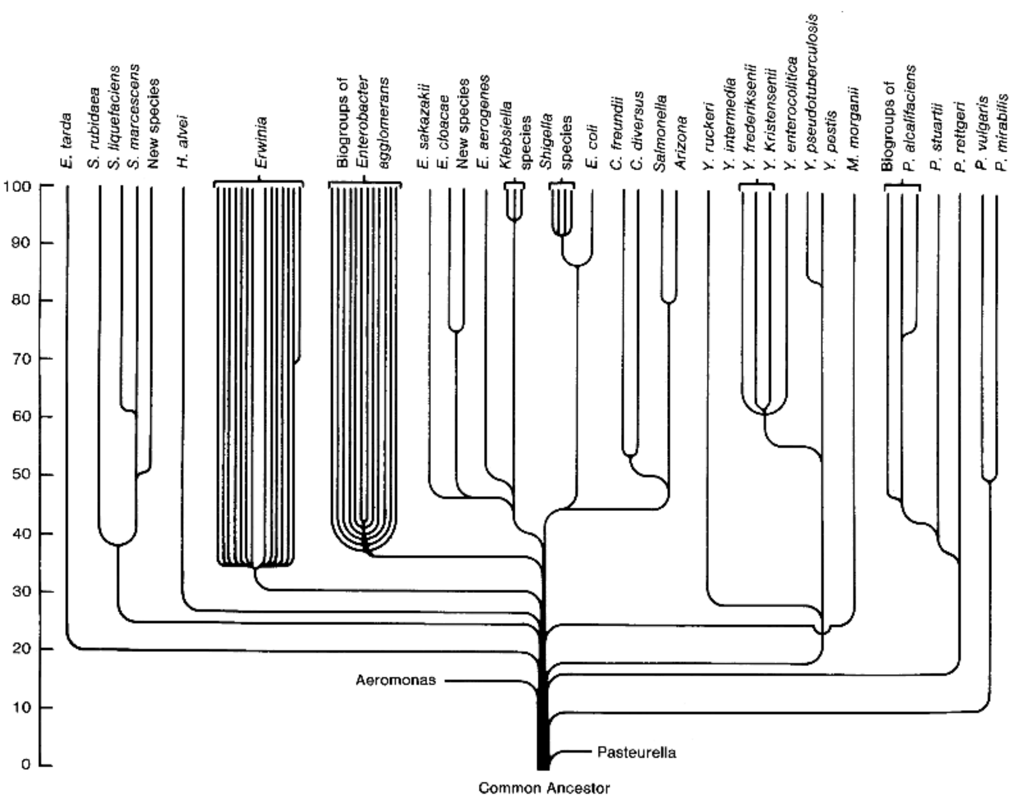

FIGURE BXII.γ.190. Divergence of *Enterobacteriaceae*. The ordinate is percentage of relatedness. This figure is a simplified attempt to depict relatedness of species of enterobacteria to other species. It assumes a common ancestor from which all of the organisms have diverged. The horizontal branches depict the degree of relatedness of the group of organisms to all organisms that have not yet branched. For example, *E. tarda* is 20% related to all organisms except *Aeromonas*, *Proteus*, *Providencia* and *Pasteurella*; *Citrobacter* species are 45% related to all species that branch above them and *C. diversus* and *C. freundii* were speciated at a point in time such that they are now 50% related.

TABLE BXII.γ.192. Comparison of the classification with that in the *Bergey's Manual of Systematic Bacteriology*, First Edition, and *Bergey's Manual of Determinative Bacteriology*, Ninth Edition[a]

[a]NL, not listed.

[b]*Enterobacter intermedius* and *Kluyvera cochleae* have identical 16S rRNA sequences.

[c]Name used in *Bergey's Manual of Systematic Bacteriology*, First Edition, 1984.

[d]Name used in *Bergey's Manual of Determinative Bacteriology*, Ninth Edition, 1994.

States and in the United Kingdom. Outbreaks due to *E. coli* O157:H7 have occurred in the United States, Europe, Asia, and Africa. In the United States, this organism is the leading cause of hemolytic uremic syndrome, the main cause of acute kidney failure in children (Boyce et al., 1995). *Enterobacteriaceae* are also significant causes of waterborne disease outbreaks.

Maintenance Procedures The following procedures have been used for many years in the Enteric Reference Laboratory, CDC, and seem to work well for all the genera and species of *Enterobacteriaceae*. Many other procedures have been described in the literature, but there have been few, if any, good comparative studies.

Long term preservation of cultures. Compared to many other organisms, strains of *Enterobacteriaceae* are simple to grow and maintain. However, strains will die if they are allowed to dry on plating media, agar slants or in "deeps." This die off is mainly due to drying. Freezing and storage at low temperature is the method of choice for long term preservation and maintenance. An alternative method is lyophilization and storage at 4°C, which is used routinely, with good results, by the American Type Culture Collection.

Preparation of a permanent frozen stock of the "whole culture." All important cultures of *Enterobacteriaceae* should be frozen and stored in liquid nitrogen. If liquid nitrogen storage is not available, they can be stored in a laboratory freezer at −70°C, or even in a "home freezer" at −10 to −20°C. The lowest tem-

perature available should be used for long term storage. The culture to be maintained is first inoculated heavily and grown on a blood agar plate for 24 h (or longer if it grows slowly). Growth from the heavy area of growth (designated as the "whole culture," as opposed to a single colony) is removed with a cotton swab, and a very heavy suspension is made in 10% skim milk (a variety of other suspending media are also in general use). One ml of this suspension is then removed to a sterile plastic freezer vial. A permanent marking pen is used to write the genus and species names and the strain number. The vial is then frozen in an alcohol bath kept in the freezer. Vials are then transferred to a 100-compartment storage box and stored at the lowest temperature available.

Preparation of a "working stock" culture of the single colony. This procedure is recommended for cultures that are used frequently, since it avoids the inconvenience of repeatedly going to a freezer. Growth from the top of a single, isolated colony is touched and stabbed to the bottom of a 13 × 100 mm screw-cap tube of working stock medium. The culture is grown overnight and checked to insure that the tube has good growth. The tube is sealed by closing the cap tightly. These working stocks are convenient for daily use. A small amount of growth is removed with a loop and transferred to a plate or tube of a good growth medium. After incubation, the culture is ready to use. The sealing method described above does not give an air-tight fit, thus water from the semi-solid medium will begin to evaporate at a rate dependent on the tightness of the fit. Drying is not a problem for many months, but eventually the viable count of the culture may begin to drop. To avoid this problem, two alternative sealing methods are used. A small volume (about 0.3 ml) of sterile mineral oil can be added to cover the surface (about 3 mm above the interface), which prevents evaporation of the medium. This works extremely well in preventing evaporation, but the mineral oil is messy and must be considered when the culture is transferred. A second method to prevent drying is to insert a number "000" white rubber stopper into the neck of the screw-cap tube to seal it. Cultures are conveniently stored at room temperature in the dark in 40-compartment divided boxes. Many species of *Enterobacteriaceae* survive for decades with this method, but some species die more quickly than others. To avoid the death of cultures, they should be frozen in addition to being stored at room temperature.

Differentiation of genera and species of *Enterobacteriaceae* Genera and species of the family *Enterobacteriaceae* have traditionally been differentiated based on biochemical tests. Unfortunately, the media and tests are not completely standardized, and few laboratories use exactly the same formulations or procedures. Even with these variables, this approach usually results in correct identifications of the common species of *Enterobacteriaceae.* Biochemical reactions for *Enterobacteriaceae* are presented in Table BXII.γ.193. All species were studied in a single laboratory (the Enteric Reference Laboratories at the Centers for Disease Control and Prevention, Atlanta, GA, USA) by a single set of methods (Edwards and Ewing, 1972; Farmer et al., 1980a; Hickman and Farmer, 1978). Because different methods and tests are often used in different laboratories, the percentage of positive reactions obtained may differ somewhat from those presented in the chapters on specific genera. The purpose of Table BXII.γ.193 is not to advocate any given set of tests or to put undue emphasis on the percentages obtained, but to present a comprehensive comparison derived from a single set of data obtained by tests commonly done in a diagnostic laboratory. Commercial identification systems and computer-aided identification are also widely used. These methods can be supplemented by identification based on genus- and/or species-specific tests, which can be both sensitive and specific. (An example is bacteriophage O1, which is both sensitive and specific for the most common serotypes of *Salmonella.*) Several of these tests are listed in Table BXII.γ.194. Many genera and species of *Enterobacteriaceae* also have typical patterns of resistance and susceptibility to antibiotics; thus, the antibiogram of an isolate can also be used as an aid to identification (Table BXII.γ.195). Detailed discussions of practices in clinical microbiology laboratories for isolation, maintenance, storage, computer-aided identification, use of commercial test "kits", antibiotic susceptibility testing, and difficulties presented by "problem strains" of *Enterobacteriaceae* can be found in Brenner (1992b) and Farmer (1999).

From 50 to more than 200 biochemical tests have been used in phenetic or numerical taxonomic studies of *Enterobacteriaceae* (Bascomb et al., 1971; Johnson et al., 1975; Véron, 1975; Véron and Le Minor, 1975a, b). These include tests for the fermentation of a large number of carbohydrates and polyhydroxyl alcohols, tests for the ability to use a wide variety of organic substrates as the sole source of carbon and energy, and tests for the presence of specific enzymes. A number of these tests are useful for the differentiation of species, subspecies, or biogroups within *Enterobacteriaceae* (Véron and Le Minor, 1975a, b). Some tests of particular diagnostic value are for nitrate reductase type A or type B (Pichinoty and Piéchaud, 1968; Pichinoty et al., 1969), tetrathionate reductase (Richard, 1977), fermentation or growth on D-galacturonate (Le Minor et al., 1979), presence of α-glutamyl transferase (Giammanco et al., 1980), and fermentation or growth on 2-ketogluconate (Buissière et al., 1981). A summary of data obtained at the Institut Pasteur for these tests is given in Table BXII.γ.196. Other nonroutine tests of value in differentiating between phenotypically similar organisms are ascorbate and D-arabitol for *Buttiauxella* and *Kluyvera*; L-fucose, 5-ketogluconate, D-xylose, and D-sorbose to differentiate *Klebsiella* from *Enterobacter*; susceptibility to *Hafnia*-specific bacteriophage to differentiate *Hafnia* from other genera; pectinase to differentiate erwiniae from other genera; ascorbate, D-glucose fermentation at 5°C within 21 d, and irgasan susceptibility to differentiate *Kluyvera* species; tyrosine clearing to differentiate *Leminorella* species from biochemically similar species; growth in *trans*-aconitate, adonitol, benzoate, *m*-erythritol, gentisate, D-malate, L-rhamnose, and *m*-tartrate to differentiate *S. liquefaciens*, *S. proteamaculans*, and *S. grimesii*; growth in histamine, D-melizitose, and D-tartrate to differentiate *S. rubidaea* subspecies; and bioluminescence, pigment on Loeffler's blood serum, colony color on MacConkey agar, and adsorption of bromthymol blue to differentiate *Photorhabdus* and *Xenorhabdus* species. Reactions for species in these specialized tests are given in the following genus chapters.

Molecular methods can be used to identify bacteria at taxonomic levels from the family down to the strain; furthermore, molecular tests based on virulence and pathogenicity genes can be used to distinguish pathogenic and nonpathogenic isolates. Many of these methods have been described for *Enterobacteriaceae.* For example, detection of the *phoE* gene by PCR amplification provides a sensitive and specific test for *Escherichia* and *Shigella.* A growing number of genus or species-specific probes have been reported in the literature. A number of systems for identification by either complete or partial 16S rRNA gene sequencing are now under development.

[a]Each number is the percentage of positive reactions after 2 d at 36°C unless otherwise indicated (gelatin liquefaction and deoxyribonuclease; *Photorhabdus luminescens*).

[b]Table taken from Farmer, 1999.

[c]In a Request for an Opinion published in 1987, Le Minor and Popoff proposed replacement of the type species of *Salmonella* (*Salmonella choleraesuis* subsp. *choleraesuis*) with *Salmonella enterica* as the former was considered to be a source of confusion. Although the Request was denied by the Judicial Commission, their proposal resulted in an alternative naming convention which has found widespread endorsement in the public health community. This matter was revisited in July 2002 by the Judicial Commission during the IUMS Congress in response to several new Requests for an Opinion and will likely result in a decision to replace the type strain *Salmonella choleraesuis* subsp. *choleraesuis* with *Salmonella enterica* subsp. *enterica* LT2, while preserving the former rather than placing it on the list of rejected names. We view the six subspecies of *Salmonella choleraesuis* as deprecated. Readers are also advised that the names *Salmonella enteritidis*, *Salmonella paratyphi*, *Salmonella typhi*, and *Salmonella typhimurium* are synonyms of *Salmonella enterica* subsp. *enterica* and refer to specific serovars. These names have not been deprecated at this time as they remain in use by some public health reporting agencies.

[a]Each number is the percentage of positive reactions after 2 d at 36°C unless otherwise indicated (gelatin liquefaction and deoxyribonuclease; *Photorhabdus luminescens*).

[b]Table taken from Farmer, 1999.

[c]In a Request for an Opinion published in 1987, Le Minor and Popoff proposed replacement of the type species of *Salmonella* (*Salmonella choleraesuis* subsp. *choleraesuis*) with *Salmonella enterica* as the former was considered to be a source of confusion. Although the Request was denied by the Judicial Commission, their proposal resulted in an alternative naming convention which has found widespread endorsement in the public health community. This matter was revisited in July 2002 by the Judicial Commission during the IUMS Congress in response to several new Requests for an Opinion and will likely result in a decision to replace the type strain *Salmonella choleraesuis* subsp. *choleraesuis* with *Salmonella enterica* subsp. *enterica* LT2, while preserving the former rather than placing it on the list of rejected names. We view the six subspecies of *Salmonella choleraesuis* as deprecated. Readers are also advised that the names *Salmonella enteritidis*, *Salmonella paratyphi*, *Salmonella typhi*, and *Salmonella typhimurium* are synonyms of *Salmonella enterica* subsp. *enterica* and refer to specific serovars. These names have not been deprecated at this time as they remain in use by some public health reporting agencies.

[a]Each number is the percentage of positive reactions after 2 d at 36°C unless otherwise indicated (gelatin liquefaction and deoxyribonuclease; *Photorhabdus luminescens*).

[b]Table taken from Farmer, 1999.

[c]In a Request for an Opinion published in 1987, Le Minor and Popoff proposed replacement of the type species of *Salmonella* (*Salmonella choleraesuis* subsp. *choleraesuis*) with *Salmonella enterica* as the former was considered to be a source of confusion. Although the Request was denied by the Judicial Commission, their proposal resulted in an alternative naming convention which has found widespread endorsement in the public health community. This matter was revisited in July 2002 by the Judicial Commission during the IUMS Congress in response to several new Requests for an Opinion and will likely result in a decision to replace the type strain *Salmonella choleraesuis* subsp. *choleraesuis* with *Salmonella enterica* subsp. *enterica* LT2, while preserving the former rather than placing it on the list of rejected names. We view the six subspecies of *Salmonella choleraesuis* as deprecated. Readers are also advised that the names *Salmonella enteritidis*, *Salmonella paratyphi*, *Salmonella typhi*, and *Salmonella typhimurium* are synonyms of *Salmonella enterica* subsp. *enterica* and refer to specific serovars. These names have not been deprecated at this time as they remain in use by some public health reporting agencies.

[b]Table taken from Farmer, 1999.

[c]In a Request for an Opinion published in 1987, Le Minor and Popoff proposed replacement of the type species of *Salmonella* (*Salmonella choleraesuis* subsp. *choleraesuis*) with *Salmonella enterica* as the former was considered to be a source of confusion. Although the Request was denied by the Judicial Commission, their proposal resulted in an alternative naming convention which has found widespread endorsement in the public health community. This matter was revisited in July 2002 by the Judicial Commission during the IUMS Congress in response to several new Requests for an Opinion and will likely result in a decision to replace the type strain *Salmonella choleraesuis* subsp. *choleraesuis* with *Salmonella enterica* subsp. *enterica* LT2, while preserving the former rather than placing it on the list of rejected names. We view the six subspecies of *Salmonella choleraesuis* as deprecated. Readers are also advised that the names *Salmonella enteritidis*, *Salmonella paratyphi*, *Salmonella typhi*, and *Salmonella typhimurium* are synonyms of *Salmonella enterica* subsp. *enterica* and refer to specific serovars. These names have not been deprecated at this time as they remain in use by some public health reporting agencies.

TABLE BXII.γ.194. Screening tests for genera and species of *Enterobacteriaceae* often isolated from human clinical specimens[a]

Organism (genus, species, or serovar)	Test or property[b, c, d]
Salmonella	Lactose$^-$, sucrose$^-$, H_2S^+, 01 phage^{+e}, MUCAP$^+$, agglutinates in polyvalent serum[d], typical colonies on media selective/differential for *Salmonella* (brilliant green agar, SS agar, Rambach agar, etc.), lysed by the *Salmonella* specific bacteriophage[e], often antibiotic resistant
Salmonella Typhi	H_2S^+ (trace amount only), agglutinates in group D serum
Shigella	Nonmotile, lysine$^-$, gas$^-$, agglutinates in polyvalent serum, biochemically inactive, often antibiotic resistant, molecular test: *phoE*$^+$
Shigella dysenteriae	Agglutinates in group A serum, D-mannitol$^-$
Shigella dysenteriae O1	Catalase$^-$, agglutinates in O1 serum, Shiga toxin$^+$
Shigella flexneri	Agglutinates in group B serum, D-mannitol$^+$
Shigella boydii	Agglutinates in group C serum, D-mannitol$^+$
Shigella sonnei	Agglutinates in group D serum, D-mannitol$^+$
Escherichia coli	Extremely variable biochemically, indole$^+$, MUG$^+$, grows at 44.5°C, sometimes antibiotic resistant, molecular test: *phoE*$^+$
Escherichia coli O157:H7	Colorless colonies on sorbitol-MacConkey agar, MUG$^-$, D-sorbitol$^-$ (or delayed), agglutinates in O157 serum and H7 serum
Yersinia	Grows on CIN agar; often more active biochemically at 25°C than 36°C; motile at 25°C, nonmotile at 36°C; urea$^+$
Yersinia enterocolitica (pathogenic serogroups)	CR-MOX$^+$, pyrazinamidase$^-$, salicin$^-$, esculin$^-$, agglutinates in O sera: 3; 4, 32; 5, 27; 8; 9; 13a, 13b; 18; 20; or 21
Yersinia enterocolitica O3 (a pathogenic serogroup)	D-Xylose$^-$, agglutinates in O3 serum, tiny colonies at 24 h on plating media
Yersinia enterocolitica nonpathogenic serogroups	CR-MOX$^-$, pyrazinamidase$^+$, salicin$^+$, esculin$^+$, no agglutination in O sera: 3; 4, 32; 5, 27; 8; 9;13a, 13b; 18; 20 or 21
Citrobacter	Citrate$^+$, lysine decarboxylase$^-$, often grows on CIN agar, strong characteristic odor
Hafnia	Lysed by *Hafnia*-specific bacteriophage[e], often more active biochemically at 25°C than 36°C
Klebsiella	Mucoid colonies, encapsulated cells, nonmotile, lysine$^+$, very active biochemically, ferments most sugars, VP$^+$, malonate$^+$, resistant to carbenicillin and ampicillin
Enterobacter	Variable biochemically, citrate$^+$, VP$^+$, resistant to cephalothin
Serratia	DNase$^+$, gelatinase$^+$, lipase$^+$, resistant to colistin and cephalothin
Serratia marcescens	L-arabinose$^-$
Serratia, other species	L-arabinose$^+$
Proteus-Providencia-Morganella	Phenylalanine$^+$, tyrosine hydrolysis$^+$, often urea$^+$, resistant to colistin
Proteus	Swarms on blood agar, pungent odor, H_2S^+, gelatin$^+$, lipase$^+$
Proteus mirabilis	Urea$^+$, indole$^-$, ornithine decarboxylase$^+$, maltose$^-$
Proteus vulgaris	Urea$^+$, indole$^+$, ornithine decarboxylase$^-$, maltose$^+$
Providencia	No swarming, H_2S^-, ornithine decarboxylase$^-$, lipase$^-$
Morganella	Very inactive biochemically, no swarming, citrate$^-$, H_2S^-, ornithine decarboxylase$^+$, gelatin$^-$, lipase$^-$, urea$^+$

[a]Table taken from Farmer, 1999.

[b]Abbreviations: CIN, cefsulodin-irgasan-novobiocin agar (a plating medium selective for *Yersinia*); CR-MOX, Congo red, magnesium oxalate agar (a differential medium useful for distinguishing pathogenic from nonpathogenic strains of *Yersinia*); MUCAP, 4-methyl-umbelliferyl caprylate (a genus-specific test for *Salmonella*); MUG, 4-methyl-umbelliferyl-β-D-glucuronidase; ONPG, *o*-nitrophenyl-β-D-galactopyranoside; *phoE*, a test done by PCR that is sensitive and specific for *E. coli/Shigella*; VP, Voges–Proskauer.

[c]This table gives only the general properties of the genera, species, and serogroups; exceptions occur. See Table BXII.γ.193 for full biochemical reactions. The properties listed for a genus or group of genera generally apply for each of its species, and the properties listed for a species generally apply for each of its serogroups.

[d]Biochemical test results are given as percentages in Table BXII.γ.193. The serological tests refer to slide agglutination in group or individual antisera (O1, O3, etc.) for *Salmonella*, *Shigella*, *E. coli*, or *Yersinia*, respectively.

[e]These are bacteriophage tests useful for identification.

Taxonomy and Nomenclature Compared with the 1st edition of *Bergey's Manual of Systematic Bacteriology* and the 9th edition of *Bergey's Manual of Determinative Bacteriology*, the present volume contains nomenclatural changes, new genera, and new species. In Table BXII.γ.192, the authors' proposed classification is compared with that in the previous two *Manuals*. Nomenclatural synonyms exist for a number of species, as shown in Table BXII.γ.192.

Arsenophonus A second species has provisionally been added to the genus as *Arsenophonus triatominarum*. The *candidatus* status was used because this species has only been recognized on the basis of its 16S rDNA sequence, and has not been isolated or characterized biochemically (Hypsa and Dale, 1997).

***Candidatus* Phlomobacter fragariae** The designation "Candidatus" is given to presumed new species that have not been cultivated. One such organism has been described whose 16S rDNA sequences place it within the family *Enterobacteriaceae* (Zreik et al., 1998). It has been named, *Candidatus* Phlomobacter fragariae. It is restricted to the phloem of strawberries and is associated with marginal chlorosis of strawberry (Zreik et al., 1998).

Citrobacter *Citrobacter koseri*, *Citrobacter diversus*, and *Levinea malonatica* are all synonyms for the same species. In response to a request for an opinion (Frederiksen, 1990), the Judicial Commission issued the opinion that *C. diversus* was a *nomina rejicienda* (rejected name). Therefore, the correct name is *C. koseri*. Eight new *Citrobacter* species were recently described (Brenner et al., 1993; Schauer et al., 1995). *Citrobacter farmeri* was formerly known as a biogroup of *C. amalonaticus*. The remaining 6 named and 2 unnamed species were previously included in *C. freundii* or had been previously identified as atypical citrobacteria.

Enterobacter *Enterobacter cancerogenus* (formerly *Erwinia cancerogena*) was shown to be a senior subjective synonym of *Enterobacter taylorae* and is therefore the correct name for this species (Grimont and Ageron, 1989). In several recently proposed classifi-

TABLE BXII.γ.195. Intrinsic antimicrobial resistance in some of the common *Enterobacteriaceae*[a]

Genus/Species	Most strains are resistant to
Buttiauxella species	Cephalothin
Cedecea species	Polymyxins, ampicillin, cephalothin
Citrobacter amalonaticus	Ampicillin
Citrobacter freundii	Cephalothin
Citrobacter diversus	Cephalothin, carbenicillin
Edwardsiella tarda	Colistin
Enterobacter cloacae	Cephalothin
Enterobacter aerogenes	Cephalothin
Many other *Enterobacter* species	Cephalothin
Escherichia hermannii	Ampicillin, carbenicillin
Ewingella americana	Cephalothin
Hafnia alvei	Cephalothin
Klebsiella pneumoniae	Ampicillin, carbenicillin
Kluyvera ascorbata	Ampicillin
Kluyvera cryocrescens	Ampicillin
Proteus mirabilis	Polymyxins, tetracycline, nitrofurantoin
Proteus vulgaris	Polymyxins, ampicillin, nitrofurantoin, tetracycline
Morganella morganii	Polymyxins, ampicillin, cephalothin
Providencia rettgeri	Polymyxins, cephalothin, nitrofurantoin, tetracycline
Other *Providencia* species[b]	Polymyxins, nitrofurantoin
Serratia marcescens[c]	Polymyxins, cephalothin, nitrofurantoin
Serratia fonticola	Ampicillin, carbenicillin, cephalothin
Other *Serratia* species	Polymyxins[d], cephalothin

[a]Table taken from Farmer, 1999.

[b]Most strains of *Providencia stuartii* are also resistant to cephalothin and tetracycline.

[c]*Serratia marcescens* can also be resistant to ampicillin, carbenicillin, streptomycin, and tetracycline.

[d]Resistance to polymyxins is common in *Serratia* species, but some strains have zones of 10–12 mm or larger.

cations, *Enterobacter agglomerans* and other species in the "*E. agglomerans* group" have been classified in the genus *Pantoea*. The *E. agglomerans* group was extremely heterogenous and a number of species have been proposed for strains previously included in this species (see discussions of *Erwinia*, *Leclercia*, and *Pantoea* below and Table BXII.γ.192). *E. aerogenes* is genetically and phenotypically closer to *K. pneumoniae* than to *Enterobacter cloacae* (Brenner et al., 1972c; Steigerwalt et al., 1976; Bascomb et al., 1971; Grimont and Grimont, 1992). The names *"Klebsiella aerogenes"* and *Klebsiella mobilis* have been used for *E. aerogenes*. The type strain of *E. cloacae* is not representative of the species. If it is maintained, typical strains identified in clinical laboratories might not be called *E. cloacae* (Grimont and Grimont, 1992). This problem is dealt with in detail in the chapter on *Enterobacter*. Recently obtained biochemical test data and DNA–DNA hybridization data indicate that *Enterobacter intermedius* is a senior subjective synonym for the recently described species *Kluyvera cochleae* (A.G. Steigerwalt and J.J. Farmer, unpublished data).

Erwinia Plant isolates of erwiniae have been mainly studied by phytomicrobiologists and phytopathologists. The media, biochemical and other phenotypic tests used for their isolation, enrichment, cultivation, and identification are quite different from those used for other *Enterobacteriaceae*. The 35–37°C incubation temperature used for most other *Enterobacteriaceae* is near, at, or above the maximum growth temperatures of erwiniae. The isolation of erwiniae from humans or animals is rarely reported. It is not known, however, if they are actually rarely occurring, whether their seeming lack of occurrence reflects improper isolation and enrichment procedures, or, if they are isolated, their identification fails. A study using optimal isolation procedures and an optimum incubation temperature would help to resolve this problem. Also needed is a study to characterize all erwiniae by tests and methods used for other *Enterobacteriaceae*. Erwiniae have been shown to be quite diverse on the basis of DNA relatedness studies (Gardner and Kado, 1972; Brenner et al., 1973b; Brenner et al., 1973b, and now 16S rRNA sequence studies (Kwon et al., 1997). Several recently proposed classifications have expanded the genus *Pantoea* to include the Herbicola or Herbicola-Lathyri group of the genus *Erwinia*. Similarly, there have been proposals to change the circumscription of the genus *Pectobacterium* to include a number of species formerly contained in the genus *Erwinia*, and the new genus *Brenneria* was recently described for other species formerly in *Erwinia* (see Table BXII.γ.192 and chapters on *Erwinia*, *Pantoea*, *Pectobacterium*, and *Brenneria*).

Escherichia* and *Shigella The four nomenspecies of *Shigella* and *E. coli* are a single genomospecies on the basis of DNA relatedness (Brenner et al., 1972a, 1973a). *Shigella* and *E. coli* strains are often extremely difficult to separate biochemically since there are aerogenic (gas-producing) shigellae and lactose-negative, anaerogenic, nonmotile *E. coli*. Such strains can cause a dysentery-like diarrhea, so pathogenicity does not provide definitive separation. Shigellae can be considered metabolically inactive biogroups of *E. coli*. Based mainly on molecular data, it has been argued that these organisms do not represent distinct species, but a continuum of closely related lines of descent from a common ancestor. In this *Manual*, they are classified as distinct species because of the ease of communication these names provide in medical microbiology and because of the resistance and confusion that would be caused by reclassification. However, the original usage implying that shigellae were pathogenic and *E. coli* was not is certainly not true. Tamura et al. (1986) proposed an alternative classification. They defined a new genus *Leclercia*, with the single species *L. adecarboxylata*, which was originally named *Escherichia adecarboxylata*.

Hafnia *Hafnia alvei* remains the only named species in this genus. DNA studies revealed two separate DNA relatedness groups within *H. alvei*, with approximately one-half of the strains in each relatedness group (Steigerwalt et al., 1976). A second species was not designated since no single biochemical test or series of tests served to unequivocally separate the two relatedness groups (F.W. Brenner and J.J. Farmer III, personal communication). *"Hafnia protea"* is an illegitimate name for *Obesumbacterium proteus*. There were two biogroups within *O. proteus*. Biogroup 2 is *O. proteus*, whereas biogroup 1 is a metabolically inactive biogroup of *H. alvei* that has become adapted to the brewery environment.

Klebsiella In 1984, Orskov proposed a classification in which *Klebsiella ozaenae* and *Klebsiella rhinoscleromatis* would be classified as subspecies of *K. pneumoniae* (Orskov, 1984a). While there is no doubt that these 3 nomenspecies are the same genomospecies on the basis of DNA relatedness studies (Brenner, Steigerwalt, and Fanning, 1972), many laboratories still accept their original classification and report them as separate species. *Klebsiella ornithinolytica* was described by Sakazaki et al. (1989a) for strains previously determined to be a biogroup of *Klebsiella planticola* by Farmer et al., 1985a). These strains have been variously referred to as ornithine-positive *K. oxytoca*, NIH (Japan) Group 12, CDC

TABLE BXII.γ.196. Additional biochemical reactions of *Enterobacteriaceae*[a, b, c]

Species	Nitrate reductase	Tetrathionate reductase	D-Galacturonate	2-keto-Gluconate	γ-Glutamyl transferase

[a]Symbols: +, 90% or more of strains are positive; d, 10.0–89.9% positive; −, 0–9.9% positive; blank space, not available; A, type A nitrate reductase; B, type B nitrate reductase.

[b]The nitrate reductase test was incubated at 32°C; all other tests were incubated at 35–37°C. The γ-glutamyl transferase test was read at 24 h; all other test results were read at 48 h.

[c]Data compiled from: Pichinoty et al. (1969), Grimont (1977b), Richard (1977), Grimont et al. (1978a), Le Minor et al. (1979), Bercovier et al. (1980a), Bercovier et al. (1980b), Brenner et al. (1980e), Giammanco et al. (1980), Ursing et al. (1980a), and Buissière et al. (1981).

Klebsiella Group 47 (indole-positive, ornithine-positive); and indole-positive, ornithine-positive biogroup of *Klebsiella planticola*. Laboratories agreed on the phenotypic properties of this organism, but they disagreed on whether DNA relatedness data indicated that it should be retained as a biogroup of *K. planticola* or that it should be a separate species.

Kluyvera The recently described species *K. cochleae* (Müller et al., 1996) appears to be a junior subjective synonym for *Enterobacter intermedius* (A.G. Steigerwalt and J.J. Farmer, unpublished data). In this *Manual*, this species is not included as one of the species of *Kluyvera*, but see *Enterobacter intermedius*.

Obesumbacterium proteus. See *Hafnia* above.

Pantoea In this *Manual*, the genus *Pantoea* includes species previously contained in the *Enterobacter agglomerans* complex (including *Erwinia herbicola*, *Erwinia lathyri*, *Erwinia ananas*, *Erwinia uredovora*, *Erwinia milletiae*, and *Erwinia stewartii*). Future proposals may expand its definition to include additional species to be defined from some of the remaining *Enterobacter agglomerans* DNA hybridization groups that have not yet been classified (Brenner et al., 1984a; Grimont and Grimont, 1992). See sections on *Enterobacter* and *Erwinia* above.

Photorhabdus* and *Xenorhabdus Substantial differences in biochemical reactions have been reported by different laboratories (Grimont et al., 1984b; Akhurst and Boemare, 1988; Farmer et al., 1989). Many of the differences are probably due to slow and weak reactions and to differences in media. In the proposed classification of Akhurst and Boemare, *Xenorhabdus beddingii* and *Xenorhabdus bovienii*, are classified as species (Akhurst and Boemare, 1988). They were originally described as subspecies of *Xenorhabdus nematophilus*. Four additional genomospecies within

Photorhabdus luminescens (*Xenorhabdus luminescens*) were not named because they are not phenotypically separable from *P. luminescens* (Farmer et al., 1989).

Proteus The type strain of *Proteus vulgaris* is in a DNA relatedness group that includes only one other strain out of 36 tested. The remaining strains are in four new genomospecies, which include essentially all isolates currently identified as *P. vulgaris* (Brenner et al., 1995). A request for an opinion to replace the type strain was submitted (Brenner et al., 1995), and was recently granted (H. Trüper, personal communication). MacDonell and Colwell (1985) recommended that *Plesiomonas shigelloides* be classified in the genus *Proteus* because its 5S rRNA sequence is closely related to that of *P. mirabilis*. They did not formally describe the new combination (*"Proteus shigelloides"*). Such a change is not supported by phenotypic characteristics or by DNA relatedness and the new combination has not been used.

Salmonella The classification and nomenclature of salmonellae has long been a source of confusion, even to specialists. Much of the confusion was due to the practice of naming serotypes (serovars) and equating them with species. All phylogenetic data indicate that the evolution of the genus *Salmonella* is a continuum, but several recent classifications recognize two distinct species of *Salmonella*, one of which contains six subspecies (Reeves et al., 1989a; Brenner and McWhorter-Murlin, 1998). The type species of the genus is *Salmonella choleraesuis*. Unfortunately, there is also a serotype Choleraesuis that, until recently was treated as a species. For this reason Le Minor and Popoff (1987) requested an opinion to replace the name *S. choleraesuis* with *"Salmonella enterica"*. This request was not approved by the Judicial Commission (Wayne, 1994; Judicial Commission, 1991), although the wording of the refusal seemed to leave the door open for another request to remedy the confusion caused by the name *S. choleraesuis*. This request has now been resubmitted by Euzéby (1999), who also requested that *"Salmonella typhi"* be designated as a species. In the interim, the WHO International Collaborating Centre for *Salmonella* located at the Pasteur Institute in Paris, the National *Salmonella* Center located at the Centers for Disease Control and Prevention in Atlanta, and many other reference laboratories and their constituents have begun to use *S. enterica*, so both names are currently in use. In one proposed classification there are 6 subspecies of *S. choleraesuis*: subsp. *enterica* (or subspecies I or subspecies 1), for those biochemically typical serotypes previously placed in subgenus I ; subsp. *salamae* (or subspecies II or subspecies 2) , for biochemically atypical serotypes previously in subgenus II; subsp. *arizonae* (or subspecies IIIa or subspecies 3a) for the monophasic strains previously in *"Arizona hinshawii"* or subgenus III; subspecies subsp. *diarizonae* (or subspecies IIIb or subspecies 3b) for the diphasic strains previously in *"A. hinshawii"* or subgenus III; subsp. *houtenae* (or subspecies IV or subspecies 4) for the biochemically atypical strains previously in subgenus IV; and subsp. *indica* (or subspecies VI or subspecies 6) for more recently defined atypical strains that differ from the biochemical patterns of subspecies I-IV. The second species is *Salmonella bongori*, a small number of biochemically unique serotypes that have been classified as subsp. *bongori* (or subspecies V or subspecies 5) but are considered to be separate species in the proposed classification of Reeves et al., (1989a) and in this *Manual*. The practice in medical bacteriology is to use names for the serotypes in subsp. *enterica*. For example, the serotypes formerly reported as *S. typhi* and *S. typhimurium* would now be reported as *S. choleraesuis* (or *"S. enterica"*) subsp. *enterica* (or I or 1) serotype Typhi or Typhimurium. Note that the serotype name is capitalized and nonitalicized. Alternatively these serotypes could be reported simply as *Salmonella* serotype Typhi and *Salmonella* serotype Typhimurium. Serotypes in the other subspecies are reported similarly. Some laboratories choose to use names (where the serotypes are named) and some choose to use the antigenic formulae. Serotypes in subsp. *arizonae* and subsp. *diarizonae* are not named. Therefore a typical report, would be *Salmonella* serotype 60:k:z (= *Salmonella enterica* subsp. *diarizonae* serotype 60:k:z). *Salmonella enterica* subsp. *indica* serotype Brookfield has the antigenic formula 66:z41:-. Any of the following reports would be accurate: *Salmonella* serotype Brookfield, *Salmonella* subsp. *indica* serotype Brookfield, *Salmonella* subsp. V Brookfield, as would any of the above designations with the antigenic formula used instead of the name Brookfield. Much of the literature still uses the "serotype as species" classification and uses the Linnean system of writing the genus and species in italics. Examples include *Salmonella typhi*, *Salmonella typhimurium*, and *Salmonella enteritidis*.

Yokenella *Yokenella*, with its single species *Y. regensburgei*, was described by Kosako et al. in 1984. The genus *Koserella* with its single species *K. trabulsii*, was described by Hickman-Brenner et al. in 1985a *Y. regensburgei* and *K. trabulsii* were shown to be subjective synonyms by Kosako et al. in 1987 Other synonyms for this organism are *Hafnia* hybridization group 3, Enteric Group 45, NIH (Japan) biogroup 9. Even though *K. trabulsii* had priority by virtue of its earlier alphabetical appearance on Validation List No. 17 in the *International Journal of Systematic Bacteriology*, both groups of investigators agreed that *Yokenella* should be the genus name.

Unnamed Enteric Groups A number of groups belonging to the family *Enterobacteriaceae* have been characterized in the Enteric Reference Laboratory at the CDC but not given genus and species names. Four Enteric Groups are briefly described below. Their biochemical profiles are included in Table BXII.γ.193.

Enteric Group 58 Enteric Group 58 consists of strains that were first recognized in 1981 and described in 1985 (Farmer et al., 1985a). The first five isolates were from human clinical specimens; four from wounds (foot, ankle, leg, and hip), and one from feces. Since the original report in 1985, the number of isolates at CDC has grown to 21, including an isolate from a case of bacteremia. Enteric Group 58 has the general properties of the family *Enterobacteriaceae*.

Enteric Group 60 Enteric Group 60 consists of four strains first recognized in 1981 and described in 1985 (Farmer et al., 1985a). All of the strains were from human clinical specimens (three from urine and one from sputum). Enteric Group 60 is inactive biochemically and was originally thought to be most like *Morganella morganii*. However, it is sensitive to colistin and tyrosine-negative, reactions incompatible with *Morganella*. Enteric Group 60 has the general properties of the family *Enterobacteriaceae*. Its closest phylogenetic relatives are not yet known.

Enteric Group 68 Enteric Group 68 consists of a small group of strains isolated from human urine that were first recognized in 1981 and described in 1985 (Farmer et al., 1985a). The group is positive for DNase, but otherwise quite different from *Serratia*. Enteric Group 68 also has the general properties of the family *Enterobacteriaceae*. Its closest phylogenetic relatives are not yet known.

Enteric Group 69 Enteric Group 69 is the name given to a group of strains isolated from refrigerated beef carcasses (Farmer et al., 1985a). The strains were phenotypically similar to *E. sa-*

kazakii in most biochemical reactions, including production of a yellow pigment. However, they were only 43% related to *E. sakazakii* by DNA–DNA hybridization. Recent DNA relatedness data by Kosako et al. (1996) indicated that *Enterobacter kobei* is the closest relative of Enteric Group 69.

Genus I. **Escherichia** *Castellani and Chalmers 1919, 941T*[AL]

FLEMMING SCHEUTZ AND NANCY A. STROCKBINE

Esch.er.i' chi.a. M.L. fem. n. *Escherichia* named after Theodor Escherich, who isolated the type species of the genus.

Straight cylindrical rods, 1.1–1.5 × 2.0–6.0 μm, occurring singly or in pairs. Conform to the general definition of the family *Enterobacteriaceae*. Gram negative. Motile by peritrichous flagella or nonmotile. Aerobic and facultatively anaerobic having both a respiratory and a fermentative type of metabolism, but anaerogenic biotypes occur. Oxidase negative. Chemoorganotrophic. **Both acid and gas are formed from most fermentable carbohydrates, but *i*-inositol is not utilized and D-adonitol is utilized only by *Escherichia fergusonii*. Lactose is fermented by most strains of *Escherichia coli*,** but fermentation may be delayed or absent in *Escherichia blattae*, *Escherichia hermannii*, *Escherichia fergusonii*, and *Escherichia vulneris*. **Do not grow in KCN (with the exception of *E. hermannii* and a small proportion of *E. vulneris*). Usually do not produce H_2S.** *E. coli* occur naturally in the lower part of the intestine of warm-blooded animals, *E. blattae* in the hind-gut of cockroaches, and *E. fergusonii*, *E. hermannii*, and *E. vulneris* are found in the intestine, as well as extraintestinal sites of warm-blooded animals. Seven copies of the *rrn* operon with genes coding for 16S, 23S, and 5S rRNA are present on the chromosome of *E. coli*. Comparative sequence analysis between the genes for 16S rRNA of *E. coli*, *E. vulneris*, and *E. hermannii* and homologous genes from all eubacteria places *E. coli* and *E. vulneris* together in a tightly related cluster with shigellae, and *E. hermannii* between *Salmonella* spp. and *Citrobacter freundii* (Cilia et al., 1996). Based on 16S rRNA sequencing, escherichiae belong in the *Gammaproteobacteria*.

The mol% G + C of the DNA is: 48–59.

Type species: **Escherichia coli** (Migula 1895) Castellani and Chalmers 1919, 941 (*Bacillus coli* Migula 1895, 27.)

FURTHER DESCRIPTIVE INFORMATION

Cell morphology Escherichiae are straight, cylindrical, Gram-negative rods with rounded ends that are 1.1–1.5 μm in diameter and 2.0–6.0 μm in length. They occur singly or in pairs and can be motile by peritrichous flagella or nonmotile. Fig. BXII.γ.191 shows negatively stained preparations of each of the *Escherichia* species. See Nanninga (1985) for a comprehensive treatment of the ultrastructure of *E. coli*.

Phylogenetic and systematic treatment The genus consists of five species: *E. coli*, *E. hermannii*, *E. fergusonii*, *E. vulneris*, and *E. blattae*. Biochemical reactions that will help in differentiating between the species of *Escherichia* are listed in Table BXII.γ.197.

Biochemical reactions Escherichiae produce strong acids and usually gas from the fermentation of D-glucose (positive in the Methyl Red test) and do not produce acetyl-methyl carbinol (acetoin) (negative in the Voges–Proskauer test). Sodium acetate is frequently used as a sole carbon source, except by *E. blattae* and a majority of *E. vulneris* strains. Citrate (Simmons' citrate agar) cannot be used by *E. coli* and *E. vulneris*, whereas a smaller proportion of *E. fergusonii* and *E. hermannii* exhibit immediate or delayed use of this substrate. Growth on Simmons' citrate agar by *E. blattae* is variable and probably strain specific.

Lysine is decarboxylated by the majority of strains. Exceptions include "metabolically inactive" *E. coli* strains, the majority of enteroinvasive *E. coli* strains (EIEC), and *E. hermannii*. Ornithine is decarboxylated by all species except by *E. vulneris* and a little less than half of *E. coli* strains. Indole is produced by all species except *E. blattae* and *E. vulneris*.

Other tests that help in differentiating between the species of *Escherichia* include growth in potassium cyanide, malonate utilization, and acid production from D-adonitol, D-arabitol, cellobiose, dulcitol, lactose, D-mannitol, melibiose, D-sorbitol, and mucate. See Table BXII.γ.197.

Molecular data Findings from the comparison of 16S rDNA sequences performed with strains of *E. coli*, *Salmonella* spp., and *C. freundii* have shown a close phylogenetic relatedness between these bacteria (Ahmad et al., 1990; Cilia et al., 1996; Chang et al., 1997). Analysis of 16S rDNA sequences separates the two *Salmonella* species (*S. enterica* and *S. bongori*) from the complex of *E. coli* and *Shigella*, and shows that *E. hermannii* is more closely related to *Salmonella enterica* and *C. freundii* (Christensen et al., 1998). This analysis is unable to separate inter-operon variation of *E. coli* from strains of *E. coli* and from *Shigella*. Patterns of sequence heterogeneity in strains from the *E. coli* Collection of Reference (ECOR) (Ochman and Selander, 1984) have been located at regions V1 and V6 of cloned 16S rRNA genes (Martinez-Murcia et al., 1999).

Average DNA relatedness assessed by DNA–DNA hybridization among *Escherichia* species ranges from 29% to 94% (Table BXII.γ.198). DNAs from different strains of *E. coli* are closely related (average, 84%; Table BXII.γ.198). With the exception of *S. boydii* serotype 13, the DNAs of *E. coli* and the four *Shigella* species show such a high degree of relatedness (average 80–87%, except *S. boydii* type 13, which is about 65%) that these species should be considered as a single species (Brenner et al., 1973a). The distinction between these bacteria prevails, however, for reasons of historical/medical precedent and to avoid confusion in the literature and with existing surveillance systems.

Based on complete sequencing of the K-12 strain MG1655 (Blattner et al., 1997), it is estimated that the *E. coli* lineage diverged from the *Salmonella* lineage some 100 million years ago (Lawrence and Ochman, 1998). This is a little less than the 120–160 million years estimated by calibration of the rate of 16S rRNA evolution in bacteria (Ochman and Wilson, 1987). The chromosome of *E. coli* strain MG1655 is 4,639,221 bp and contains 4,288 open reading frames (ORFs). Approximately 18% of these ORFs represent genes that have been acquired and have persisted

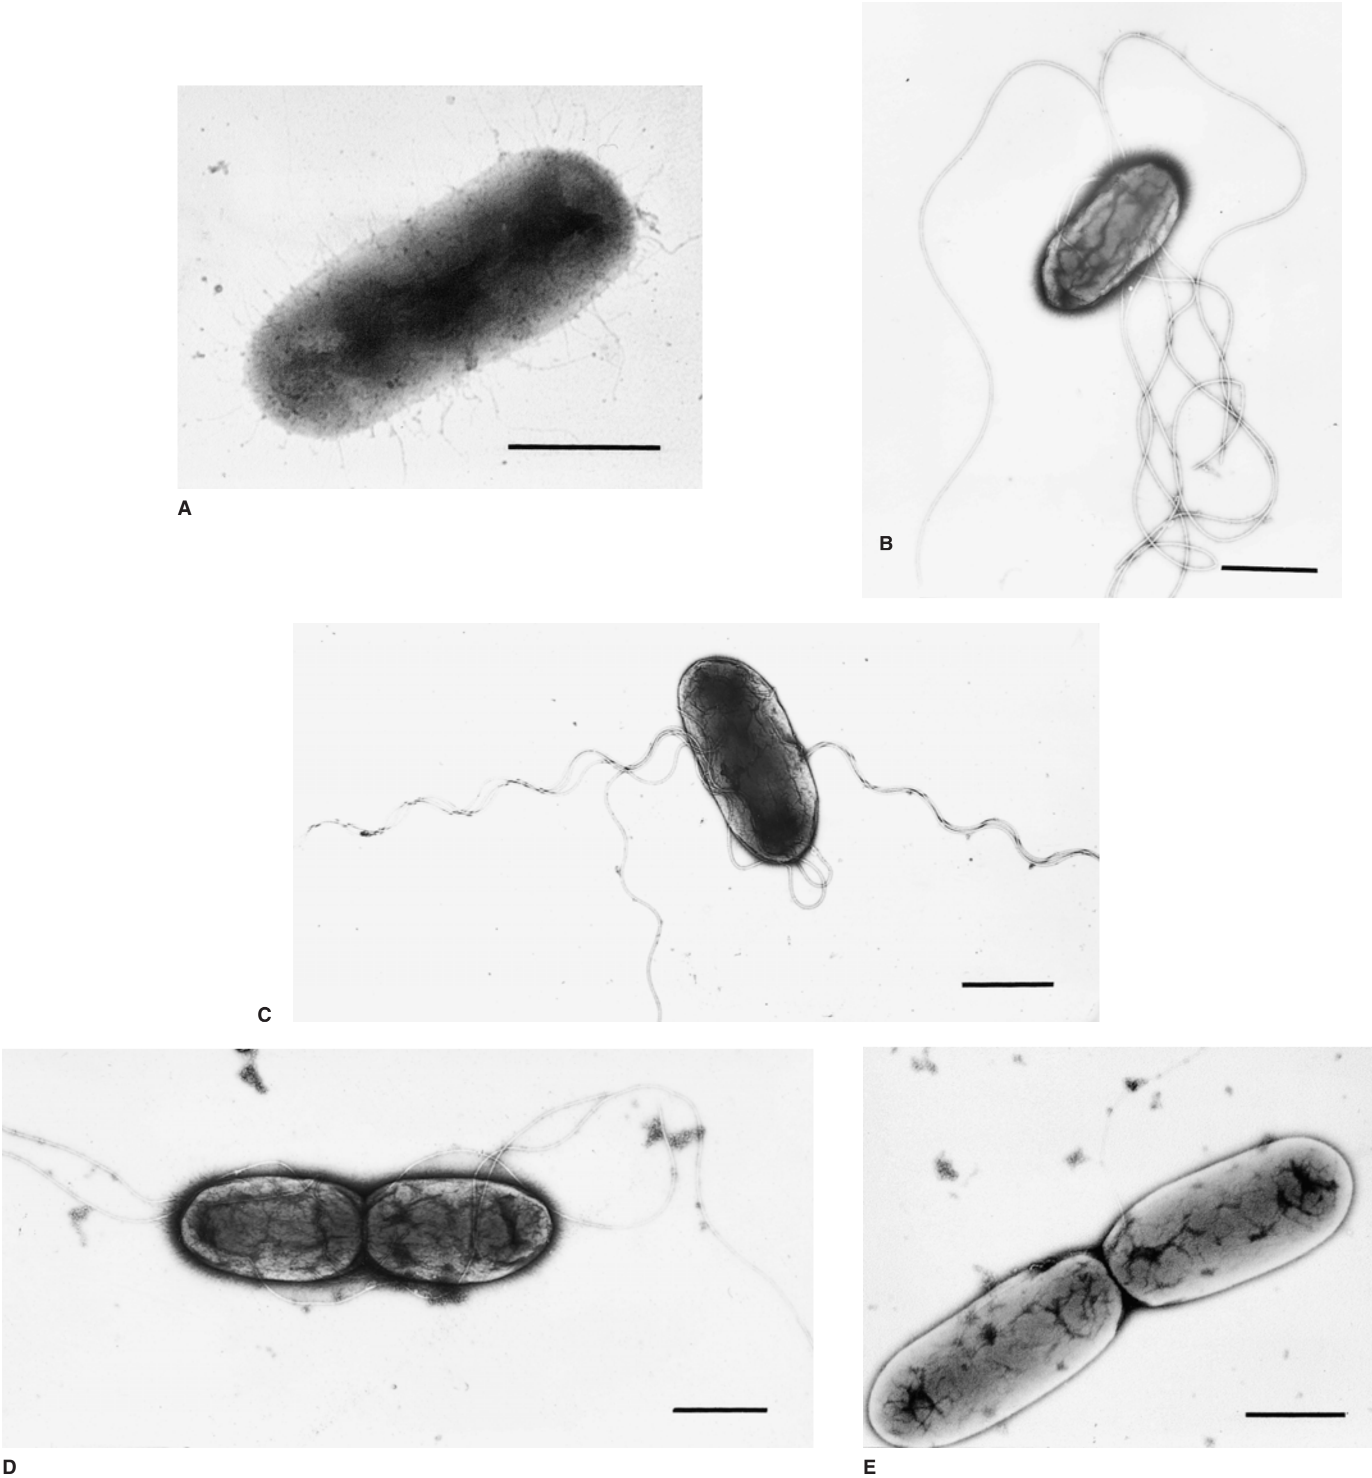

FIGURE BXII.γ.191. Electron micrographs of *E. blattae* strain 2928-78 (*A*), *E. coli* O157:H7 strain EDL933 (*B*), *E. fergusonii* strain 2460-89 (*C*), *E. hermannii* strain 2456-88 (*D*), and *E. vulneris* strain 2485-88 (*E*) prepared by negatively staining in 0.5% (w/v) uranyl acetate. Bar = 1000 nm. (Micrograph courtesy of Charles D. Humphrey, CDC.)

since divergence. This is similar to estimates based on analysis of codon usage, indicating that 16% of sequenced genes arose through horizontal transfer (Médigue et al., 1991). The ability of individual strains and lineages to acquire foreign DNA results in great heterogeneity in both individual genes and in the size of the *E. coli* chromosome. This is exemplified by the unusual serotype O157:H7, the genome of which is 5.5 Mb in size, 859 Kb larger than that of the laboratory strain K-12 (Hayashi et al., 2001; Perna et al., 2001). The genome sizes of 14 *E. coli* strains from the five major subgroups in the ECOR (Ochman and Selander, 1984) range from 4.66–5.30 Mb (Bergthorsson and Ochman, 1995), and the uropathogenic *E. coli* strain J96 genome is

E. vulneris	39	29	33	36	78

[a]Data compiled from Ewing, 1986b.

reported to be 5.12 Mb (Melkerson-Watson et al., 2000) as estimated by pulsed field gel electrophoresis (PFGE).

Of the five species in the genus *Escherichia*, *E. coli* is the most studied. Because the amount of knowledge about the other four species is limited, the descriptive information to follow applies to *E. coli*, unless indicated otherwise.

Cell wall composition The chemical composition and molecular structure of the cell wall of *E. coli* has been extensively studied and is described in detail by Neidhardt and Umbarger (1996) and Park (1996). The structural rigidity of the cell wall is provided by the murein sacculus, which consists mainly of a single monomolecular sheet of murein, a complex polymer composed of roughly equal amounts of polysaccharides (*N*-acetylglucosamine [GlcNAc] and *N*-acetylmuramic acid [MurNAc]) and peptides (L-alanine, D-glutamic acid, L-*meso*-diaminopimelic acid (DAP), and D-alanine). Linear chains of alternating units of GlcNAc and MurNAc are linked together by β-1→4 glycosidic bonds, and short chains of the above peptides in alternating D and L optical isomers are attached to the sugars through amide linkages to the carboxyl groups of each muramic acid. Adjacent glycan strands are cross-linked to each other through the peptide side chains to create one giant molecule that provides structural support to the cell. Notable features of the murein of *E. coli* include the presence of a small percentage of peptide chains that either lack the D-alanine or terminate in an additional D-alanine and the absence of amidation involving the carboxyl groups of glutamic acid and DAP. A molecule of lipoprotein is also attached to about every tenth muropeptide.

Outer membrane The outer membrane of an average *E. coli* cell contains over a million molecules of lipopolysaccharide (LPS), which consist of three covalently linked domains: (1) lipid A (endotoxin), (2) the core region of phosphorylated nonrepeating oligosaccharides, and (3) the O antigen polymer of immunogenic repeating oligosaccharides (1–40 units).

Fine structure

Flagella Motile organisms of the genus typically possess 5–10 flagella per cell, which are randomly situated around the cell surface (peritrichous flagellation). The flagellar filament is about 20 nm in diameter and may be up to 20 μm long. It consists of subunits of a single protein, flagellin, which is encoded by the *fliC* gene. Fifty-three antigenically distinct types of flagellin have been described (Ørskov and Ørskov, 1984a). Electron microscopic studies of these antigenically distinct types of flagellar

filaments revealed differences in surface structure; six unique flagellar morphotypes have been described (Lawn et al., 1977). Unlike *Salmonella*, most *E. coli* strains have only one flagellin gene and do not undergo phase variation. Exceptions have been described (Ratiner, 1967, 1982, 1999). See Macnab (1996) for a complete description of the structure and genes involved in motility.

Fimbriae In addition to the proteinaceous flagella, most strains have fimbriae (pili) or fibrillar proteins often extending in great numbers from the bacterial surface and far out into the surrounding medium. A typical *E. coli* K-12 cell contains 100–500 type 1 fimbriae arranged peritrichously, each with a diameter of approximately 7 nm and a length of 0.2–2.0 μm. More than 30 different fimbriae have been described in *E. coli*, which commonly expresses more than one type at a time. The characteristics, biogenesis, and classification schemes of fimbriae are reviewed by Low et al. (1996). Fimbriae have historically been classified by phenotypic properties. One widely used scheme classifies fimbriae according to their adhesive properties for red blood cells from different host species in the presence of mannosides. By this method, two main types of fimbriae are recognized: mannose-sensitive (MS) fimbriae, which are unable to agglutinate red blood cells in the presence of α-D-mannose, and mannose-resistant (MR) fimbriae, which are able to agglutinate red blood cells in the presence of this sugar. MS fimbriae, which include the so-called type 1 fimbriae (pili), are found in the majority of *E. coli* strains and comprise a group of more or less serologically related antigens. Because they are expressed by pathogens as well as commensal organisms, their role in virulence has been difficult to establish. Evidence for the role of type 1 fimbriae in virulence is reviewed by Abraham and Jaiswal (1997). Type 1 fimbriae mediate avid bacterial attachment to mucosal surfaces, to noncellular host constituents, and to various inflammatory cells. They bind to certain oligomannoside-containing glycoproteins present on mucosal surfaces, including the Tamm–Horsfall glycoprotein, which is synthesized in the kidney and present in urinary slime (Ørskov et al., 1980a); fibronectin, a glycoprotein that is a member of a family of proteins found in the extracellular matrix (ECM), plasma, and other body fluids; and laminin, a glycoprotein present in basement membranes (Kukkonen et al., 1993). The genes involved in the synthesis and regulation of type 1 fimbriae are located on the chromosome. Expression of type 1 fimbriae is subject to being turned on or off (phase variation) as a result of the inversion of a 314 base-pair fragment of DNA containing the promoter region of the gene encoding the major fimbrial subunit (*fimA*). Expression of type 1 fimbriae is influenced by environmental and growth conditions and is controlled by global regulatory factors such as leucine-responsive regulatory protein (Lrp), integration host factor (IHF) and histone-like protein H-NS. See Abraham and Jaiswal (1997) and Low et al. (1996) for a review of the environmental factors and genes involved in synthesis and regulation of type 1 fimbriae.

MR fimbriae are serologically diverse (Ørskov et al., 1980b, 1982; Ørskov and Ørskov, 1990) and often function as virulence factors to mediate adherence that is species- and organ-specific. The genes for these proteins may be located on plasmids or on the chromosome. When located chromosomally, they often cluster together with other virulence genes in regions of the chromosome referred to as pathogenicity islands (PAIs). More than any other virulence factor, the MR pili of *E. coli* illustrate the species' capacity to adapt to the receptor-specific epithelial cells of certain hosts primarily through horizontal acquisition of gene cassettes on plasmids, phages, or other mobile DNA elements that will allow for colonization. Evidence for the horizontal transfer of fimbrial genes in *E. coli* comes from the remarkable similarity between the genetic organization of its fimbrial operons and those of other members of the family *Enterobacteriaceae* and from the strikingly low C + G content and different codon usage pattern among the fimbrial genes compared to those observed overall among other genes on the *E. coli* chromosome.

Fimbriae may also be classified based on their morphology. One group consists of thick, rod-shaped fimbriae with a diameter of 7 nm (range 3.4–8 nm), a length of 0.5–2 μm, and an axial hole diameter of 2.0–2.5 nm. Fimbriae with these dimensions are represented by the rigid pyelonephritis (P), sialic acid (S), type 1, F6 (987P), colonization factor antigen I (CFA/I), coli surface antigen 1 (CS1) and CS2 pili, and by the bundle-forming CS8 (CFA/III) and CS21 (longus), the latter with homology to the type 4 fimbrial family. Enteropathogenic *E. coli* (EPEC) is known to produce a type 4 fimbria called the bundle-forming pilus (BFP). Another flexible, bundle-forming fimbrial structure of 2–3 nm diameter, designated aggregative adherence fimbriae I (AAF/I), shows no homology to the type 4 class of fimbriae. Together with another recently described AAF/II fimbria, it exhibits sequence and organizational resemblance to the Dr family. Another group consisting of thinner, more flexible fibrillae with a width of 2–5 nm and a length of 0.5–2.0 μm is represented by F4 (K88), F5 (K99), F41, and CS3. Helical fibrillae, where two fibrillae are arranged in a helix, are represented by CS5 and CS7.

Nonfimbrial and related adhesins Bacterial adherence may also be mediated by adhesions that are afimbrial (AFA) or nonfimbrial (NFA). Some of these proteins form larger multimers that aggregate around the bacterial cell as an amorphous structure reminiscent of capsular K antigens. Afimbrial adhesins are found in both uropathogenic *E. coli* (UPEC) and in diffusely adhering *E. coli* (DAEC) and represented by the Afa/Dr family consisting of Dr (previously referred to as O75X) and Dr-II (*drb*), the F1845 pilus (*daa*), and AFAI-IV (*afa*). Dr fimbriae and related adhesins recognize different epitopes of the Dr blood group antigen (Nowicki et al., 1990) and bind to a complement-regulatory protein, the common receptor decay accelerating factor (DAF). *E. coli* strains expressing Dr fimbriae are able to enter epithelial cells by interacting with DAF (Goluszko et al., 1997). Other adhesins such as the M agglutinin and AIDA-I adhesin, a plasmid-encoded outer membrane protein involved in diffuse adherence of certain types of *E. coli* (Benz and Schmidt, 1989), are commonly present.

Colonial and cultural characteristics; life cycles Depending on the degree of polymerization of the O antigen polysaccharide, the phenotypes of strains growing on agar media are described as smooth (S) or rough (R). S forms, which usually grow on nutrient agar as convex, glistening, moist, gray colonies (2–3 mm diameter) with a defined edge or in fluid medium as turbid growth, have developed polysaccharide side chains, while R forms, which usually grow as flat, dry, dull, wrinkled colonies (1–5 mm diameter) with a blurred edge on agar and agglutinate spontaneously in fluid media, have lost their polysaccharide side chains by mutation (Lüderitz et al., 1966). There are intermediate forms between these extremes. Mucoid and slime-producing forms occur. *E. hermannii* is yellow-pigmented, as are half of the described *E. vulneris* strains. See Raetz (1996) and Hull

(1997) for a discussion of the chemical structure, biosynthesis, and biological/virulence properties of LPS.

Nutrition and growth conditions Of the range of temperatures, pH values, water activities, and pressures over which bacterial growth can occur, *E. coli* strains survive and grow over the mid-range (15–45°C) of these environmental conditions. Most strains can grow over a temperature range of approximately 40°C. The normal temperature range for balanced growth extends from 21° to 37°C; however, strains that can grow at temperatures as low as 7.5–7.8°C (Shaw et al., 1971) and as high as 49°C (Herendeen et al., 1979) have been described. A minimum growth temperature for *E. vulneris* of 1.6°C (0.8–2.6°C) was reported for a strain isolated from refrigerated meat (Ridell and Korkeala, 1997). *E. coli* is neutrophilic and will grow over the mid-range of pH, from about pH 5.0 to 9.0 (Ingraham and Marr, 1996).

Metabolism and metabolic pathways Glucose and other carbohydrates are fermented with the production of pyruvate, which is further converted into lactic, acetic, and formic acids. Part of the formic acid is split by a complex hydrogenlyase system into equal amounts of CO_2 and H_2.

Phylogeny The establishment of the *Escherichia coli* Collection of Reference (ECOR) in 1984 (Ochman and Selander, 1984) and subsequent studies of the strains in ECOR and comparisons with other *E. coli* strains have contributed substantially to our understanding of the evolution and population structure of *E. coli*. ECOR is a collection of 72 strains from humans and 16 other mammalian species from various geographical areas that have been grouped into five main groups—A, B (comprising subgroups B1 and B2), C, D, and E—according to their electrophoretic types and enzyme allele (allozyme) profiles, based on the results of multilocus enzyme electrophoresis (MLEE) (Selander et al., 1986). The original data for 35 enzymes (Selander et al., 1987) have been expanded to include allozymes of four esterase loci (Goullet and Picard, 1989), and, based on allelic variation at 38 enzyme-encoding loci, multilocus genotypes have been used to construct a dendrogram based on the neighbor joining algorithm (Herzer et al., 1990), demonstrating the clonal structure of the species. The phylogenetic groups are distinguishable but not identical by random amplified polymorphic DNA (RAPD), restriction fragment length polymorphism (RFLP) of *rrn* genes (ribotyping) (Desjardins et al., 1995), and to a lesser extent by repetitive-element PCR (rep-PCR) fingerprinting using ERIC2 and BOXA1R primers (Johnson and O'Bryan, 2000). Generating a phylogenetic tree of the ECOR and 15 O157 strains by fluorescent amplified-fragment length polymorphism (FAFLP) demonstrated close correlation with the MLEE groups of ECOR and placed the STEC/VTEC O157 strains on an outlier branch (Arnold et al., 1999). Thus, there is sufficient evidence that the ECOR strains broadly represent genotypic variation in clonal groups of *E. coli* in spite of the fact that many isolates are commensal forms from healthy carriers and that only 11 out of the 72 strains are from human disease: 1 strain from a case of asymptomatic bacteriuria, 4 from acute cystitis, and 6 from acute pyelonephritis. Other MLEE studies have showed clonal relationships of diarrheagenic *E. coli*, and a collection of 78 diarrheagenic *E. coli* (DEC) representing 15 clonal groups has been established (Whittam et al., 1993). A similar collection of STEC/VTEC strains has been collected by the STEC Center based at the National Food Safety and Toxicology Center at Michigan State University and is designed to facilitate research on the Shiga/Verocytotoxin producing *E. coli* by providing a standard reference collection of well-characterized strains and a central, on-line accessible database.*

Numerous studies have indicated that *E. coli* and the four named species of *Shigella* should be regarded as being one species (Brenner et al., 1972a, b, 1973a; Goullet, 1980; Ochman et al., 1983; Whittam et al., 1983; Hartl and Dykhuizen, 1984; Karaolis et al., 1994; Stevenson et al., 1994; Whittam, 1996; Pupo et al., 1997). Findings from MLEE studies combined with those from *mdh* (malate dehydrogenase) housekeeping gene sequence studies (Pupo et al., 1997) and ribotyping (Rolland et al., 1998) confirm that the genus *Shigella* comprises a group of closely related pathogenic *E. coli* strains and indicate that *Shigella*, EIEC, and other diarrheagenic *E. coli* strains do not have a single evolutionary origin, but are derived from different ancestral strains many times. Furthermore, pathogenic strains belonging to pathogenic groups of EIEC, EPEC, and ETEC were found to be closely related to ECOR group A strains by MLEE and have *mdh* sequences identical to five ECOR strains from group A, which is thought to represent commensal strains. It has been suggested that any *E. coli* strain may acquire virulence factors from numerous sources, including plasmids, bacteriophages, and other mobile DNA elements from a large pool of strain-specific genes whose origin could be outside the species boundaries, and that this is how a commensal form is turned into a pathogenic form (Pupo et al., 1997; Hurtado and Rodriguez-Valera, 1999; Donnenberg and Whittam, 2001). In their analysis, Lawrence and Ochman (1998) surmised that about 10% of the *E. coli* K-12 genome consists of genes that were acquired in over 200 events of lateral gene transfer, which occurred subsequent to the divergence of *E. coli* and *Salmonella* some 100 million years ago. While mutations have contributed substantially to the heterogeneity of *E. coli*, the importance of these recombinational events should not be underestimated, and transfer of smaller or bigger segments of DNA between different clonal lineages and other species has probably contributed more to the evolution of *E. coli* than anyone could have imagined. Ongoing and future studies will be directed toward increasing our understanding of the principles that govern gene patterns and the relations between individual traits in terms of their significance for virulence and host adaptation. The combined efforts should contribute to a general IDEA (Index of Diversity in Evolution and Adaptation) that will bridge the phylogenetic approach based on the clonal concept on one side and the horizontal transfer of gene cassettes on the other side.

Mutants, plasmids, phages, and bacteriocins The fact that *E. coli* mutants can easily be produced in the laboratory has substantially contributed to our understanding of many genetic mechanisms, ranging from the characterization and function of an individual gene to the description of complex operons. Plasmids carrying resistance genes (R plasmids) have been used as vectors and introduced into both laboratory strains and wild-type strains, and phages and other mobile elements such as transposons have been used widely in both research and applied biotechnology. Virulence genes are often found on plasmids (see pathogenicity section below). *E. coli* strains produce a variety of secreted antibiotically active polypeptides, bacteriocins, and microcins, which have the ability to kill or inhibit competing bacterial strains. Colicins, encoded by plasmids of *E. coli*, act on other

**Editorial Note:* At the time of publication, this information could be obtained at http://www.shigatox.net.

E. coli or closely related bacteria that do not carry that particular Col plasmid. Small lipoproteins are important components of the secretory apparatus, which facilitates release of colicin and plasmid- and phage-encoded proteins across the outer membrane. For additional information on *E. coli* mutants, plasmids, and phages see Campbell (1996), Bachmann (1996), Helinski et al. (1996), and Harwood (1993).

Antigenic structure

O antigens The main aspect of this analysis is the O antigen determination based on antigenicity of the LPS; O group designations run from O1 to O173 but O groups O31, O47, O67, O72, O93, O94, and O122 have been removed. Also included are the provisional O groups OX3 and OX7 listed by Ewing (1986b), which will receive the designations O174 and O175, respectively. An additional six new O groups representing STEC/VTEC strains are currently being investigated and will receive O designations O176 through O181 (Scheutz, unpublished data). Subtypes exist within most O groups and are designated ab, ac, etc., e.g., O128ab and O128ac. Many of these O antigens cross-react with other O antigens and to some extent to K antigens within *E. coli*, with other members of the genus and with other enterobacteria. Recent molecular typing using primers just outside the O antigen gene cluster (*rfb*) of 148 representative O groups observed unique amplified fragments for each O group with sizes ranging from 1.7 to 20 kb (Coimbra et al., 2000). Subsequent *Mbo*II digestion of PCR-amplified products resulted in clearly identifiable and reproducible O patterns for the great majority of O groups with a variation of band numbers for each pattern ranging from 5 to 25. Computer analysis identified a total of 147 O patterns and allowed subdivision of 13 O groups. However, two or more O groups shared a pattern among 13 other O patterns. The restriction method (*rfb*-RFLP) is more rapid and may prove to be more sensitive than conventional serotyping since 100% of strains are typeable, particularly those that are O rough or nonagglutinating. Additionally, it should facilitate the typing of strains outside the existing O antigen scheme, which is restricted to include only O groups of clinical, epidemiological, or scientific relevance. The success and general application of such a typing scheme will require international collaboration to develop standardized methods for generating, comparing, and maintaining a database of O patterns.

K antigens The K antigens are the acidic capsular polysaccharide (CPS) antigens. K antigens may be separated into two distinct groups designated group I and group II. Group I antigens, which are composed of high-molecular mass (>100 kDa) CPS, are only found in strains with O groups O8, O9, O20, and O101, and are expressed at both 18° and 37°C. Group I antigens are subdivided according to the absence (IA) or presence (IB) of amino sugars on their CPS. The CPSs of group IA antigens share structural identity or resemblance to those from *Klebsiella* spp., whereas the CPSs of group IB antigens share no structural resemblance to those from other bacteria. Representative strains expressing group IA antigens do not contain the *rol* (*cld*) gene encoding the regulator of lipopolysaccharide O-chain length, whereas a similar subset of strains expressing group IB antigens contains the *rol* gene (Dodgson et al., 1996). Portions of the CPSs of some group I antigens are attached to the lipid A-core in a form that has been designated K_{LPS}, which will behave similarly to the traditional O antigens. A good example of a group I K_{LPS} is K84, which may be operationally defined as an O antigen and was originally designated as O93.

Group II antigens, which are composed of low molecular mass (<50 kDa) CPS, are found primarily in strains with O groups that are associated with extraintestinal disease. The CPSs of many group II antigens have structural resemblance or near identity to those from Gram-positive bacteria. These antigens differ widely in composition and structural features and may be divided into subgroups based on their acidic components. Twenty to fifty percent of the CPS chains are bound to phospholipids. They were originally thought to be temperature dependent, i. e., only expressed at 37°C. However, K2, K3, K10, K11, K19, K54/K96, and K98, which are tentatively classified as group I/II antigens (Finke et al., 1990), show no temperature regulation of their capsules and, like group I antigens, do not depend on an elevated CMP-KDO concentration for capsule expression. Based on genetic data, a subset of the group I/II antigens (K3, K10, and K54/K96) has been designated group III antigens (Pearce and Roberts, 1995). A number of K antigens are closely related (indicated below by "~") or identical (indicated below by "="). The CPSs of some group IB antigens are structurally identical to the side chains of O antigens and are only considered as K antigens when co-expressed with another authentic O antigen. The following 60 different K antigens are recognized: K1, K2a/ac, K3, K4, K5, K6, K7 (=K56), K8, K9 (=O104), K10, K11, K12 (=K82), K13 (~ K20 and ~ K23), K14, K15, K16, K18a, K18ab (=K22), K19, K24, K26, K27, K28, K29, K30, K31, K34, K37, K39, K40, K41, K42, K43, K44, K45, K46, K47, K49 (=O46), K50, K51, K52, K53, K54 (~ K96), K55, K74, K84, K85ab/ac (=O141), K87 (=O32), K92, K93, K95, K97, K98, K100, K101, K102, K103, KX104, KX105, and KX106. The inclusion of an "X" before the number represents a temporary K antigen designation. A description of the serology, chemistry, and genetics of *E. coli* O and K antigens is given by Ørskov et al. (1977).

H antigens Flagellar or H antigens make up the third main group of serotyping antigens. A total of 56 H antigens have been described, but two, H13 and H22, have been removed as being *C. freundii*, and H50 has been withdrawn because it is identical to H10. Cross-reactions are also seen between the H antigens.

Fields et al. (1997) described a tentative molecular method for the differentiation of flagellar antigen groups in *E. coli* based on restriction fragment length polymorphisms (RFLP) in *fliC* using the restriction enzyme *Rsa*I. A wide variety of *fliC* restriction fragment patterns was reported among isolates of 53 different flagellar antigen groups; the majority of the RFLP patterns observed corresponded to a unique H antigen group. Limited numbers of RFLP patterns were observed among members of some H groups, suggesting that the sequence of *fliC* within certain H groups is fairly well conserved. Four patterns were observed among strains expressing the H7 antigen. Interestingly, the same pattern was detected among all *E. coli* strains of serotype O157:H7 and 16 of 18 of serotype O55:H7, reflecting the common lineage of these strains observed by multilocus enzyme typing (Whittam et al., 1993). Nevertheless, sequencing of a total of 20 H7 *fliC* genes, representing 10 different serotypes (Reid et al., 1999; Wang et al., 2000), revealed a notable polymorphism in the *fliC* gene and identified 10 sequences with differences ranging from 0.06% to 3.12%. Recently, a collection of reference strains representing 48 H types was resolved into 62 patterns (F types) using *Hha*I restriction of the *fliC* gene (Machado et al., 2000). A single F type was associated with each of 39 H types and more than one

F type was associated with the other nine H types. Antigenically related H12 and H45 gave a single F type. The determination of *Hha*I-*fliC* F types could allow deduction of all H types and subdivision of some of these. The two above-mentioned molecular typing methods hold promise of a rapid, more refined and specific typing scheme for the H antigens, which may also be helpful in determining phylogenetic relatedness between different clones of *E. coli*. Furthermore, molecular typing has the advantage of allowing typing of nonmotile strains or of strains that do not (sufficiently) express the immunoreactive H antigen, and is likely to expand the present number of significantly different H types. The observed polymorphism in a single determinant, such as the H7 *fliC* gene, stresses the importance of solid and extensive validation of molecular typing with reference to the existing serotyping scheme, and calls for caution in the interpretation of patterns obtained by DNA fingerprinting methods.

Serotyping Subdivision of *E. coli* can be carried out in many ways, but serotyping remains one of the most useful ways to subdivide the species on a global basis. This typing method is based on the many antigenic differences found in structures on the bacterial surface. A serotype is recorded in the following way: O18ac:K1:H7 or O111:H2 (the latter antigenic formula indicates that K antigens are not present in the strain). MR fimbriae, which are present only in some, often pathogenic, serotypes, can also be used for the serological characterization (Ørskov et al., 1977, 1980b; Ørskov and Ørskov, 1990) in which case the complete serotype is recorded as O4:K3:H5; F13 or O147:H19; F4ac. Serotyping procedures are described in Gross and Rowe (1985) and Ørskov and Ørskov (1984a).

Even though complete serotyping involving the many known O, K, H, and F antigens has been carried out in only a very few laboratories, it is well known that the existing number of serotypes is very high.

Antibiotic or drug sensitivity Like other Gram-negative bacteria, *E. coli* is intrinsically resistant to hydrophobic antibiotics, such as macrolides, novobiocins, rifamycins, actinomycin D, and fusidic acid (Nikaido, 1996). The structure of the outer membrane of *E. coli* and its role in mediating intrinsic resistance to these molecules was reviewed by Nikaido (1996). Resistance to these compounds is attributed, in part, to the low permeability of the outer membrane bilayer to lipophilic solutes; however, active efflux mechanisms may have a synergistic effect on resistance in certain cases (Nikaido, 1996).

Acquired resistance to aminoglycosides, beta-lactams, chloramphenicol, macrolides, sulfonamides, tetracycline, and trimethoprim has been described for *E. coli* strains (reviewed by Quintiliani and Courvalin, 1995). Acquired resistance can develop by four distinct mechanisms: alteration of the target site, enzymatic detoxification of the antibiotic, decreased drug accumulation, and bypass of an antibiotic-sensitive step. The first three mechanisms may be mediated by chromosomal mutations or the acquisition of plasmids carrying resistance genes. The fourth mechanism is primarily attributable to the horizontal transfer of antibiotic resistance genes on a plasmid or transposon. The biochemical mechanisms and genetic basis of acquired resistance to antimicrobial agents of clinical importance was discussed by Quintiliani and Courvalin (1995). Genetic methods for the detection of antibacterial resistance genes were reviewed by Tenover et al. (1995).

Pathogenicity *E. coli* is a natural and essential part of the bacterial flora in the gut of humans and animals. Most *E. coli* strains are nonpathogenic and reside harmlessly in the colon; however, certain serotypes or clones play an important role in both intestinal and extraintestinal diseases. The diverse pathogenesis of this bacterium in apparently healthy individuals is largely attributable to its possession of a variety of specific virulence factors. In hosts with compromised defenses, *E. coli* can also be an excellent opportunistic pathogen.

E. COLI IN HUMAN INTESTINAL DISEASES *E. coli* strains isolated from intestinal diseases have been grouped into at least six different main categories based on epidemiological evidence, phenotypic traits, clinical features of the disease they produce, and specific virulence factors. The currently recognized categories of diarrheagenic *E. coli* include enteropathogenic *E. coli* (EPEC) (actually a subgroup of attaching and effacing *E. coli* (A/EEC) defined as *eae* positive *E. coli* belonging to both the classical EPEC serotypes and nonclassical EPEC serotypes), enterotoxigenic *E. coli* (ETEC), enteroinvasive *E. coli* (EIEC), enteroaggregative *E. coli* (EAggEC), diffusely adherent *E. coli* (DAEC), and Shiga toxin-producing *E. coli* (STEC), which are also referred to as Vero cytotoxin-producing *E. coli* (VTEC). These categories are reviewed below with emphasis on their virulence factors.

ENTEROPATHOGENIC *E. COLI* (EPEC) Enteropathogenic *E. coli* was the first category of diarrheagenic *E. coli* to be recognized. The term *enteropathogenic E. coli* (EPEC) was originally used to refer to strains belonging to a limited number of O groups that were epidemiologically associated with infantile diarrhea (Neter et al., 1955). This rather imprecise definition, which allowed for the inclusion of a heterogeneous group of pathogens, was used for decades and became increasingly problematic as groups of *E. coli* that could produce diarrheal disease by the production of enterotoxins or invasion of intestinal epithelial cells were recognized. The confusion generated by the discovery of new pathogenic groups of *E. coli* and the findings that EPEC strains, which lacked the virulence properties of these newly recognized groups, caused disease in adult volunteers (Levine et al., 1978) prompted researchers in 1982 to define EPEC as "diarrheagenic *E. coli* belonging to serogroups epidemiologically incriminated as pathogens but whose pathogenic mechanisms have not yet been proven to be related to either heat-labile enterotoxins or heat-stable enterotoxins or *Shigella*-like invasiveness" (Edelman and Levine, 1983). As more was learned about the strains associated with infant diarrhea, the definition was refined to include only certain O:H serotypes associated with illness. Table BXII.γ.199 lists some of the O:H serotypes that have been regarded for many years as EPEC. Since 1982, advances in our understanding of the molecular aspects of EPEC pathogenesis have allowed researchers to move beyond the serologic markers that correlate with disease to develop a definition based on pathogenic characteristics. A definition adopted in 1995 identified the most important characteristics of EPEC as its ability to cause attaching and effacing (A/E) histopathology and its inability to produce Shiga toxins (Kaper, 1996). The pathogenesis of EPEC is highlighted below and has been reviewed in detail by Nataro and Kaper (1998) and Williams et al. (1997).

The first advance in understanding the pathogenesis of EPEC infection was the discovery that EPEC strains adhere to HEp-2 cells in cell culture (Cravioto et al., 1979) in a distinctive pattern termed localized adherence (LA) (Scaletsky et al., 1984). Expression of the LA phenotype in EPEC requires a plasmid re-

[a]Data from Cravioto et al. (1979), Levine and Edelman (1984), Levine et al. (1985), Scaletsky et al., 1985,Robins-Browne (1987), Gomes et al. (1989b), Knutton et al. (1989, 1991), Scotland et al. (1989, 1992, 1996), Ørskov and Ørskov (1992), Donnenberg (1995).

[b]O18:H^-, H7, H14; O26:H34 and O44:H34 have also been listed but only in Knutton et al. (1991). O18 strains are probably not EPEC (Knutton et al., 1989; Ørskov and Ørskov, 1985). O44:H18 is now considered to belong to the group of enteroaggregative *E. coli* (Smith et al., 1994).

[c]Nonmotile strains of *E. coli* are regarded as descendants of motile strains that have lost their motility by mutation(s). Their original H antigen was often deduced from comparison of biochemical reactions (Kauffmann and Dupont, 1950; Staley et al., 1969).

[d]Abbreviations: EPEC, enteropathogenic *E. coli*; STEC/VTEC, Shiga toxin-producing *E. coli* /Vero cytotoxin-producing *E. coli*; EAggEC, enteroaggregative *E. coli*.

ferred to as the EPEC adherence factor (EAF) plasmid (Baldini et al., 1983). A 1-kb DNA probe originally thought to encode the EPEC adherence factor (EAF) necessary for LA was cloned from this plasmid (Nataro et al., 1985a) and has been used extensively as a marker to study the prevalence of EPEC infections (Nataro et al., 1985a; Echeverria et al., 1987, 1991; Gomes et al., 1989a, b; Moyenuddin et al., 1989; Senerwa et al., 1989; Cravioto et al., 1991; Kain et al., 1991; Strockbine et al., 1992; Begaud et al., 1993). EAF plasmids have been found in many EPEC serotypes and range in size from 26 to 76 MDa (Scotland et al., 1989) but typically are 50–70 MDa. Evidence supporting a role for the EAF plasmid in pathogenesis was provided by feeding studies showing that volunteers ingesting a plasmid-cured EPEC strain developed less diarrhea than those ingesting the plasmid-containing parental strain (Levine et al., 1985). Genes at two loci are necessary for expression of the LA phenotype: a cluster of 14 genes on the EAF plasmid involved in biogenesis of the bundle forming pilus (BFP), a type-IV pilus, which includes genes encoding bundlin (*bfpA*), the major structural subunit of the type-IV pilus, a prepilin peptidase, which processes pre-bundlin to its mature form, and 12 other proteins, and *dsbA* on the chromosome (Donnenberg et al., 1997).

A hallmark of the histopathology of EPEC infections is the presence of attaching and effacing (A/E) lesions in the intestinal tract. On electron micrographs of jejunal biopsies from children infected with EPEC, the bacteria are seen intimately attached to the epithelial cells on cup-like pedestals composed of depolymerized cytoskeletal proteins (Knutton et al., 1987). Microvilli are disrupted as a result of the cytoskeletal rearrangements and effaced by vesiculation (Fig. BXII.γ.192). The intimate attachment of EPEC is mediated by a protein known as intimin, which is a 94-kDa outer membrane protein encoded by the *eae* gene (*E. coli* attaching and effacing) (Jerse and Kaper, 1991). A 1-kb fragment of the *eae* gene referred to as CVD434 has been cloned (Jerse et al., 1990) and used to screen for attaching and effacing *E. coli* A/EEC (Bokete et al., 1997), and to characterize enteropathogenic *E. coli* (Scotland et al., 1996). Intimins belong to a growing family of proteins. In human EPEC strains, intimins α, β, γ, λ (δ not now used, although it is in the literature because it is a variant of the ε variant), and ε derivatives have been found to be serotype-specific and exhibit specific different binding affinities (Agin and Wolf, 1997). Intimins are also found in rabbit EPEC RDEC-1 strains, A/EEC strains from dogs (Beaudry et al., 1996), pigs (Zhu et al., 1995), and in *C. freundii* (Int_{CF}) and *Citrobacter rodentium* (Int_{CR}). Five strains initially identified as *Hafnia alvei* were reported to contain the *eae* gene (Albert et al., 1992), and a protein referred to as Int_{HA} has been characterized and compared to the above intimins. However, the strains are actually unusual biotypes belonging to the genus *Escherichia* (Janda et al., 1999), most likely *E. coli*. The *eae* gene is only one of many genes located on a pathogenicity island (PAI) known as the locus of enterocyte effacement (LEE) (McDaniel et al., 1995).

EPEC strains secrete at least four proteins, Esps for EPEC secreted proteins, encoded by LEE. EspA, B, D, and Tir proteins are secreted via the type III apparatus and are required for attaching and effacing activity. Protein secretion, the transcription

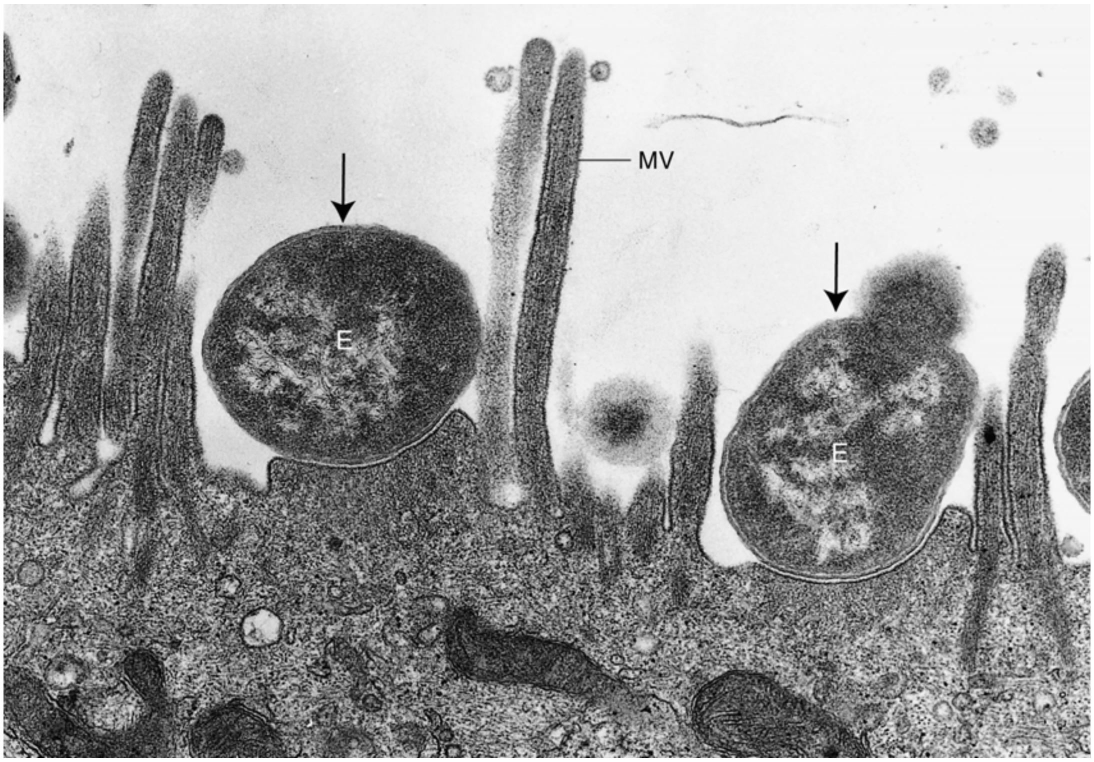

FIGURE BXII.γ.192. EM of cultured human intestinal mucosa infected with EPEC strain E2348 (*E*) for 8 h. Bacteria are seen intimately attached to the epithelial cells on cup-like pedestals composed of depolymerized short filament cytoskeletal proteins (*arrows*). Brush border microvilli (*MV*) are disrupted as a result of the cytoskeletal rearrangements and effaced by vesiculation. (Reproduced with permission from S. Knutton et al., Infection and Immunity *55:* 69–77, 1987, ©American Society for Microbiology.)

of the intimin gene (*eae*), and the synthesis of the bundle-forming pilus are all affected by growth conditions (Haigh et al., 1995; Jarvis et al., 1995; Kenny and Finlay, 1995) and a plasmid-encoded regulatory region. The plasmid locus is either referred to as the *per* (plasmid-encoded regulator) genes (*perABCD*) (Gómez-Duarte and Kaper, 1995) or as an integrated part of the bundle-forming pilus (*bfp*) operon, genes *bfpT*, *V*, and *W* (Tobe et al., 1996).

EPEC interferes with normal pathways of signal transduction in epithelial cells. EPEC will induce tyrosine phosphorylation; phosphorylation of myosin light chain, vinculin, and α-actinin; *in vitro* release of intracellular calcium; phospholipase C activity, resulting in elevated levels of inositol phosphates and diacylglycerol, in turn activating protein kinase C; reactions that induce host cell proteins to initiate cytoskeletal rearrangement; and bacterial uptake (Rosenshine et al., 1992; Manjarrez-Hernandez et al., 1996).

EPEC is not invasive in the same way as *Shigella*, *Yersinia*, and *Salmonella* (Geyid et al., 1996), although some EPEC strains may exhibit *in vitro* invasion of epithelial cells at levels comparable to those seen in EIEC (Donnenberg et al., 1989; Pelayo et al., 1999). A 4.5-kb fragment from a large so-called EPEC plasmid of an O111:H^- strain negative for both EAF and *eae* will confer epithelial cell invasivity and the attaching and effacing ability on a noninvasive laboratory strain (Fletcher et al., 1990, 1992). Only a smaller proportion of EPEC strains hybridize with the cloned fragment.

Of the EPEC O:H serotypes shown in Table BXII.γ.199, only 16 of the possible 175 recognized O groups are represented and only a few H antigens, e.g., H2, H6, H7, H12, H21, and H34, occur among several of these 16 O groups. The more recently described serotypes possessing EPEC-associated virulence markers have been added to the list. Some of these are O86:H8, O88:H25, O103:H2, O127:H40, O142:H34, O145:H45, O157:H8, O157:H16, and O157:H45.

Enterotoxigenic *E. coli* (ETEC) Enterotoxigenic *E. coli* strains are important causes of diarrhea in both humans and domestic animals. ETEC strains do not invade epithelial cells but produce one or more enterotoxins that are either heat-labile (LT), which is closely related to cholera toxin, or heat-stable (ST) (Cohen and Giannella, 1995). LT-I and ST are plasmid-encoded (LT-II is chromosomally encoded) and found alone or together, and are often associated with a limited number of O:K:H serotypes and O groups. Table BXII.γ.200 shows some of the most common serotypes from humans. These enterotoxins cause intestinal secretion either by activation of guanylate (ST) or adenylate (LT) cyclase and are subdivided based on their biological activities, receptors, and chemical and antigenic properties. STh and STp are used to indicate strains of human or porcine origin. The gene encoding another heat-stable enterotoxin called enteroaggregative heat-stable toxin 1 (EAST1), originally thought to be produced by EAggEC only, may also be present in addition to the STa gene. The different variants of enterotoxins are summarized in Table BXII.γ.201.

There is host specificity among ETEC strains causing diarrhea in humans or different species of domestic animals. This is mainly due to the specific recognition between bacterial colonization factors and the epithelial receptors during host-parasite inter-

TABLE BXII.γ.201. Variants of enterotoxins found in ETEC strains[a]

Toxin type	Subtypes		Comments
LT: Heat-labile enterotoxins			
LT-I	LTp (LTp-I)	LTh (LTh-I)	Associated with disease in both humans and animals
LT-II	LT-IIa	LT-IIb	No specific association with disease. Rare in human isolates
ST: Heat-stable enterotoxins			
STa (STI)	STp (STIa)	STh (STIb)	Produced by ETEC and several other Gram-negative bacteria. In ETEC, ST is often found together with the genes for EAST1.
STb (STII)			Induces histological damage in the intestinal epithelium. Most often found in porcine ETEC.

[a]Suffixes commonly used are: h, human variant; p, porcine variant.

action. Most of the fimbriae found in ETEC are typically MR fimbriae. In human ETEC strains at least 21 different surface structures called CS, for coli surface antigens, or CFA, for colonization factor antigens, usually plasmid encoded, have been described (Gaastra and Svennerholm, 1996). In animals, the most common fimbriae are F4 (which was originally described as K88), F5 (originally named K99), F6 (originally named 987P), F17, F41, F42, CS31A, F141, and F165. These fimbriae are found in enterotoxigenic strains from newborn piglets, pigs, lambs, and newborn calves. A close association between the EAST1 toxin and CS31A, which is related to F4, among pathogenic bovine *E. coli* has been suggested (Bertin et al., 1998).

More recently, the fimbrial F18 antigen (provisionally designated F107, 2134P, or 8813) has been found in both porcine ETEC and STEC/VTEC strains. It is characteristic that the fimbriae usually are found in a limited number of serotypes. The antigenic variants of F18 fimbriae (F18ab and F18ac) are biologically distinct. F18ab fimbriae are expressed poorly both *in vitro* and *in vivo* and are frequently linked with the production of Stx2e/VT2e and O group O139, while F18ac are more efficiently expressed *in vitro* and *in vivo* and most often are linked with enterotoxin (STa, STb) production, and O groups O141 and O157.

Enteroinvasive *E. coli* (EIEC) Enteroinvasive *E. coli* are very similar to *Shigella*. Like *Shigella*, they are capable of invading and multiplying in the intestinal epithelial cells of the distal large bowel in humans. Approximately two thirds of EIEC strains are lactose negative and virtually all are lysine negative. Multiple chromosomal and plasmid genes are associated with virulence (Acheson and Keusch, 1995). EIEC are restricted to a very limited number of serotypes, most of which are nonmotile (Table BXII.γ.202).

Enteroaggregative *E. coli* (EAggEC) Enteroaggregative *E. coli* are characterized by a distinct aggregative adherence (AA) pattern to HEp-2 cells *in vitro* first described by Nataro et al. (1987). This pattern is distinguished by the prominent autoagglutination of bacterial cells to each other, to the surface of the HEp-2 cells, as well as to the glass cover slip in a characteristic layering best described as a "stacked brick" configuration. The AA pattern is plasmid-mediated (Nataro et al., 1985b) and was suspected to be a putative agent of diarrheal disease as early as 1988 (Vial et al., 1988). Volunteer studies with EAggEC have indicated that certain types will cause diarrhea and other enteric symptoms including borborygmia and cramps (summarized in

Nataro, 1995), and epidemiological studies have implicated EAggEC as a cause of travelers' diarrhea (Brook et al., 1994; Scotland et al., 1994). Only about half of the case-control studies that have been carried out find significantly higher isolation rates in cases than in controls (summarized by Law and Chart, 1998). Most recently, EAggEC have been associated with acute and chronic diarrhea and abdominal colic in young children in Germany (Huppertz et al., 1997), and with four outbreaks of gastroenteritis in the UK (Smith et al., 1997b). A DNA probe, referred to as CVD432, has been cloned from the plasmid of strain O42, serotype O44:H18 (formerly an EPEC O:H serotype) and used to identify EAggEC (Baudry et al., 1990). A plasmid encoded flexible, bundle-forming fimbrial structure, designated aggregative adherence fimbria I (AAF/I), is encoded by two regions (Nataro et al., 1992, 1993). Region 2 encodes a transcriptional activator of the AraC family of DNA-binding proteins (Nataro et al., 1993). At least one toxin similar to the heat-stable toxin of ETEC, ST designated EAST1, has been identified in an EAggEC strain (Savarino et al., 1991, 1993). The gene encoding EAST1 has been shown to be broadly distributed among diarrheagenic *E. coli*: 100% of 75 O157:H7 STEC/VTEC, 41% of 227 EAggEC, 41% of 149 ETEC, 22% of 65 EPEC, and 38% of 47 *E. coli* from asymptomatic children hybridized with the EAST1 DNA probe (SS126) (Savarino et al., 1996). Despite the common occurrence of the EAST1 gene in many diarrheagenic *E. coli* groups, outbreaks had not been attributed to EAST1-only-producing *E. coli* until recently, when an outbreak in Japan was associated with an O166:H? strain positive for the EAST1 gene (Nishikawa et al., 1999). In Spain, a case-control study suggested that EAST-1 positive *E. coli* strains are associated with diarrheal diseases in Spanish children, whereas EAggEC strains are not (Vila et al., 1998). The significance of these findings remains to be established. Many serotypes have been observed and some of the most commonly reported serotypes are listed in Table BXII.γ.203.

Diffusely adherent *E. coli* (DAEC) Diffusely adherent *E. coli* are defined by the presence of the diffuse adherence (DA) pattern of *E. coli* strains to HEp-2 cells (Scaletsky et al., 1984; Nataro et al., 1985b). A surface fimbriae designated F1845 confers the DA phenotype, and a DNA probe has been cloned (Bilge et al., 1989). Another adhesin (designated AIDA-I) has also been associated with DA of *E. coli* of serotype O126:H27 (Benz and Schmidt, 1989). The role of DAEC in diarrhea is unclear.

[a]Many other serotypes of EAggEC have been published by several authors.

Shiga toxin-producing *E. coli* (STEC) or Vero cytotoxin-producing *E. coli* (VTEC) Shiga toxin-producing *E. coli* or Vero cytotoxin-producing *E. coli* strains are characterized by their ability to produce either one or both of at least two antigenically distinct, usually bacteriophage-mediated cytotoxins referred to as Stx1 or VT1 (first described as Shiga-like toxin I, SLTI) and Stx2 or VT2 (first described as Shiga-like toxin II, SLTII). Whereas STEC/VTEC refers to all *E. coli* strains that produce Stx/VT in culture supernatants (Konowalchuk et al., 1977, 1978), the term *enterohemorrhagic E. coli* (EHEC) has been used to refer to strains that have the same clinical and pathogenic features associated with the prototype organism *E. coli* O157:H7 (Levine, 1987). In practice, EHEC is used to describe a subgroup of STEC/VTEC that causes hemorrhagic colitis.

Shiga toxins or Vero cytotoxins belong to the Shiga toxin family, comprises the following members: Shiga toxin, which is produced by *Shigella dysenteriae* type 1, Stx1/VT1, STx2/VT2, and Stx2/VT2 variants (Stxv/VT2v). Stx/VT genes, products, and synonyms are summarized in Table BXII.γ.204. Stx2e/VT2e, one of the variants, is produced by STEC/VTEC strains causing edema disease (Marques et al., 1987), a usually fatal disease, in weanling pigs and referred to as Stx2e/VT2e. Unlike all other Stxs/VTs, this is not cytotoxic to HeLa cells and binds to a different receptor, Gb4. The functional receptor for human Stx/VT is the glycolipid globotriosyl ceramide Gb3 (galactose-α-(1-4)-galactose-β-(1-4)-glucose ceramide) (Lingwood et al., 1987; Waddell et al., 1988) found in human renal endothelial cells (Obrig et al., 1993).

Stxs/VTs inhibit protein synthesis by depurination of adenine in 28S rRNA (*N*-glycosidases), thus inhibiting the elongation factor 1 (EF-1)-dependent aminoacyl-tRNA binding to 60S ribosomal subunits (Endo et al., 1988). In Vero cells the result is cell death by apoptosis (Inward et al., 1995).

Nomenclature of Shiga toxins/verocytotoxins The recognition and investigation of cytotoxin-producing *E. coli* infections by several groups has resulted in the use of differing systems of nomenclatures for the toxins produced by these bacteria. In 1994, O'Brien et al. (1994) developed a proposal for rationalizing the nomenclature of the *E. coli* cytotoxins. In their proposal, they recommended guidelines for classifying and designating members of the toxin family and stated the toxins shall be referred to by two alternate but interchangeable names, Shiga-like toxins (SLT) and Vero cytotoxins (VT). Two years later, a proposal to simplify the Shiga-like toxin nomenclature was published by Calderwood et al. (1996). In this proposal, the word "like" was omitted and the toxins and genes were renamed to reflect their relationship to Shiga toxin, the prototype toxin for the family. To avoid confusion in the literature, it was suggested that cross-reference to existing VT nomenclature could be used. While the omission of the word "like" has received general acceptance in the scientific community, strong arguments for maintaining the existing phenotype nomenclatures for *E. coli* cytotoxins were immediately put forward (Karmali et al., 1996), and the two systems of nomenclature are still being widely used. Toxins included in the Shiga toxin/Verocytotoxin family share the following properties: DNA sequence homology and operon structure (A subunit gene immediately upstream of the B subunit gene); polypeptide subunit structure (five B subunits to one A subunit in the mature holotoxin); enzymatic activity (*N*-glycosidases); binding to specific glycolipid receptors and biological properties, including enterotoxicity in ligated rabbit ileal loops;

[a]Data compiled from references Bastian et al. (1998), Bertin et al. (2001), Calderwood et al. (1996), Gannon et al. (1990), Ito et al. (1990), W.M. Johnson et al. (1991), Karmali et al. (1996), Kokai-Kun et al. (2000), Lin et al. (1993a, b), Takeda et al. (1993), and Tyler et al. (1991).

[b]Toxin types are defined according to antigenic variability, differences in toxicity for tissue culture cells and/or animals, their capacity to be activated by mouse elastase, and differences in DNA or amino acid sequences.

[c]There are several toxins suffixed by d in the literature: The Stx2d/VT2d toxins of O91:H21 (Melton-Celsa and O'Brien, 1998), the VT2d (= stx2-O group/ strain designation and/or year) variants by Paton et al. (1992, 1993a, 1995b), Piérard et al. (1998), and the SLT-IId/VT2d (= Stx2f/VT2f) toxin produced by strain H.I.8 (serotype O128:H2) as proposed by Gyles (1994). We support the use of the d designation for activatable Stx2/VT2 toxins as proposed by Melton-Celsa and O'Brien, (1998).

[d]Stx2-O118/VT2-O118 (formerly known as VT2d-Ount) is expected to be nonactivatable based on analysis of the nucleotide sequence (Denis Piérard and Angela Melton-Celsa; unpublished); the original strain has been retyped as O118:H12 (Lothar Beutin and Flemming Scheutz, unpublished).

[e]This designation has also been referred to for the Stx2f/VT2f toxin produced by strain H.I.8 (serotype O128:H2).

[f]The nucleotide sequence of the former stx_{2ev}/*vtx*2ev of strain H.I.8 (serotype O128:H2) is nearly identical to the recently published stx_{2f}/*vtx*2f found in strain T4/97 (serotype O128:H2) from feral pigeons (Schmidt et al., 2000). As its nucleotide sequence is distinctly different from those of the other Stx2/VT2 toxins and variants as well as Stx1/VT1, we support the proposal of renaming stx_{2ev}/*vtx*2ev as stx_{2f}/*vtx*2f.

neurotoxicity in mice; and cytotoxicity to receptor-expressing tissue culture cell lines, such as Vero and HeLa cell lines. Classification of the toxins into major toxin types, designated with Arabic numbers, is based on differences that result in no cross-neutralization by homologous polyclonal antisera and no DNA–DNA cross-hybridization of their genes under conditions of high stringency. Toxin subtypes, designated with letters added to the type name, share cross-hybridization of their genes under high stringency but show significant differences in biologic activity, including the capacity to be activated; serologic reactivity; or receptor binding. Table BXII.γ.204 summarizes the currently reported Shiga toxin/Verocytotoxin genes and toxins, prototype organisms, and their previous designations in the literature.

The distinction between toxin types 2c and 2d in Table BXII.γ.204 is based on differences in the A subunit determining whether the toxin is activatable (Stx2d/VT2d) or nonactivatable (Stx2c/VT2c). The other Stx2/VT2 subtypes described in the literature, which have not been tested for all properties, have been tentatively placed together with toxin type 2c, primarily based on similarities in nucleotide sequences that place them in a phylogenetically related Stx2/VT2 cluster including all variants. Based on their degree of overall nucleotide sequence similarity, Stx2/VT2 toxins fall into two phylogenetically distinct groups (Bastian et al., 1998; Piérard et al., 1998). Toxins in group 1, which include Stx2/VT2, Stx2c/VT2c (including variants Stx2-O22/VT2-O22, Stx2-O157-TK-51/VT2-O157-TK-51, Stx2-OX3/b-031/VT2-OX3/b-031, Stx2-O48/VT2-O48), and Stx2d/VT2d, share 99.1–99.2% and 95.9–98.5% nucleotide sequence similarity in their A and B subunits, respectively; while toxins in group 2, which include Stx2-OX3/a-031/VT2-OX3/a-031, Stx2-O111-PH/VT2-O111-PH, and Stx2-O118/VT2-O118, share 96.9–99.9 % and 99.6–100% nucleotide sequence similarity in their A and B subunits, respectively. The similarities of individual sequences between group 1 and group 2 are 93.4–96.0% for the A subunits and 86.2–89.3% for the B subunits. The extent of, and differences between, toxicity for tissue culture cells and/or animals and their capacity to be activated are not fully established for all the types. Further analysis against all the criteria necessary to allow definitive placement with appropriate other toxin types is required. In the absence of this information, suffixes have been added after the O group of the source organisms, and, when necessary, the original strain designation. Stx2/VT2 subtype toxins found in the same original strain are suffixed "/a", "/b" etc. as in Stx2-OX3/a-031/VT2-OX3/a-031 and Stx2-OX3/b-031/VT2-OX3/b-031.

For a brief presentation and practical use of the subtyping of Stx/VT genes with 4 Stx1/VT1 and 9 Stx2/VT2 oligonucleotide DNA probes, and 3 Stx1/VT1 and 8 Stx2/VT2 primer pairs, see Smith et al. (1993), Yamasaki et al. (1996), Piérard et al. (1997), and Bastian et al. (1998).

Like EPEC, some STEC/VTEC strains have been shown to cause attaching and effacing lesions *in vivo* (Hall et al., 1990), in animal models (Francis et al., 1986; Tzipori et al., 1986; Sherman et al., 1988), and *in vitro* (Knutton et al., 1989). Two separate groups have cloned, sequenced, and characterized the *eae* homologue from VTEC O157:H7 (Beebakhee et al., 1992; Yu and Kaper, 1992). Homology between EPEC and STEC/VTEC sequences was 86% and 83% at the nucleotide and amino acid levels, respectively (Yu and Kaper, 1992), and the STEC/VTEC *eae* sequence was 97% homologous to the EPEC *eae* gene for the first 2200 bp and 59% homologous over the last 800 bp (Beebakhee et al., 1992). Both *eae* sequences show 50% homology to the central region of the *Yersinia pseudotuberculosis inv* gene (Jerse et al., 1990; Beebakhee et al., 1992), and the predicted amino acid sequence of the STEC/VTEC *eae* gene share 31% identity and 51% similarity with the invasin molecule of *Yersinia pseudotuberculosis* (Yu and Kaper, 1992).

Serotype specific heterogeneity of the *eae* gene in STEC/VTEC strains O55:H7 or H^{-}, O111:H8 and O157:H7 or H^{-}, and in O groups O26, O103, and O157 has been demonstrated (Gannon et al., 1993; Louie et al., 1994).

Almost all STEC/VTEC O157:H7 strains harbor a large 60-65 MDa plasmid (Johnson et al., 1983), designated pO157, that plays a role in virulence (Karch et al., 1987) and a small plasmid of 6.6 kb found in O157:H7 STEC/VTEC strains appear to synthesize colicin D (Bradley et al., 1991). O26:H11 strains also possess at least one plasmid in the range of 55–70 MDa. Restriction enzyme patterns of plasmids from other O:H serotypes (including O5, O91, O103, O111, O121, and O127) show a notable similarity with the large plasmids in O157 and O26 strains (Levine et al., 1987). A 3.4-kb fragment from a large plasmid of O157:H7 (prototype EDL 933) has been cloned and used as a DNA probe (referred to as CVD419) to identify EHEC plasmids (Levine et al., 1987); i.e., large plasmids found in Verocytotoxin producing *E. coli* strains. DNA probing with gene probes defining the incompatibility group of plasmids indicates that the STEC/VTEC plasmids share an approximately 23-kb fragment with EPEC plasmids and that the large plasmids of both EPEC and STEC/VTEC constitute a family of transfer-deficient Inc F-IIA plasmids (Hales et al., 1992), while sequencing of pO157 reveals high homology to the orf1 of the RepFIB replicon (Schmidt et al., 1996a).

The large plasmid of O157 encodes the EHEC-hemolysin (Ehx), which is homologous to the *E. coli* α hemolysin (Schmidt et al., 1994, 1995a), and a novel catalase-peroxidase, KatP (Brunder et al., 1996). In contrast to α hemolysin, Ehx can be detected only on blood agar plates containing washed sheep erythrocytes. The zones of hemolysis on these plates are smaller and more turbid than those caused by α hemolysin and require overnight incubation before they become visible (Beutin, 1991; Beutin et al., 1988, 1989). A role for Ehx in the pathogenesis of diarrheal disease has not been demonstrated. Because α hemolysin-producing strains are uncommon in feces, these hemolysins serve as useful phenotypic markers for the detection of the majority of STEC/VTEC organisms.

The genes encoding the Ehx constitute a typical RTX (repeats in toxin) determinant, the Ehx-operon, with the gene order CABD (Schmidt et al., 1996a). The *ehxA* gene encodes the active protein, and *ehxB* and *ehxD* share high sequence homology with other RTX transport proteins (Schmidt et al., 1995a, 1996a). Like α hemolysin, the Ehx is a highly active cytolysin of the RTX family with a similar but not identical pore-forming capacity (Schmidt et al., 1996b). The Ehx plasmid DNA probe (CVD419) covers the *ehxA* and part of the *ehxB* gene (Schmidt et al., 1995a).

Two other enterohemolysins Ehly1 and Ehly2 have been described (Beutin et al., 1993b; Stroeher et al., 1993). Ehly1 is a 33-kDa cell-associated protein encoded by a bacteriophage, ΦC3888, found in O26:H11 STEC/VTEC. Ehly1 has no known sequence homology to any other DNA or protein sequence. The Ehly2 enterohemolysin is also encoded by a bacteriophage, ΦC3208, found in O26:H11. It is in part homologous to DNA of bacteriophageλ; but completely unrelated to Ehly1 (Beutin et al., 1993b).

Most information on the source and transmission of STEC/VTEC has been learned from outbreak investigations. Findings

from these investigations showed that most outbreaks are related to carriage of the organism in ruminants, especially cattle, which show no symptoms of disease. During the period from 1982 to 1993, at least 20 outbreaks of O157:H7 have been reported in the USA (summarized in Anonymous, 1994). These outbreaks have affected 1509 patients, resulting in the hospitalization of 346 patients, 86 cases of HUS, and 19 deaths. This increased dramatically in the following years with 13 outbreaks in 1993 and 30 outbreaks in 1994 (Armstrong et al., 1996). The largest multistate outbreak in the USA occurred in early 1993 with more than 700 illnesses and 4 deaths (Bell et al., 1994; Davis, 1994). It has been estimated that *E. coli* O157:H7 causes 73,000 illnesses annually in the United States and non-O157 STEC/VTEC, 37,000 illnesses; and that 91 deaths occur each year in the USA (Mead et al., 1999). In Canada, 15 outbreaks were reported in 1982–1987 with 242 cases, 24 cases of HUS, and 15 deaths (Karmali, 1989). The first recognized community outbreak of O157:H7 in Europe occurred in the UK in the summer of 1985 affecting at least 24 persons. Eleven patients were hospitalized and one died (Morgan et al., 1988). In England and Wales, O157:H7 was isolated from 39% of sporadic cases of hemorrhagic colitis (Smith et al., 1987) and 33% of sporadic HUS cases (Scotland et al., 1988). In an outbreak of HUS in the West Midlands, O157:H7 was isolated from 33% of cases (Taylor et al., 1986a; Willshaw et al., 2001). Subsequent outbreaks and sporadic cases in the UK have been reported (Salmon et al., 1989). Scotland has one of the highest rates of infection with O157 increasing from 1.37/100,000 of the population in 1989 (Thomas et al., 1996a) to 32.3/100,000 in 1996 (Reilly and Carter, 1997). The worst food poisoning outbreak with O157 STEC/VTEC in Scotland occurred in 1996 with 501 cases; 151 were hospitalized and 20 elderly died (Ahmed and Donaghy, 1998).

O157 STEC/VTEC has been isolated from outbreaks and from sporadic cases of diarrhea and HUS in many parts of the world: Canada, UK, Argentina, Germany, Central Europe, Chile, and Italy (summarized by Griffin, 1995; see also Chapters 2–9 in Kaper and O'Brien, 1998). Sakai City in Japan experienced the largest outbreak of O157 STEC/VTEC ever recorded in July 1996, which was part of several outbreaks that summer with an estimated number of a little less than 8,000 cases and 6 deaths (Infectious Disease Surveillance Center, Japan, 1997).

Other STEC/VTEC O:H serotypes have caused outbreaks of diarrhea and HUS: O111:H$^-$, O145:H$^-$, and O?:H19 in Japan (Kudoh et al., 1994); O26:H11 in the Czech Republic (Bielaszewská et al., 1990), USA (Brown et al., 1998), and Ireland (McMaster et al., 2001); O103:H2 in France (Mariani-Kurkdjian et al., 1993); O104:H21 in the USA (Centers for Disease Control, 1995); O111:H$^-$ in Australia (Cameron et al., 1995), Italy (Caprioli et al., 1994), USA (Banatvala et al., 1996; Centers for Disease Control, 2000), Spain (Blanco et al., 1996), and France (Boudailliez et al., 1997; Mariani-Kurkdjian et al., 1997); O113:H21 in Australia (Paton et al., 1999); and O119 in France (Deschenes et al., 1996). A clone of sorbitol fermenting O157:H7 STEC/VTEC has been isolated from patients with diarrhea and HUS (Gunzer et al., 1992; Karch et al., 1993) and caused an outbreak in Germany (Ammon et al., 1999). Studies in Europe indicate that non-O157 STEC/VTEC strains are increasing in frequency as a cause of hemolytic-uremic syndrome (HUS) and found much more commonly in children with diarrhea (Verweyen et al., 1999; Scheutz et al., 2001; Tozzi et al., 2001).

Among the over 400 STEC/VTEC serotypes, and apart from O157:H$^-$ and O157:H7, those in O groups O26, O103, O111, and O145 are most commonly isolated from humans worldwide. These, along with strains that have caused outbreaks, are clearly recognized as pathogens. Table BXII.γ.205 shows the non-O157 STEC/VTEC serotypes that have been isolated from humans.

E. coli in human extraintestinal infections

Extraintestinal pathogenic E. coli (ExPEC) Extraintestinal pathogenic *E. coli* (ExPEC) are *E. coli* strains that possess currently recognized extraintestinal virulence factors or have been demonstrated to possess enhanced virulence in an appropriate animal model (Russo and Johnson, 2000). ExPEC strains primarily belong to pathogenic clones of a limited number of O:K:H serotypes (Ørskov and Ørskov, 1975), usually with MR fimbriae (P and S fimbriae), siderophores (e.g., aerobactin), host defense-avoidance mechanisms such as capsules (Ørskov and Ørskov, 1977; Ørskov et al., 1982), O antigens, and serum resistance and toxins (often α-hemolysin). ExPEC is common in all age groups and may occur at almost any extraintestinal site. The most common infections include urinary tract infections (UTIs) ranging from uncomplicated to febrile to invasive, pyelonephritis, neonatal, and postneurosurgical meningitis and septicemia. This group is epidemiologically and phylogenetically distinct from commensal and intestinal strains of *E. coli* (Picard et al., 1999). Virulence genes are often located on pathogenicity islands (PAIs), which have the tendency to delete with high frequencies or may undergo duplications and amplifications. They are often associated with tRNA loci, which may represent target sites for the chromosomal integration of these elements (Hacker et al., 1997). Many produce toxins that can lyse erythrocytes of different mammalian species. The best characterized of these is α-hemolysin, which is often produced by strains causing UTIs (J.R. Johnson, 1991) and is believed to play an important role. α-Hemolysin is secreted and can be demonstrated in culture fluid filtrates (Beutin, 1991). Hemolytic colonies can also be identified by the clear zone of hemolysis produced on blood agar plates after 3–4 h of incubation.

Uropathogenic E. coli (UPEC) This somewhat misleading acronym (clones or virulence factors are not syndrome-specific) has been used to refer to the majority of specific clonal groups of uropathogenic *E. coli* isolated from UTIs including pyelonephritis. They are characterized by a number of virulence factors that together play a role in their pathogenesis. First, UPEC is dominated by a limited number of O groups with O groups O1, O2, O4, O6, O7, O18ac, O75, O16, and O15 as the most commonly isolated (Ørskov and Ørskov, 1985). These strains are also represented by a limited number of K antigens: K1, K2, K3, K5, K12, and K13. Common serotypes include O1:K1:H7, O2:K1:H4, O4:K12:H1, O4:K12:H5, O6:K2:H1, O6:K5:H1, O6:K13:H1 (cystitis), O16:K1:H6, and O18ac:K5:H7. Furthermore, the majority of UPECs express P fimbriae of F types F7 through F16 and /or S fimbriae.

Neonatal meningitis E. coli (NMEC) Neonatal meningitis *E. coli* is frequently associated with O groups O7, O18ac, O1, and O6 that have the K1 antigen identical to the capsule of *N. meningitidis* type B (Sarff et al., 1975). O83:K1 strains are also common but apparently only in Europe (Ørskov and Ørskov, 1985). One of the most commonly isolated types is an S fimbriated clone of serotype O18ac:K1:H7.

E. coli in animal infections As is the case in humans, certain strains of *E. coli* can cause disease in animals. In farm animals, *E. coli* strains are associated with a variety of pathological

TABLE BXII.γ.205. Serotypes of non-O157 STEC/VTEC isolated from humans[a,b,c]

[f]Provisional designation for new O antigens.

conditions, which include colibacillary diarrhea, colibacillary toxemia in pigs, systemic colibacillosis, coliform mastitis, and UTIs. Colibacillary diarrhea is an acute diarrheal disease due to ETEC infection, which occurs primarily in 1–3-d-old calves, lambs, and piglets. A limited number of O groups are represented among these ETEC strains. In England and Wales, the most common O groups of *E. coli* isolates from pigs with diarrhea are O149, O8, O158, O147, and O157 (Wray et al., 1993). Colibacillary toxemia in pigs can take several forms: shock in weaner syndrome, hemorrhagic enteritis, and edema disease. These disease syndromes are also attributable to *E. coli* belonging to a small number of O groups (O8, O45, O138, O139, O141, and O149). Rapid absorption of endotoxin from the bowel is hypothesized to play a role in the pathogenesis of the shock in weaner syndrome and hemorrhagic enteritis, while the toxin Stx2e/VT2e, which is produced by many of the strains having the above specified O groups, has been shown to play a role in the pathogenesis of edema disease (Macleod et al., 1991). Systemic colibacillosis occurs when septicemic strains of *E. coli* pass through the intestinal or respiratory mucosa into the bloodstream of calves, lambs, and poultry. Once they enter the bloodstream, they can cause either a generalized infection or a localized infection, such as meningitis and/or arthritis in calves and lambs or air sacculitis and pericarditis in poultry. *E. coli* strains are also an important cause of mastitis in cows. Endotoxin is believed to play a role in the inflammatory response observed during this disease.

The roles of various adherence mechanisms and toxins in the pathogenesis of the infections were reviewed by Wray and Woodward (1997). Fimbrial antigens and putative colonization factors associated with strains of *E. coli* causing disease in animals cited include F1, F4 (K88), F5 (K99), F41, F6 (987P), F17, F18, CS31A, F165, M326, C1213, F42, F11, curli, type IV pilins, and Nfa. Toxins produced by *E. coli* causing disease in animals include the heat-labile enterotoxins LTI and LTII, heat-stable enterotoxins STa

and STb, cytotoxic necrotizing factors 1 and 2 (CNF1 and CNF2), and Shiga/Verocytotoxins.

Other typing methods For a description of other methods for subdivision of *E. coli*, i.e., phage typing, colicin typing, biotyping, typing by outer membrane protein (OMP) pattern, typing by antibiotic resistance patterns, and typing by direct hemagglutination, see Ørskov and Ørskov (1984a) and Sussman (1985). Phage typing is very useful for certain antigens because antisera are difficult to produce. This is particularly true for K1 (Gross et al., 1977), K3, K5, K7, K12, K13 (Nimmich et al., 1992), and K95 (Nimmich, 1994). A phage-typing scheme for STEC/VTEC O157:H7 established in 1987 (Ahmed et al., 1987) and extended in 1990 (Khakhria et al., 1990) has proven very useful in the epidemiological surveillance of STEC/VTEC O157 (Frost et al., 1993; Saari et al., 2001) infections and is applicable even in low-technology laboratories. In general, phage typing of O157 should be supplemented with one of the molecular typing methods mentioned below. Because of their discriminatory power, speed, use of commercially available reagents and equipment, and amenability to automation and electronic networking, molecular subtyping methods have become very popular for subtyping of *E. coli*, particularly strains involved in causing outbreaks of foodborne disease. Molecular subtyping methods for *E. coli* O157:H7 and other foodborne bacterial pathogens were reviewed by Barrett (1997). Some recently described methods include macrorestriction endonuclease analysis with PFGE (Preston et al., 2000; Zhang et al., 2000; Swaminathan et al., 2001); detection of insertion sequences and characterization of virulence genes by DNA probes or PCR (Thompson et al., 1998; Zhang et al., 2000); detection of amplified fragment length polymorphisms (Iyoda et al., 1999); computer identification by rRNA gene restriction patterns (Machado et al., 1998); and the analysis of randomly amplified polymorphic DNA (Hopkins and Hilton, 2001). In 1996, a molecular subtyping network in the United States, designated PulseNet, for the electronic comparison of DNA fingerprints generated by macrorestriction endonuclease analysis with PFGE was developed to subtype *E. coli* O157:H7. PulseNet has proved an exceptionally valuable tool for detecting outbreaks of *E. coli* O157:H7 infection. The development of standardized laboratory and data analysis protocols and their successful use in providing surveillance for *E. coli* O157:H7 and other foodborne bacterial pathogens was reviewed by Swaminathan et al. (2001).

Enrichment and Isolation Procedures

Many simple agar media can be used for isolation. Media used for selective isolation from feces usually contain substances that partly or completely inhibit growth of bacteria other than *Enterobacteriaceae* (tetrathionate, deoxycholate, bile salts, etc.). The addition of Maranil (dodecylbenzolsulfonate) at a concentration of 0.005% will inhibit swarming of *Proteus* organisms. For details, see Edwards and Ewing (1972) or Kauffmann (1966) or any catalogue from one of the medium-producing companies. At Statens Serum Institut, Copenhagen, a medium developed in the media department of the institute, bromothymol blue (BTB) agar, is used.[1]

Maintenance Procedures

E. coli strains can be kept viable for many years in beef extract agar stabs (tightly closed, e.g., by corks soaked in melted paraffin wax) or on Dorset egg medium. Cultures are initially incubated at 37°C followed by storage in the dark at room temperature (20–22°C). After a few weeks or months, such cultures often contain many mutational forms such as R forms and acapsular forms; consequently, we prefer to store important cultures in beef broth containing 10% glycerol at −80°C. Screw-capped vials are used for easy access.

Procedures for Testing Special Characters

Kilian and Bülow (1976) found that a very high percentage (97%) of *Escherichia coli* and the majority (57%) of *Shigella* strains, exclusively among the *Enterobacteriaceae*, produce β-glucuronidase (GUD). Prolonged incubation of 28 h increases positivity to 99.5% (Rice et al., 1990), which is in accordance with the presence of the *uidA* (GUD) gene in all *E. coli* strains (McDaniels et al., 1996). This test (referred to as the GUD-, PGUA-, MUG-, GUR-, or GLUase-HR test) therefore is very suitable as a screening test for *E. coli*, with the unfortunate exception of most STEC/VTEC O157 strains, which are phenotypically negative. None of the other four species of the genus *Escherichia* are positive for this enzyme (Rice et al., 1991). Both genotypic and phenotypic assays for glutamate decarboxylase (GAD) used by environmental scientists have been described as highly specific for *E. coli*. Unfortunately, these tests have only recently been shown to exhibit the same specificity on a smaller collection of pathogenic isolates of *E. coli* (Grant et al., 2001).

Differentiation of the genus *Escherichia* from other genera

See Table BXII.γ.193 of the family *Enterobacteriaceae* for characteristics that can be used to differentiate this genus from other genera of the family.

Taxonomic Comments

The identification of *Escherichia* strains seldom causes problems; however, many studies have shown that "*Escherichia* is a genus (or species) made up of phenotypically variable strains" (Farmer and Brenner, 1977). DNA–DNA hybridization studies have been an invaluable tool for solving problems in this field. The genus *Shigella* is closely related to *Escherichia*, and only historical reasons make it acceptable that these two genera are not united. Several typical EIEC types have been found that have pathogenic traits that are similar to those of *Shigella*. The Sereny test (Sérèny, 1957), which demonstrates the capacity to cause keratoconjunctivitis in the guinea pig, typical of *Shigella* strains, is also found in these special *Escherichia* strains. Day et al. (1981) described a tissue culture technique that can be used as a substitute for the Sereny test. Typically, such dysentery-associated *E. coli* strains have O antigens that are closely related or identical to *Shigella* O antigens. Brenner et al. (1972a), by DNA reassociation studies, found species-level relatedness between *Shigella* strains and these special *Escherichia* strains, as well as nonpathogenic *E. coli* strains.

1. Bromothymol blue agar (selective for *Enterobacteriaceae*). Combine the following ingredients: peptone (Orthana Ltd., Copenhagen), 10.0 g; NaCl, 5.0 g; yeast extract (Oxoid), 5.0 g; and distilled water, 1000 ml. The pH is adjusted to 8.0, agar powder is added, and the preparation is autoclaved at 120°C for 20 min. The following components are then added aseptically from sterile stock solutions: Maranil solution [Paste A75 (dodecylben-zolsulfonate), Henkel, Germany], 1.0 ml; sodium thiosulfate (50% solution), 2.0 ml; bromothymol blue (Riedel de Haen, Germany; 1.0% solution), 10.0 ml; lactose (33% solution), 27 ml; and glucose (33% solution), 1.2 ml. The pH is adjusted to 7.7–7.8. To obtain optimum results, the amount of glucose must be adjusted for every new batch of yeast extract, peptone, and agar. This medium is very useful for differentiation of lactose-fermenting colonies based on their color.

Not unexpectedly, many strains are phenotypically intermediate between *Escherichia* and *Shigella*, but for obvious reasons a special taxonomic status for such strains is not warranted. In the older literature the name Alkalescens-Dispar is used, but, as stated by Brenner (1978), this group is virtually indistinguishable from *E. coli* strains and is, in fact, a biogroup of *E. coli* that is anaerogenic, lactose-negative (or delayed), and nonmotile.

While most or all characters that classically have been used for definition of the genus *Escherichia* are chromosomally determined, several traits that are not characteristic of *Escherichia* have been found in otherwise typical *Escherichia* strains. Lautrop et al. (1971) and Layne et al. (1971) described H_2S-positive strains of *Escherichia*, and this character was plasmid-determined. It is not known which selective forces account for the simultaneous isolation of H_2S-positive *Escherichia* strains in different parts of the world.

Other "forbidden" phenotypic traits have similarly been described in *Escherichia*, many of which are plasmid-determined. Ørskov et al. (1961) found many urease-producing strains among typical serotypes from piglet diarrhea. Wachsmuth et al. (1979) demonstrated the plasmid-determined nature of a similar urease-positive phenotype in human *E. coli* strains. Citrate-utilizing *E. coli* strains were described by Washington and Timm (1976) and were found to be plasmid determined in similar strains by Sato et al. (1978). Carbon dioxide-dependent cultures can be found (Eykyn and Phillips, 1978). A citrate-positive, malonate-positive biogroup and a biogroup negative in these reactions were described (Burgess et al., 1973).

Differentiation of the species of the genus *Escherichia*

Characteristics useful in distinguishing the five species of *Escherichia* are given in Table BXII.γ.193 of the family *Enterobacteriaceae* and in Table BXII.γ.197 of the genus *Escherichia*.

List of species of the genus Escherichia

1. **Escherichia coli** (Migula 1895) Castellani and Chalmers 1919, 941[AL] (*Bacillus coli* Migula 1895, 27.)

co′li. Gr. n. *colon* large intestine, colon; M.L. gen. n. *coli* of the colon.

The characteristics are as described for the genus and as listed in Table BXII.γ.193 of the family *Enterobacteriaceae*. Occurs naturally in the lower part of the intestine of warm-blooded animals, and as intestinal (some foodborne) and extraintestinal pathogens of humans and animals.

The mol% G + C of the DNA is: 48.5–52.1 (T_m).

Type strain: ATCC 11775, CCM 5172, CIP 54.8, DSM 30083, IAM 12119, NCDO 1989, NCTC 9001. Serotype O1:K1(L1):H7.

GenBank accession number (16S rRNA): X80725.

Additional Remarks: Other sequences are listed in Table BXII.γ.206.

2. **Escherichia blattae** Burgess, McDermott and Whiting 1973, 4[AL]

blat′tae. L. fem. n. *blatta* cockroach; L. gen. n. *blattae* of the cockroach.

The characteristics are as described for the genus and as listed in Table BXII.γ.193 of the family *Enterobacteriaceae*. *E. blattae* was isolated from the hindgut of healthy cockroaches, *Blatta orientalis*, in England (Burgess et al., 1973) and on Easter Island (Nogrady and Aubert, personal com-

[a]Some strain numbers have been lost; sequences were most probably obtained using *E. coli* K-12.

[b]Bacterial collection from which each strain is deposited: ATCC (American Type Culture Collection); BioM (BioMérieux, Marcy l'Etoile, France), CIP (Collection de l'Institut Pasteur).

[c]Accession numbers under which sequence is available.

[d]Method by which each sequence has been obtained: rRNA (total rRNA sequenced using reverse transcriptase), PCR (total PCR products sequenced using T7-DNA polymerase); *rrn*X (sequence of a single operon, X).

[e]Not available.

munication). It appears as two biotypes, one of which is citrate and malonate positive, the other negative, and it is the only species within *Escherichia* that is gluconate positive (Burgess et al., 1973). *E. blattae* has not been associated with disease either in humans or in cockroaches.

The mol% G + C of the DNA is: not determined.

Type strain: ATCC 29907, CDC 9005-74, DSM 4481, NCTC 12127.

GenBank accession number (16S rRNA): X87025.

3. **Escherichia fergusonii** Farmer, Fanning, Davis, O'Hara, Riddle, Hickman-Brenner, Asbury, Lowery and Brenner 1985c, 223[VP] (Effective publication: Farmer, Fanning, Davis, O'Hara, Riddle, Hickman-Brenner, Asbury, Lowery and Brenner 1985b, 77.)*
fer.gu.so′ni.i. M.L. masc. (substantive) *fergusonii* coined to honor the American microbiologist William W. Ferguson, who made many contributions to enteric bacteriology and was one of the first to show the role of certain strains of *E. coli* in infantile diarrhea (Farmer et al., 1985b).

The characteristics are as described for the genus and as listed in Table BXII.γ.193 of the family *Enterobacteriaceae*. Has been isolated from human clinical specimens (stool, urine, blood, and an abdominal wound), the feces of captive raptors belonging to the order *Falconiformes* or *Strigiformes* (Bangert et al., 1988), and from unspecified sites for other warm-blooded animals.

The mol% G + C of the DNA is: not determined.

Type strain: ATCC 35469, CDC 0568-73.

Additional Remarks: Other sequences are listed in Table BXII.γ.206.

4. **Escherichia hermannii** Brenner, Davis, Steigerwalt, Riddle, McWhorter, Allen, Farmer, Saitoh and Fanning 1983a, 438[VP] (Effective publication: Brenner, Davis, Steigerwalt, Riddle, McWhorter, Allen, Farmer, Saitoh and Fanning 1982a, 705.)*
her.man′ni.i. M.L. *hermannii* of Hermann, named in honor of George J. Hermann, former chief of the Enteric Section at the CDC, for his many contributions to enteric bacteriology, and Lloyd G. Herman, formerly of the Environmental Services Branch, National Institutes of Health, Bethesda, MD, for his contributions to the study of yellow-pigmented bacteria (Brenner et al., 1982a).

The characteristics are as described for the genus and as listed in Table BXII.γ.193 of the family *Enterobacteriaceae*. Those that together distinguish it from most other members of this family include growth in the presence of KCN, fermentation of cellobiose, and production of yellow pigment. Has been isolated from human clinical specimens (wounds, sputum, lung, stool, blood, and spinal fluid) and recently from the sludge of an industrial wastewater treatment plant (Kiernicka et al., 1999). The sludge isolate shows promise for bioremediation; it grows in and degrades high concentrations of chlorobenzene.

The mol% G + C of the DNA is: 53–58 (T_m).

Type strain: ATCC 33650, CDC 980-72, DSM 4560.

Additional Remarks: Other sequences are listed in Table BXII.γ.206.

5. **Escherichia vulneris** Brenner, McWhorter, Leete Knutson and Steigerwalt 1983d, 438[VP] (Effective publication: Brenner, McWhorter, Leete Knutson and Steigerwalt 1982b, 1137.)*
vul.ner′is. L. n. *vulnus* a wound; L. gen. n. *vulneris* of a wound; *Escherichia vulneris* the *Escherichia* of a wound.

The characteristics are as described for the genus and as listed in Table BXII.γ.193 of the family *Enterobacteriaceae* (Brenner et al., 1982b). Has been isolated from human clinical specimens, primarily wounds, the majority of which occurred on the arms or legs, but also blood, throat, sputum, vagina, urine, and stool, and other warm-blooded animals. The type species was isolated from the intestine of a cowbird in Michigan, USA.

The mol% G + C of the DNA is: 58.5–58.7 (T_m).

Type strain: ATCC 33821, CDC 875-72, DSM 4564, NIH 580.

GenBank accession number (16S rRNA): X80734.

Additional Remarks: Other sequences are listed in Table BXII.γ.206.

**Editorial Note:* This species was formerly known as Enteric Group 10.

**Editorial Note:* This species was formerly known as Enteric Group 11.

**Editorial Note:* This species was formerly known as Enteric Group 1.

Genus II. **Alterococcus** *Shieh and Jean 1999, 341*^{VP} *(Effective publication: Shieh and Jean 1998, 644)*

THE EDITORIAL BOARD

Al.te.ro.coc′ cus. L. *alter* another; Gr. n. *coccus* a grain or berry; M.L. masc. n. *Alterococcus* another coccus.

Spherical cells 0.8–0.9 µm in diameter, occurring singly or in pairs. **Motile by means of a single flagellum**. Gram negative. **Facultatively anaerobic**, capable of aerobic and anaerobic fermentation. Chemoheterotrophic. **Oxidase and catalase positive**. Optimum temperature for growth, 45°C. No growth occurs at 30°C or 60°C. **Halophilic**; growth occurs in the presence of 1–3% NaCl (optimum, 2.0%), but not 0% or 5% NaCl. The major cellular fatty acid is *anteiso*-15-carbon acid ($C_{15:0\ anteiso}$). Cause agar liquefaction. Habitat: coastal hot springs.

The mol% G + C of the DNA is: 65.5–67.0.

Type species: **Alterococcus agarolyticus** Shieh and Jean 1999, 341 (Effective publication: Shieh and Jean 1998, 644)

FURTHER DESCRIPTIVE INFORMATION

Butyrate and propionate are formed during both aerobic and anaerobic growth in PY semisolid medium[1]. Butyrate with propionate and/or formate is produced during both aerobic and anaerobic growth in PYG broth[2].

ENRICHMENT AND ISOLATION PROCEDURES

Water samples are decimally diluted with sterile NaCl-MOPSO buffer[3] and spread on PY agar. The plates are incubated aerobically at 50°C in the dark for 3–7 d. Colonies that cause agar liquefaction on the incubated plates are purified by successive streaking.

MAINTENANCE PROCEDURES

Early stationary-phase cultures grown in PY broth are inoculated into sterile 60% seawater at a ratio of 0.25 ml in 5 ml (1:20) and stored for two or three months at 45°C.

DIFFERENTIATION OF THE GENUS *ALTEROCOCCUS* FROM OTHER GENERA

The genus is the only one known to contain Gram-negative, halophilic, thermophilic bacteria that degrade agar and grow both aerobically and anaerobically. The only other Gram-negative genera that contain heterotrophic, halophilic, thermophilic bacteria are *Rhodothermus*, *Thermotoga*, *Thermosipho*, and *Spirochaeta*. *Rhodothermus* contains obligately aerobic rods, whereas *Alterococcus* contains cocci. The genera *Thermotoga* and *Thermosipho* contain strictly anaerobic rods, whereas *Alterococcus* is facultatively anaerobic. *Spirochaeta* contains facultatively anaerobic species, but the cells are spiral, not coccoid.

TAXONOMIC COMMENTS

16S rDNA-based phylogenetic analysis of the type strain of *Alterococcus agarolyticus* has indicated that the species is most closely related to members of the family *Enterobacteriaceae*. In this edition of the *Manual*, the genus is placed in this family, which belongs to the order *Enterobacteriales* in the class *Gammaproteobacteria*.

List of species of the genus Alterococcus

1. **Alterococcus agarolyticus** Shieh and Jean 1999, 341^{VP} (Effective publication: Shieh and Jean 1998, 644.)
a.gar.o.ly′ ti.cus. Malayan n. *agar* agar, a complex gelling polysaccharide from marine red algae; Gr. adj. *lyticum* dissolving; M.L. adj. *agarolyticus* agar-dissolving.

The characteristics are as described for the genus and as listed in Table BXII.γ.207. Young colonies on agar media are white, circular, and opaque. Glucose, cellobiose, galactose, lactose, sucrose, trehalose, and xylose are fermented. Sensitive to ampicillin, chloramphenicol, erythromycin, penicillin G, and tetracycline.

Isolated from two hot springs in the intertidal zone of Lutao Island, Taiwan.

The mol% G + C of the DNA is: 65.8.

Type strain: ADT3, CCRC 19135.

GenBank accession number (16S rRNA): AF075271.

TABLE BXII.γ.207. Phenotypic characteristics of *Alterococcus agarolyticus*[a,b]

Characteristic	Reaction
Fermentation of:

[b]Data from Shieh and Jean (1998).

1. PY broth is composed of (g/l deionized water): Bacto Peptone (Difco), 4.0; Bacto yeast extract (Difco), 2.0; NaCl, 20.0; $MgSO_4 \cdot 7H_2O$, 0.5; $CaCl_2$, 0.01; and 3-(*N*-morpholino)-2-hydroxypropanesulfonic acid (MOPSO; Sigma), 4.5. This broth medium is adjusted to pH 7.0. Bacto agar (Difco) is added to this medium at 5 and 15 g/l for the preparation of PY semisolid and plating media, respectively.

2. PYG medium is composed of two parts. Part 1 consists of the following ingredients dissolved in 900 ml of distilled water: Bacto Peptone (Difco), 4.0 g; Bacto yeast extract (Difco), 2.0 g; NaCl, 20.0 g; $MgSO_4 \cdot 7H_2O$, 0.5 g; $CaCl_2$, 0.01g; and Tris buffer (Sigma), 6.0 g. The pH is adjusted to 7.8. Part 2 consists of glucose (5.0 g) dissolved in 100 ml of distilled water. Parts 1 and 2 are autoclaved separately and combined aseptically after cooling to room temperature.

3. NaCl-MOPSO buffer consists of (g/l deionized water): NaCl, 25.0 and MOPSO (*N*-morpholino)-2-hydroxypropanesulfonic acid), 0.45; pH 7.0.

Genus III. **Arsenophonus** *Gherna, Werren, Weisburg, Cote, Woese, Mandelco and Brenner 1991, 564*[VP]

JOHN H. WERREN

Ar.se.no.pho′ nus. Gr. n. *arsen* a male; Gr. suff. *phonus* slayer; N.L. masc. n. *Arsenophonus* male-killer.

Cells are Gram-negative, nonmotile, nonsporeforming, nonflagellated, long to highly filamentous rods, which divide by septation. **The bacteria infect insect tissues.** The type species can be cultivated on cell-free media. Colonies are mucoid, gray-white, round, and convex with entire edges. Enzymatically digested proteins best serve as nitrogen sources. Does not utilize KNO_3, $(NH_4)_2SO_4$, complete defined amino acid mixtures, or acid-hydrolyzed peptones as nitrogen sources. Sugars sucrose, fructose, and D-glucose are utilized as primary carbon sources. Weak growth occurs with maltose, trehalose, cellobiose, and D-xylose. Acid is produced with D-glucose, fructose, and sucrose. Growth is negative with L-arabinose, glycerol, dulcitol, lactose, D-mannitol, raffinose, and *i*-inositol. Positive for catalase and gelatin liquefaction; negative for Voges–Proskauer, methyl red, nitrate reduction, indole, oxidase, hydrogen sulfide, O-nitrophenyl-β-D-galactopyranoside, lysine and ornithine decarboxylase, urease, and arginine dehydrolase. Cells grow at pH 6.2–8.7 (optimum pH range 7.4–8.0), and a temperature range of 15–35°C (30°C optimum).

There is currently only one validly named species in the genus (and an additional *Candidatus* species). However, **the genus may be widespread in insects**, based upon recent evidence. Therefore, the genus description may well change as additional information becomes available.

The mol% G + C of the DNA is: 39.5.

Type species: **Arsenophonus nasoniae** Gherna Werren, Weisburg, Cote, Woese, Mandelco and Brenner 1991, 564.

FURTHER DESCRIPTIVE INFORMATION

General biology The genus *Arsenophonus* was originally described from a single bacterial species that is the causative agent of the "son-killer" trait in the parasitic wasp *Nasonia vitripennis* (insect order *Hymenoptera*). Subsequently, a second species has been proposed for the genus (*Candidatus* Arsenophonus triatominarum), isolated from a reduviid bug (insect order *Heteroptera*). Despite being found in divergent insects, the two are similar in morphology, patterns of infection of host insect tissues, and 16S rDNA sequence (97.8% similarity). Biochemical characterization of "*Candidatus* Arsenophonus triatominarum" has not yet

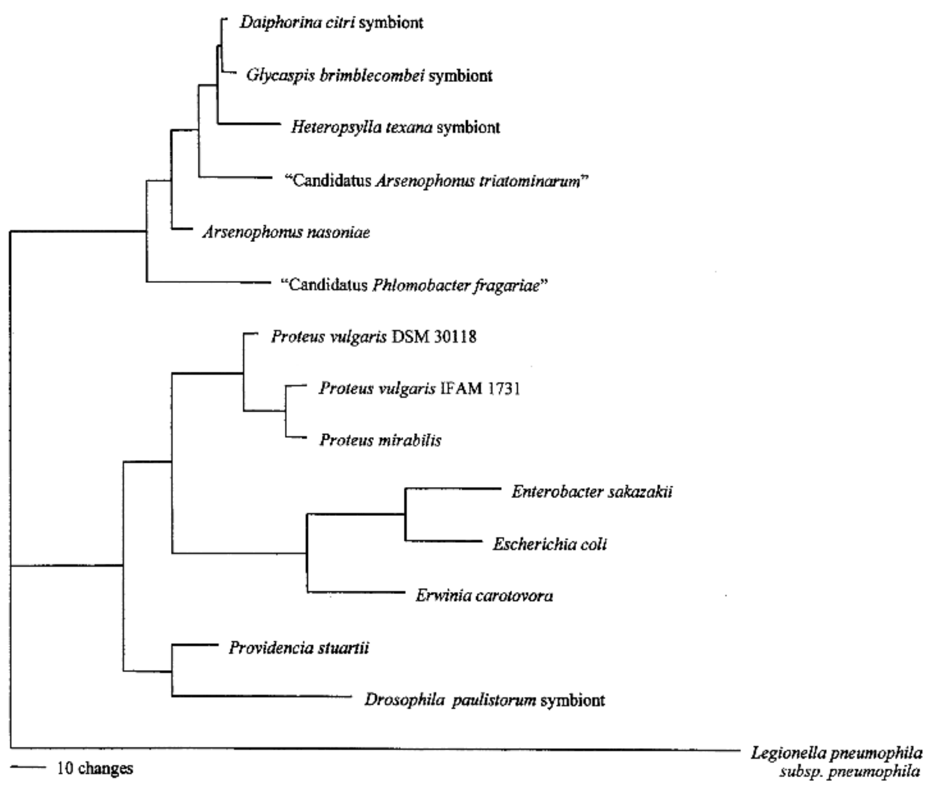

FIGURE BXII.γ.193. A phylogenetic tree based on 16S rDNA sequences is presented based on a parsimony analysis using a heuristic search and stepwise addition (D.L. Swofford, 1996, PAUP 4.0 Sinauer, Sunderland, MA) with *Legionella pneumophila* defined as the outgroup. Partial 16S rDNA nucleotide sequences (1476 sites) of *Arsenophonus nasoniae*, *Candidatus* A. triatominarum, other endosymbiotic and free-living bacteria were analyzed. Names of the insect host species are shown for the psyllid secondary symbionts and the unidentified bacterium from *D. paulistorum*. In all other cases the bacterial genus and species are shown. Numbers above nodes are bootstrap percentages from 1000 replicate searches. The sequence data for *Diaphorina citri* secondary symbiont was provided by T. Fukatsu (Subandiyah et al., 2000). Other sequences were obtained from the NCBI database (accession numbers AF263561, AF263562, U91786, M90801, U91515, X07652, AJ233425, X07652, AF008582, AB004746, AB035924, AJ233411, AF008581, U20273, and X73402).

been performed; nor are its effects on the host insect known. *A. nasoniae* can be grown on cell-free media; "*Candidatus* A. triatominarum" has not yet been grown in cell-free culture, but can be maintained on insect tissue culture.

Phylogenetic analysis using 16S rDNA sequences (see below) indicates that closely related bacteria are secondary symbionts in several species of psyllid insects (insect order *Homoptera*), although the taxonomic status of these bacteria has not yet been resolved. Taken together, the results suggest that *Arsenophonus* (and related bacteria) may have a wide distribution as infectious agents of insects. Another closely related bacterium, *Candidatus* Phlomobacter fragariae, causes disease in strawberry (Zreik et al., 1998).

Phylogenetic analyses Based on 16S rDNA phylogeny *Arsenophonus* is a lineage in the *Gammaproteobacteria* (Gherna et al., 1991; Hypsa and Dale, 1997), within the family *Enterobacteriaceae*. The phylogenetic analysis places *A. nasoniae* and the *Candidatus* A. triatominarum as close relatives (97.8% similarity) (Fig. BXII.γ.193). Other closely related organisms (Fig. BXII.γ.193) are secondary symbionts found in psyllid insects (98.6–97.6% similarity). Although they are closely related, the specific phylogenetic relationships between *A. nasoniae*, *Candidatus* A. triatominarum, and the psyllid secondary symbionts are not clearly resolved. These may eventually be placed in the genus *Arsenophonus* when further characterization is completed. *A. nasoniae*, *Candidatus* A. triatominarum, and the three psyllid secondary endosymbionts form a monophyletic clade with *Candidatus* Phlomobacter fragariae (97.0% similarity to *A. nasoniae*). This monophyletic group is strongly supported by various phylogenetic analyses. *Candidatus* Phlomobacter fragariae is found within the phloem of strawberry and is associated with strawberry marginal chlorosis disease (Zreik et al., 1998). Plant phloem associated bacteria can be vectored by phloem feeding insects such as psyllids and aphids, which may suggest a biological basis for its phylogenetic similarity to psyllid secondary endosymbionts. The apparent monophyly of this bacterium with *Arsenophonus* and the psyllid secondary endosymbionts (Subandiyah et al., 2000; Thao et al., 2000b) suggests that separate generic status for this bacterium may not be warranted. However, additional sequences and biological characterization are needed to resolve the issue. The closest known bacteria outside of the "*Arsenophonus* group" include *Proteus vulgaris*, *Proteus mirabilis*, and *Providencia stuartii* (94.2–94.3% similarity).

List of species of the genus Arsenophonus

1. **Arsenophonus nasoniae** Gherna, Werren, Weisburg, Cote, Woese, Mandelco and Brenner 1991, 564[VP]
na.so′ ni.ae. N.L. n. *Nasonia* a genus of parasitoid wasps; *nasoniae* of the genus *Nasonia*.

The cells are nonmotile nonsporeforming, long rods to highly filamentous (0.40–0.57 × 6.9–10.0 μm) in culture. Filamentous cells can also be found in insect tissues. Biochemical features are presented in the genus description. *A. nasoniae* is the causative agent of the "son-killer" trait in the parasitic wasp *N. vitripennis*. *Nasonia* wasps parasitize the pupae of various dipterans (flies). They sting the host pupa and lay their eggs underneath the puparial wall. The insects hatch and feed upon the host fly to complete development. In female wasps infected with the bacterium, male eggs fail to hatch, whereas female eggs develop normally (Werren et al., 1986). Genetic experiments indicate that the bacterium acts by blocking the development of unfertilized eggs, which normally develop into males in this haplodiploid species. The son-killer bacterium is found in *N. vitripennis* populations throughout North America at frequencies around 10%, and has also been detected in the sibling species *N. longicornis* (Balas et al., 1996).

The bacterium is introduced into the dipteran host pupa during stinging by the infected female, where it replicates and is ingested by the feeding wasp larvae (Huger et al., 1985). As a result, the bacteria can be transmitted maternally from an infected female to her developing larvae, and horizontally when more than one female parasitizes the same host. The bacteria initially invade the midgut epithelium and subsequently spread to various tissues, including brain, fat body, muscles, eyes, and hemocytes. Massive infections of tissues can be observed in adults without major negative effects on insect viability. In insect tissues, the bacteria are pleomorphic, with rods being the most common morphology. Both male and female larvae can become infected by host feeding during larval development. Female reproductive tracts are often infected with the bacteria, whereas infections are not observed in male reproductive tissues. In adult wasps, drop-like bacterial masses can be discharged from the midgut epithelium into the gut lumen, suggesting a possible additional fecal route for infectious transmission. The mechanism by which *A. nasoniae* causes lethality of male eggs is unknown. Experiments indicate that unfertilized eggs, which normally develop into males in the haplodiploid insect host, fail to develop when the female is infected. Levels of male embryo mortality can vary in different infected females (Balas et al., 1996).

A. nasoniae can be isolated from infected insects by surface sterilization of the insect followed by maceration of the insect onto GC media with Kellogg's supplement, and serial streaking of the macerated material. Characteristic gray-white mucoid colonies will develop in 2–4 d at 26°C. Bacteria can also be isolated by antiseptic removal of hemolymph from fly pupae parasitized by infected *Nasonia* females, and inoculation of the hemolymph onto GC media with Kellogg's supplement.

The type strain grows poorly or does not grow on many standard media. It can be grown on brain–heart infusion broth (Difco no. 0037) or solid media. However, improved growth was found on a GC media base (Difco no. 0289) supplemented with Kellogg's additive (Kellogg et al., 1963). Even on this medium, bacterial growth is slow relative to many culturable bacteria, and visible colonies may take 2–3 d at 26°C. Growth is best on solid media. Broth cultures show elevated frequencies of filamentous bacteria relative to agar base solid media. The type strain was isolated from an *N. vitripennis* son-killer strain collected near Salt Lake City, Utah.

The mol% G + C of the DNA is: 39.5 (T_m).
Type strain: SKI4, ATCC 49151.
GenBank accession number (16S rRNA): M90801.

2. *Candidatus* Arsenophonus triatominarum Hypsa and Dale 1997, 1143.
tri′ a.to′ min.a.rum. N.L. n. *Triatominae* subfamily of reduviid bugs; *triatominarum* of the *Triatominae*.

Cells are nonmotile, nonsporeforming, nonflagellated highly filamentous rods (1–1.5 × >15 μm), and divide by septation. Bacteria grow within the cytoplasm of cells of the reduviid bug *Triatoma infestans*. Phylogenetic analysis of 16S ribosomal gene sequence indicates a close phylogenetic re-

lationship to *A. nasoniae* (97.8% similarity), as do general morphological characteristics and the pattern of infection within tissues of their respective hosts. The bacterium cannot be grown on cell-free minimal medium, but can be maintained in *A. albopictus* cell culture. Biochemical characteristics of the bacterium have not yet been determined.

"*Candidatus* A. triatominarum" was isolated from the hemolymph of *Triatoma infestans*, a reduviid bug also known to be a vector of *Trypanosoma cruzi*, the causative agent of Chagas disease in humans. Within infected *T. infestans*, heavy infections can be found in neural ganglia, visceral muscles, salivary glands, nephrocytes, testes, ovaries, and dorsal vessels. In contrast to *A. nasoniae*, the bacterium could not be grown of a variety of tested cell-free media, including media upon which *A. nasoniae* can be cultured (Hypsa and Dale, 1997). Phenotypic effects of the bacterium on *T. infestans* are unknown. Strain TI1 was isolated from hemolymph of *T. infestans* individuals from a laboratory colony, and cultured in *Aedes albopictus* cell line C6/36.

The mol% G + C of the DNA is: unknown.

Deposited strain: TI1.

GenBank accession number (16S rRNA): U91786.

Genus IV. **Brenneria** *Hauben, Moore, Vauterin, Steenackers, Mergaert, Verdonck and Swings 1999a, 1*[VP] *(Effective publication: Hauben, Moore, Vauterin, Steenackers, Mergaert, Verdonck and Swings 1998a, 394.)*

LYSIANE HAUBEN AND JEAN SWINGS

Bren.ne′ ri.a. M.L. fem. n. *Brenneria* named after Don J. Brenner.

Cells are 0.5–1.0 × 1.3–3.0 μm; have rounded ends; occur singly or rarely in pairs. Gram negative. Motile by peritrichous flagella. Facultatively anaerobic, but anaerobic growth by some species is weak. Optimum temperature, 27–30°C; maximum temperature for growth is 40°C. Oxidase negative. Catalase positive. Acid is produced from fructose, D-galactose, D-glucose, D-mannose, salicin, and sucrose but not from adonitol or dulcitol. Do not possess arginine decarboxylases, arginine dihydrolase, lysine decarboxylases, ornithine decarboxylases, or starch hydrolase.

The species of the genus *Brenneria* comprise a distinct phylogenetic group, as determined by 16S rRNA gene sequence comparisons, and have 12 characteristic signature nucleotides (Table BXII.γ.223 of the genus *Erwinia*).

Brenneria species cause diseases on trees (e.g., deciduous trees and walnut trees), which include blights, cankers, wilts, necrosis, and rots. Ingress by the pathogen generally occurs through natural openings and wounds. More details on disease symptoms are described for each species.

The mol% G + C of the DNA is: 50.1–56.1 (T_m, Bd).

Type species: **Brenneria salicis** (Day 1924) Hauben, Moore, Vauterin, Steenackers, Mergaert, Verdonck and Swings 1999a, 1 (Effective publication: Hauben, Moore, Vauterin, Steenackers, Mergaert, Verdonck and Swings 1998a, 394) (*Erwinia salicis* (Day 1924) Chester 1939, 406; *"Bacterium salicis"* Day 1924, 14.)

FURTHER DESCRIPTIVE INFORMATION

Metabolic features are the same as for the genus *Erwinia*.

Pectate lyases are produced by strains of *B. rubrifaciens* (Gardner and Kado, 1976).

Fermentation end products from D-glucose are CO_2 and different combinations of succinate, lactate, formate, and acetate; some form 2,3-butanediol and some ethanol (White and Starr, 1971). Starch is not hydrolyzed beyond dextrins.

16S rDNA sequence analyses of the species of the genus *Brenneria* by Kwon et al. (1997) and Hauben et al. (1998a) are in good agreement except for the type strain of *B. salicis*, and place the genus *Brenneria* within the *Enterobacteriaceae*, closely related to the genera *Pectobacterium*, *Erwinia*, *Pantoea*, and *Enterobacter* (Fig. BXII.γ.201 and Table BXII.γ.223 of the genus *Erwinia*). The gene sequences of the type strains of *B. salicis* sequenced by Kwon et al. (1997) (ATCC 15712) and Hauben et al. (1998a) (LMG 2698) differ in 73 nucleotides. A genomic fingerprinting study by AFLP of 77 *B. salicis* strains revealed the profile of strain LMG 2698 to be highly similar (>80% similarity) to the ones of other authentic *B. salicis* strains, indicating that strain LMG 2698 is an authentic *B. salicis* (Hauben et al., 1998b).

Virulent or temperate phages have been isolated, characterized, and reported to be active against strains of *B. nigrifluens* and *B. rubrifaciens* (Zeitoun and Wilson, 1969).

Antisera prepared against live or heat-killed cells, nonpurified or purified immunogens, have been used for the differentiation or identification of all *Brenneria* species (De Kam, 1976; Schaad, 1979).

ENRICHMENT AND ISOLATION PROCEDURES

The isolation procedure is the same as for the genus *Erwinia*. The affected plant material is washed in tap water, then in sterile water, and dried by paper toweling. Surface sterilization (3 min in 1:10 dilution of 5.25% active sodium hypochlorite) is sometimes detrimental for isolation. Affected tissue is removed from a young lesion or the edge of older necrotic areas by a sterile scalpel; the tissue is crushed in sterile water, saline, or buffer solution, and is streaked onto a solid medium.

The isolation of some *Brenneria* species can be facilitated by use of selective-differential media, but such media are usually not necessary. *B. nigrifluens*, *B. quercina*, and *B. rubrifaciens* will grow on MS medium (Miller and Schroth, 1972) and produce characteristic colonies. A soluble pink pigment is produced by *B. rubrifaciens*.

MAINTENANCE PROCEDURES

Stock cultures of *Brenneria* species should be grown on standard media of choice at 25–30°C until good growth occurs. The cultures can be maintained for short-term storage in a refrigerator (4–5°C).

Long-term preservation is the same as for the genus *Erwinia*. The bacteria can be successfully stored as lyophilized cultures, usually suspended in a filter-sterilized mixture of 200 ml of horse serum (Oxoid SR035C) to which 1675 mg of nutrient broth (Oxoid) and 20 g of glucose in 67 ml of distilled water is added. Strains have also been stored in liquid nitrogen and in glycerol at −80°C (broth + 15% glycerol).

DIFFERENTIATION OF THE GENUS *BRENNERIA* FROM OTHER GENERA

The differential characteristics of the species of *Brenneria* are given in Tables BXII.γ.208 and BXII.γ.209.

TABLE BXII.γ.208. Diagnostic reactions for *Brenneria* species[a]

Taxonomic Comments

The species of the genus *Brenneria* were formerly classified in the genus *Erwinia*. We refer to the taxonomic comments of the genus *Erwinia* for a discussion of this issue.

Characteristics that differentiate *Brenneria* from the genera *Pectobacterium*, *Pantoea*, and *Erwinia* are given in Table BXII.γ.223 of the *Erwinia* chapter. As it is very difficult to differentiate them phenotypically, genomic methods are recommended for differentiation.

List of species of the genus Brenneria

1. **Brenneria salicis** (Day 1924) Hauben, Moore, Vauterin, Steenackers, Mergaert, Verdonck and Swings 1999a, 1[VP] (Effective publication: Hauben, Moore, Vauterin, Steenackers, Mergaert, Verdonck and Swings 1998a, 394) (*Erwinia salicis* (Day 1924) Chester 1939, 406; *"Bacterium salicis"* Day 1924, 14.)
sa'li.cis. L. n. *salix* the willow; L. gen. n. *salicis* of the willow.

The characteristics are as given for the genus and as listed in Tables BXII.γ.208 and BXII.γ.209.

Grows poorly on nutrient agar but moderately well on YDC agar (0.5% yeast extract, 1% dextrose, 3% $CaCO_3$) or on glucose nutrient agar. Colonies on 0.5% starch potato agar (pH 6.5) are yellowish in 2–3 d. A bright yellow pigment is produced on autoclaved potato tissue. Craters form around colonies on the pectate gel of Paton (1959).

A PCR based identification and detection method was developed with primers Es1a (5′-GCGGCGGACGGGTGAGTAAA-3′) and Es4b (5′-CTAGCCTGTCAGTTTTGAATGCT-3′), annealing at 64°C, derived from the 16S rDNA sequence of *B. salicis* (Hauben et al., 1998b).

Antisera have been used for the identification of *B. salicis* (De Kam, 1976; 1986) and soluble antigens were detected in the leaves of *Salix alba* (De Kam, 1982).

Causes a vascular wilt (watermark disease) of *Salix* species. The pathogen occurs mainly in the xylem vessels of the host plant. Infected willows show wilted, dried, brown-colored leaves and a watery, transparent color of the wood. Occasionally the whole tree is killed.

The mol% G + C of the DNA is: 51.3–51.5 (T_m, Bd.).

Type strain: ATCC 15712, ICMP 1587, LMG 2698, NCPPB 447.

GenBank accession number (16S rRNA): U80210 and Z96097.

2. **Brenneria alni** (Surico, Mugnai, Pastorelli, Giovannetti and Stead 1996) Hauben, Moore, Vauterin, Steenackers, Mergaert, Verdonck and Swings 1999a, 1[VP] (Effective publication: Hauben, Moore, Vauterin, Steenackers, Mergaert, Verdonck and Swings 1998a, 395) (*Erwinia alni* Surico, Mugnai, Pastorelli, Giovannetti and Stead 1996, 725.)

[a]For symbols see standard definitions; nd, not determined.

al′ni. L. fem. n. *alnus* alder; L. gen. n. *alni* of alder, referring to the plant from which the organism was first isolated.

The characteristics are as given for the genus and as listed in Tables BXII.γ.208 and BXII.γ.209.

Abundant growth occurs in nutrient broth and on nutrient agar, YDC (0.5% yeast extract, 1% dextrose, 3% $CaCO_3$), Miller–Schroth medium. Colonies on NSA (nutrient agar containing 5% sucrose) are umbonate with translucent margins, whitish, and 2–2.5 mm in diameter after 5 days at 27°C.

Causes bark canker disease of alder (*Alnus* sp.). At first, diseased alder plants have small necrotic cankers in the bark of the trunk and in the bark of branches, twigs, and suckers. These cankers are slightly sunken, dark brown, and irregularly circular and appear to be water soaked. They usually develop at lenticels or are localized at nodes with dead twigs or on leaf scars. As the infection progresses, the necrosis spreads laterally, becoming deeper and reaching the cambium and sometimes the first layers of wood, which then turn brown. Cankers may eventually girdle and kill a branch or tree.

The mol% G + C of the DNA is: 50.1–50.7 (T_m).

Type strain: ICMP 12481, NCPPB 3934.

GenBank accession number (16S rRNA): AJ223468.

3. **Brenneria nigrifluens** (Wilson, Starr and Berger 1957) Hauben, Moore, Vauterin, Steenackers, Mergaert, Verdonck and Swings 1999a, 1[VP] (Effective publication: Hauben, Moore, Vauterin, Steenackers, Mergaert, Verdonck and Swings 1998a, 395) (*Erwinia nigrifluens* Wilson, Starr and Berger 1957, 673.)

ni.gri.flu′ens. L. adj. *niger* nigra black; L. v. *fluo* flow; M.L. part. adj. *nigrifluens* black flowing.

The characteristics are as described for the genus and as listed in Tables BXII.γ.208 and BXII.γ.209.

Colonies on Bacto-EMB (Difco) agar are dark violet with a green metallic sheen. Craters form around colonies on the polypectate medium (1 liter nearly boiling distilled water, 1 ml of bromothymol blue, 6 ml of 10% $CaCl_2 \cdot H_2O$, 2 g of sodium polypectate) of Hildebrand (1971). Growth media should contain yeast extract and should be at pH 7–8.

Causes a bark necrosis of the Persian walnut (*Juglans regia*). The disease is visible as dark brown necrotic areas on the trunks or large branches. The lesions extend well beyond the discolored bark. Exudates may be produced. The lesions are superficial, but may penetrate enough to kill the phloem.

The mol% G + C of the DNA is: 56.1 (T_m, Bd).

Type strain: ATCC 13028, ICMP 1578, LMG 2694.

GenBank accession number (16S rRNA): U80203, Z96095.

4. **Brenneria paradisiaca** (Fernández-Borrero and López-Duque 1970) Hauben, Moore, Vauterin, Steenackers, Mergaert, Verdonck and Swings 1999a, 1[VP] (Effective publica-

tion: Hauben, Moore, Vauterin, Steenackers, Mergaert, Verdonck and Swings 1998a, 396) (*Erwinia paradisiaca* Fernández-Borrero and López-Duque 1970, 22.)
pa.ra.di.si.a′ ca. M.L. n. generic name *Musa paradisiaca* banana.

The characteristics are as given for the genus and as listed in Tables BXII.γ.208 and BXII.γ.209.

Causes rhizome rot of roots and soft rot of green fruit of *Musa paradisiaca*.

The mol% G + C of the DNA is: 54.7 (T_m, Bd).

Type strain: ATCC 33242, LMG 2542, NCPPB 2511.

GenBank accession number (16S rRNA): Z96096.

5. **Brenneria quercina** (Hildebrand and Schroth 1967) Hauben, Moore, Vauterin, Steenackers, Mergaert, Verdonck and Swings 1999a, 1[VP] (Effective publication: Hauben, Moore, Vauterin, Steenackers, Mergaert, Verdonck and Swings 1998a, 395) (*Erwinia quercina* Hildebrand and Schroth 1967, 253.)
quer.ci′ na. L. n. *quercus* oak; L. suff. *ina* belonging to; M.L. part. adj. *quercina* oak-belonging.

The characteristics are as given for the genus and as listed in Tables BXII.γ.208 and BXII.γ.209.

Growth on PGPC agar (60 g homogenized potato, 10 g glucose, 10 g peptone, 1 g $CaCO_3$, 1 liter distilled water) is luxuriant, and, after 24 h, colonies are white, circular, and raised with entire margins. Craters form around colonies on polypectate gel of Hildebrand (1971), but no pectolytic activity was observed in potato or carrot tissue.

Small amounts of gas are produced (possibly from peptone) in a glucose peptone medium and in PGPC.

Causes copious oozing of sap from acorns ("drippy nut") and shoot blight of oak: *Quercus agrifolia* and *Q. wislizeni*. Acorns may rot somewhat, and cups may ooze after nutfall. Oozing takes place in late summer when temperatures average about 29°C. Superficially rots onion (but not potato) slices and induces profuse lateral root development in 3–4 days on slices of carrot, turnip, or beet.

The mol% G + C of the DNA is: from 54.6–55.1 (T_m, Bd).

Type strain: ATCC 29281, ICMP 1845, LMG 2724, NCPPB 1852.

GenBank accession number (16S rRNA): AJ223469.

6. **Brenneria rubrifaciens** (Wilson, Zeitoun and Fredrickson 1967) Hauben, Moore, Vauterin, Steenackers, Mergaert, Verdonck and Swings 1999a, 1[VP] (Effective publication: Hauben, Moore, Vauterin, Steenackers, Mergaert, Verdonck and Swings 1998a, 395) (*Erwinia rubrifaciens* Wilson, Zeitoun and Fredrickson 1967,621.)
rub.ri.fac′ i.ens. L. adj. *ruber* red; L. v. *facio* make; M.L. part. adj. *rubrifaciens* red-producing.

The characteristics are as given for the genus and as listed in Tables BXII.γ.208 and BXII.γ.209.

Produces a pink soluble pigment when grown on yeast extract glucose chalk agar (YDC, 0.5% yeast extract, 1% dextrose, 3% calcium carbonate (Dye, 1968). The structure of a 3-(3-carboxymethyl-4,5-dihydro-4,5-dioxo-2-pyrrolyl)-4,5,6-trihydroxy-pyridine-2-acetic acid (rubrifacine) is suggested (Feistner et al., 1984) as the main component of the pigment.

Grows poorly on nutrient agar, but well on YDC on which colonies are cream to yellow, low convex, smooth, shining with entire margins. Craters form around colonies on the polypectate gel B and C of Hildebrand (1971), but no pectolytic activity was observed on vegetable tissue.

Causes a phloem necrosis of Persian walnut trees (*Juglans regia*). Dark brown to black necrotic streaks from along the inner bark and outer sapwood. In places, the necrosis develops outward to the periderm, which breaks, and a dark exudate emerges.

The mol% G + C of the DNA is: 52.0–52.6 (T_m, Bd).

Type strain: ATCC 29291, ICMP 1915, LMG 2709, NCPPB 2020.

GenBank accession number (16S rRNA): U80207 and Z96098.

Genus V. **Buchnera** *Munson, Baumann and Kinsey 1991b, 566*[VP]

Paul Baumann, Linda Baumann and Nancy A. Moran

Buch.ne′ ra. M.L. fem. n. *Buchnera* named for Paul Buchner, German biologist who made extensive contributions to the study of endosymbiosis.

Round or slightly oval cells, 2–5 μm in diameter. **Gram-negative** cell wall, lack flagella. Cells divide by binary fission. Do not form resting stages or endospores. **Found in bacteriocytes** of aphids in vesicles derived from the host membranes. Capable of respiration. **Cannot be cultivated** outside the aphid host. Essential for the survival of the aphid.

The mol% G + C of the DNA is: 26–27.

Type species: **Buchnera aphidicola** Munson, Baumann and Kinsey 1991b, 567.

Further descriptive information

Cell structure and life cycle During their reproductive phase most aphids contain within their body cavity a bilobed structure called a bacteriome consisting of 60–90 polyploid cells called bacteriocytes (Douglas and Dixon, 1987). These cells are filled with host-derived vesicles (symbiosomes) containing *Buchnera* (Fig. BXII.γ.194) (Hinde 1971b; Griffiths and Beck, 1973; McLean and Houk, 1973; Akhtar and van Emden, 1994). This organism is spherical or oval in shape having a diameter of 2–5 μm and a cell wall resembling that of Gram-negative bacteria (Fig. BXII.γ.195). A thin line indicative of the peptidoglycan layer has been detected between the two unit membranes (Houk et al., 1977). The presence of peptidoglycan is also indicated by chemical analysis and by the alteration of cell wall structure observed upon addition of penicillin to the aphid diet (Griffiths and Beck, 1974; Houk et al., 1977).

In their most active reproductive stage, aphids are females that reproduce by parthenogenesis. The embryos develop within the mother, which gives birth to live young (Blackman, 1987). A representative aphid, *Schizaphis graminum*, when born weighs 24 mg and contains 2×10^5 cells of *Buchnera*. In 9–10 d, it reaches its maximum weight of 540 mg and contains 5.6×10^6 endo-

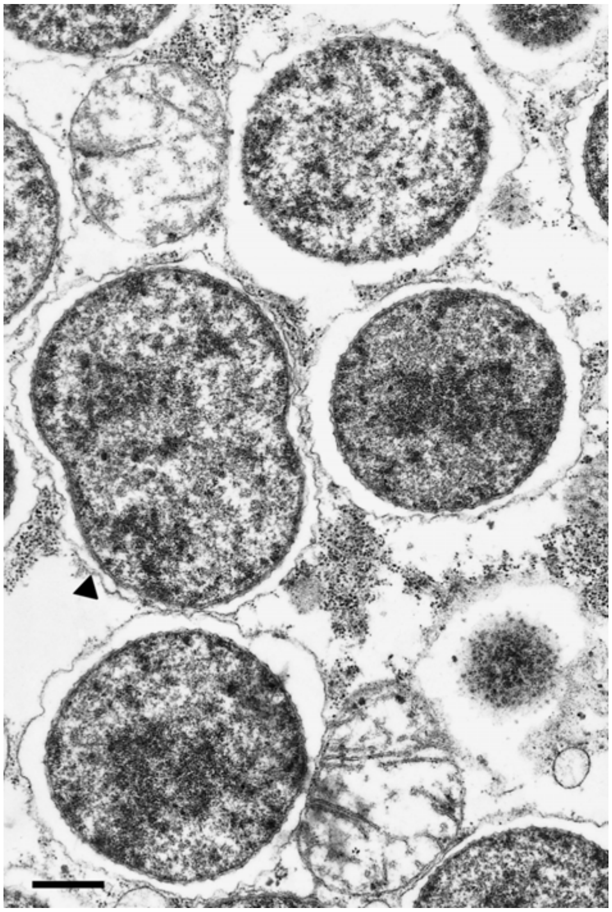

FIGURE BXII.γ.194. Electron micrograph of *Buchnera* within aphid bacteriocytes. *Arrow* indicates host-derived vesicle membrane. Bar = 1 μm. (Printed with permission of M. Kinsey and D.L. McLean.)

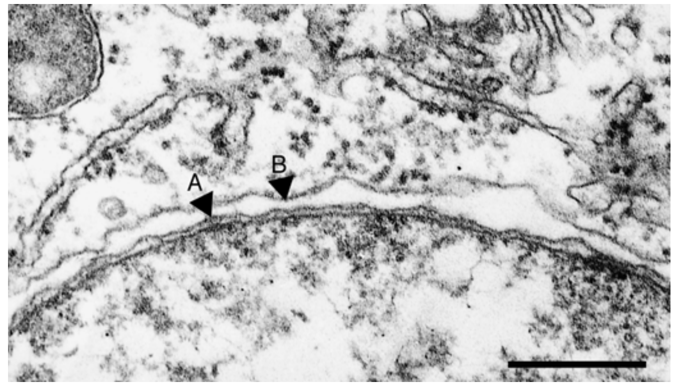

FIGURE BXII.γ.195. Electron micrograph of *Buchnera* showing the Gram-negative cell wall (*A*) and the vesicle membrane (*B*). Bar = 0.5 μm. (Printed with permission of M. Kinsey and D.L. McLean.)

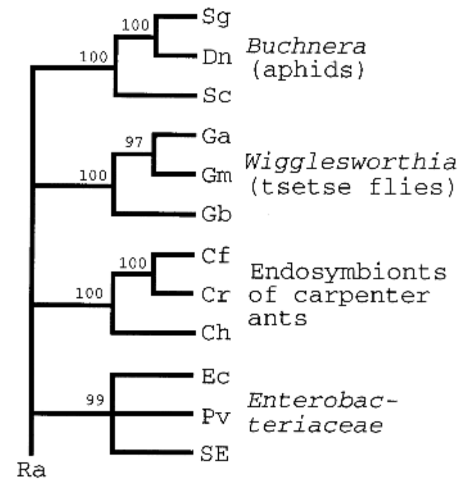

FIGURE BXII.γ.196. Phylogenetic trees resulting from parsimony analyses (D.L. Swofford, 1993, PAUP 3.1.1, Champaign, IL) using 16S rDNA nucleotide sequences (1189 sites) of *Buchnera* and other closely related insect endosymbionts as well as free-living bacteria. Numbers above nodes are bootstrap percentages from parsimony searches (1000 replicates). Data for *Wigglesworthia glossinidia* from Aksoy (1995b); the following abbreviations designate the insect hosts (in parentheses): *Ga* (*Glossina austeni*), *Gm* (*G. morsitans*), *Gb* (*G. brevipalpis*). Data for carpenter ant endosymbionts from Schröder et al. (1996); hosts: *Cf* (*Camponotus floridanus*), *Cr* (*C. rufipes*), *Ch* (*C. herculeanus*); *SE* (secondary endosymbiont of the aphid *Acyrthosiphon pisum*); *Ra* (*Ruminobacter amylophilus*).

symbionts (Baumann and Baumann, 1994). The increase in the total number of *Buchnera* parallels the increase in the weight of the aphid. The endosymbionts are partitioned between the maternal and the embryonic bacteriocytes. In mature aphids, most of the endosymbionts are found in the embryos (Humphreys and Douglas, 1997). Halfway through the reproductive period the number of maternal bacteriocytes undergoes a sharp decrease (Douglas and Dixon, 1987) and there is degradation of the endosymbionts (Hinde, 1971a; Griffiths and Beck, 1973).

Aphids may also form sexual forms; the females deposit eggs that overwinter and hatch in the spring. *Buchnera* is transmitted maternally to the embryos and the eggs. The mechanism of transmission is complex and has not been extensively studied (Hinde, 1971a; Blackman, 1987; Brough and Dixon, 1990).

Phylogenetic analyses Based on 16S rDNA phylogeny, *Buchnera* is a lineage within the *Gammaproteobacteria* (Unterman et al., 1989; Munson et al., 1991a; Moran et al., 1993; van Ham et al., 1997). The closest known organisms (Fig. BXII.γ.196) are the nonculturable *Wigglesworthia glossinidia* (endosymbionts of tsetse flies) and endosymbionts of carpenter ants as well as members of the *Enterobacteriaceae* (Aksoy, 1995b; Aksoy et al., 1995; Schröder et al., 1996). These organisms constitute four separate lineages and their relationship to each other is not clearly resolved based on 16S rDNA.

Fig. BXII.γ.197 presents the results of a phylogenetic analysis primarily restricted to *Buchnera*. Most of the characterized endosymbionts are from aphids belonging to the family *Aphididae*. Based on 16S rDNA gene sequences (Fig. BXII.γ.197a), *Buchnera* forms one cluster within which a subcluster of endosymbionts from aphids of *Aphididae* is clearly differentiated. An additional cluster consists of endosymbionts from the aphids *Melaphis rhois* (Mr) and *Schlechtendalia chinensis* (Sc), both of which are members of the tribe Melaphidini in the family *Pemphigidae*. Relationships between the remaining endosymbionts from this family as well as from two other aphid families are not clearly resolved using 16S rDNA gene sequences. Using a portion of the chromosomal *trpB*, relationships among endosymbionts of some members of the *Aphididae* and especially within the aphid genus *Uro-*

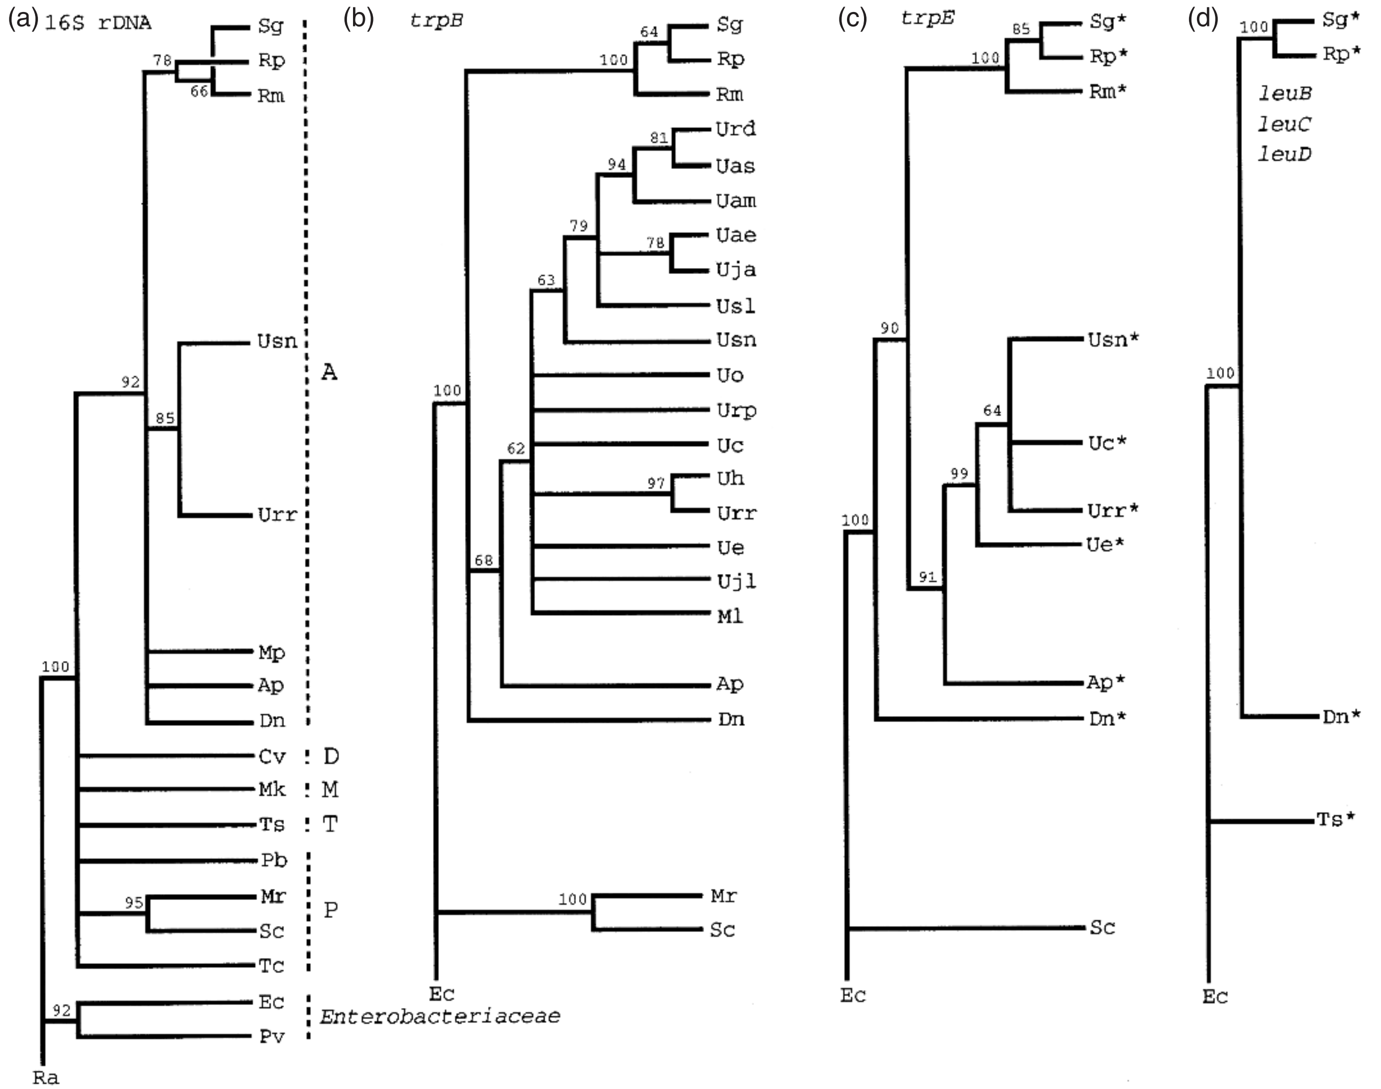

FIGURE BXII.γ.197. Phylogenetic trees resulting from parsimony analyses (D.L. Swofford, 1993, PAUP 3.1.1, Champaign, IL) using *Buchnera* (*a*) 16S rDNA (1475 sites), (*b*) *trpB* (679 sites), (*c*) *trpE* (1623 sites), and (*d*) *leuB*, *leuC*, and *leuD* (total 3140 sites). *, plasmid-associated genes; numbers above nodes are bootstrap percentages from parsimony searches (1000 replicates). Abbreviations designate insect hosts in the order from top to bottom (given in parentheses): *Sg* (*Schizaphis graminum*), *Rp* (*Rhopalosiphum padi*), *Rm* (*R. maidis*), *Urd* (*Uroleucon rudbeckiae*), *Uas* (*U. astronomus*), *Uam* (*U. ambrosiae*), *Uae* (*U. aeneum*), *Uja* (*U. jaceiae*), *Usl* (*U. solidaginis*), *Usn* (*U. sonchi*), *Uo* (*U. obscurum*), *Urp* (*U. rapunculoidis*), *Uc* (*U. caligatum*), *Uh* (*U. helianthicola*), *Urr* (*U. rurale*), *Ue* (*U. erigeronense*), *Ujl* (*U. jaceicola*), *Ml* (*Macrosiphoniella ludovicianae*), *Mp* (*Myzus persicae*), *Ap* (*Acyrthosiphon pisum*), *Dn* (*Diuraphis noxia*), *Cv* (*Chaitophorus viminalis*), *Mk* (*Mindarus kinseyi*), *Ts* (*Thelaxes suberi*), *Pb* (*Pemphigus betae*), *Mr* (*Melaphis rhois*), *Sc* (*Schlechtendalia chinensis*), *Tc* (*Tetraneura caerulescens*). Species of the *Enterobacteriaceae*: *Ec* (*E. coli*), *Pv* (*P. vulgaris*). Dashed lines in 4a designate aphid species within one family: *A*, *Aphididae*; *D*, *Drepanosiphidae*; *M*, *Mindaridae*; *T*, *Thelaxidae*; *P*, *Pemphigidae*. Data for *Ts* and *Tc* in 4a and 4d from van Ham et al. (1997); for *Rp* in 4d from Bracho et al. (1995); for other sources of data for *Buchnera* see text.

leucon could be resolved (Fig. BXII.γ.197b). These relationships are in broad agreement with more limited studies involving *Buchnera* plasmid-associated *trpE* and plasmid-associated *leuBCD* (Fig. BXII.γ.197c and d) (Bracho et al., 1995; Rouhbakhsh et al., 1996, 1997; Baumann et al., 1997, 1999; van Ham et al., 1997). In addition, the phylogenetic relationships based on *trpB* agree with the phylogeny reconstructed for the same species of *Uroleucon* using nuclear and mitochondrial sequences from the aphids (Moran et al., 1999). This pattern of congruence of phylogenies derived from chromosomal genes, plasmid genes, and host genes is strong support for a completely vertical mode of evolution, with no transfer of either bacteria or plasmids among lineages of hosts (Moran and Baumann, 1994). An implication of the congruence is that bacterial and host ancestors representing corresponding nodes on the phylogenies occurred contemporaneously, allowing dates inferred from fossil aphids to be extended to ancestral *Buchnera* (Moran et al., 1993). Phylogenetic analysis and the rate of 16S rDNA change inferred from fossil aphids has suggested that the *Buchnera*–aphid association is the result of a single infection of an aphid ancestor that occurred 150–250 million years ago. In *Buchnera* the rate of 16S rDNA evolutionary change is about twice that of free-living bacteria and about 36 times greater than in homologous regions of the host 18S rDNA (Moran, 1996; Moran et al., 1995). The increased rate of change in endosymbionts compared to free-living bacteria extends to genes other than 16S rDNA (Moran, 1996).

Nutrition and metabolism Insects, like other animals, are thought to require preformed ten essential amino acids (Dadd, 1985; Douglas, 1998). Plant sap (phloem), the diet of aphids, is rich in carbohydrates but is deficient in nitrogenous compounds (Dadd, 1985; Sandström and Pettersson, 1994). It has been thought that one of the functions of *Buchnera* is the synthesis of the essential amino acids and their provision to the aphid host (Dadd, 1985; Douglas, 1998). Some species of aphids are able to grow on synthetic diets even in the absence of some of the essential amino acids. The incorporation of antibiotics into such diets results in the elimination of the endosymbionts and the failure of the aphid to grow and reproduce. There is some sparing effect when essential amino acids are included in the antibiotic-containing diet. These results have been interpreted as being consistent with the synthesis of essential amino acids by the endosymbionts (Douglas, 1998). The most detailed experiments involve the essential amino acid tryptophan. Douglas and Prosser (1992) have shown there is a sparing effect of tryptophan on aphid growth in chlortetracycline-containing synthetic diet. In addition, these investigators detected the enzyme tryptophan synthase in *Buchnera*. Activity was absent in aphids treated with chlortetracycline that lacked the endosymbionts.

Using synthetic diets containing radiolabeled amino acids, it has been shown that the synthesis of the essential amino acids arginine, threonine, isoleucine, and lysine was eliminated by the inclusion of rifampicin in the diet (Liadouze et al., 1996). Similarly, experiments using radiolabeled sulfate showed that endosymbionts reduce sulfur and incorporate it into methionine and cysteine, which are made available to aphid tissue (Douglas, 1988). Sasaki et al. (1991) showed that treatment of aphids with rifampicin eliminated the incorporation of dietary [^{15}N]-glutamine into the essential amino acids arginine, histidine, isoleucine and/or leucine, phenylalanine, threonine, and valine.

Glutamine is one of the predominant amino acids in phloem (Sasaki et al., 1990; Sandström and Pettersson, 1994). Sasaki and Ishikawa (1995) have found that it is the predominant amino acid in aphid hemolymph. These investigators have shown that bacteriocytes take up glutamine and convert it to glutamate. Subsequently glutamate is taken up by *Buchnera*. The isolated endosymbionts incorporate the nitrogen from this compound into the essential amino acids isoleucine, leucine, valine, and phenylalanine as well as into a number of other nonessential amino acids.

Whitehead and Douglas (1993) isolated vesicles containing *Buchnera* (symbiosomes). The symbiosomes readily took up acetic, glutamic, and aspartic acid as well as tricarboxylic acid cycle intermediates and oxidized them to CO_2. Oxygen consumption was also detected and was greatly reduced by KCN. These results indicate a respiratory metabolism.

Genetics *Buchnera* contains a single copy of the genes encoding for rRNAs that are organized into two transcription units consisting of 1) 16S rRNA (GenBank accession number M63246) and 2) tRNA ^{Glu}–23S rRNA–5S rRNA (GenBank accession number U09230) (Baumann et al., 1995). A single copy of these genes is consistent with the slow growth rate of the endosymbiont (Baumann et al., 1995). Upstream of the rRNA genes are sequences that are readily recognized as −35 and −10 regions of a putative promoter.

The genome size of *Buchnera* from the aphid *Acyrthosiphon pisum* has been found to be 657 kb (Charles and Ishikawa, 1999). Approximately 113 kb of the genome of *Buchnera* from the aphid *S. graminum*, 12 kb from the endosymbiont of *Diuraphis noxia*, 11 kb from the endosymbiont of *S. chinensis*, and 6 kb from the endosymbiont of *A. pisum* have been sequenced (Ohtaka et al., 1992; Baumann et al., 1995; Sato and Ishikawa, 1997b; Baumann and Baumann, 1998; Clark et al., 1998a, 1998b; Thao and Baumann, 1998). The gene content obtained from the nucleotide sequence is an indication of the metabolic capacity of an organism. In *Buchnera* from *S. graminum* 109 open reading frames were detected. Of these, 89 corresponded to known genes and the remaining 20 had similarities to open reading frames on the *E. coli* genome, which have no known function (Blattner et al., 1997). *Buchnera* contains *dnaA*, encoding a protein that initiates bidirectional chromosome replication, and *ftsZ*, encoding a protein involved in septum formation during cell division (Lai and Baumann, 1992; Baumann and Baumann, 1998). Among other genes that were found are those encoding proteins for peptidoglycan synthesis, cell division, DNA replication, DNA transcription, ribosomal proteins, amino acid tRNA synthases, ATP synthase, electron transport, protein secretion, and glycolysis. In addition, genes for three tRNAs were detected. Genes encoding homologs of proteins involved in the *E. coli* heat shock response (*groEL*, *groES*, *htrA*, *dnaK*, *dnaJ*) and the cold shock response (*hscA*, *hscB*) were also detected (Ohtaka et al., 1992; Hassan et al., 1996; Sato and Ishikawa, 1997b; Clark et al., 1998b). In addition, some of the genes encoding enzymes for the biosynthesis of aromatic amino acids (shikimate pathway, tryptophan branch), branched chain amino acids (isoleucine, valine, leucine), lysine, cysteine, and serine, as well as genes for the complete pathway of histidine biosynthesis, were also found. The presence of genes for enzymes of amino acid biosynthesis is in marked contrast to such fastidious organisms as *Mycoplasma genitalium* and *Borrelia burgdorferi* in which the genes encoding enzymes of amino acid biosynthesis were absent (Fraser et al., 1995, 1997). Retention of amino acid biosynthetic genes may reflect the role of these pathways in the mutualistic association with the host aphids.

The overproduction of essential amino acids for the aphid host may involve modifications of some mechanisms that regulate the levels of biosynthetic enzymes (Baumann et al., 1995). One possible modification is an increase in the level of a key regulated enzyme by gene amplification. This appears to be the case in the tryptophan biosynthetic pathway of rapidly growing aphids in which the genes for the enzyme anthranilate synthase (*trpEG*) are present as tandem repeats on plasmids. In the case of *Buchnera* from *S. graminum*, *trpEG* is present as four tandem repeats that constitute a plasmid of 14.3 kb (Lai et al., 1994). The remaining genes of the tryptophan biosynthetic pathway (*trpDC[F]BA*) are chromosomal (Munson and Baumann, 1993). There are three to four copies of the *trpEG*-containing plasmid for each of the chromosomal genes. Amplification of *trpEG* is widespread in *Buchnera* of the family *Aphididae*, which is composed of rapidly growing aphids (Fig. BXII.γ.197c) (Lai et al., 1994; Rouhbakhsh et al., 1996, 1997). In each case, the region upstream of *trpE* contains two or more copies of a nine-nucleotide sequence known as a DnaA box. Since the DnaA protein binds to this sequence and initiates DNA replication, this region may be a putative origin of plasmid replication. In the slow-growing aphid *Schlechtendalia chinensis*, *trpEG* is present as one copy on the *Buchnera* chromosome (Lai et al., 1995). Curiously, the *trpEG*-containing plasmids of *Buchnera* from *D. noxia* and from *U. sonchi* contain an intact copy of *trpEG* as well as numerous copies of *trpEG* pseudogenes (Lai et al., 1996; Baumann et al., 1997). There is currently no satisfactory explanation for this observation.

An independent case in which genes for amino acid biosyn-

thesis are plasmid-borne involves the leucine biosynthetic pathway. In *Buchnera* from several aphids, all of the enzymes of leucine biosynthesis (*leuABCD*) are on plasmids (pLeu) of about 8 kb (Bracho et al., 1995; van Ham et al., 1997; Baumann et al., 1999). In *Buchnera* from the aphid *S. graminum* there are about 23 copies of pLeu per endosymbiont chromosomal gene (Thao et al., 1998). Aphids from which pLeu has been sequenced are given in Fig. BXII.γ.197d. These plasmids have no similarity to the *trpEG*-containing plasmids and lack DnaA boxes. Instead they contain open reading frames (*repA1*, *repA2*) that correspond to putative proteins related to RepA of the IncFII incompatibility group plasmids, which is involved in plasmid DNA replication (Bracho et al., 1995). Also encoded on pLeu is a conserved open reading frame of unknown function. A most remarkable finding is the presence of a 1.7-kb plasmid in *Buchnera* from the aphid *Tetraneura caerulescens*, which contains only *repA1* and an unidentified open reading frame (van Ham et al., 1997). It is possible that this plasmid represents a minimal-size replicon that under the right selection can be used for the amplification of other chromosomal genes.

GroEL overproduction In *Buchnera*, the chaperonin GroEL constitutes a major fraction of the total protein (Sato and Ishikawa, 1997b). In addition, GroEL is detected in the aphid hemolymph (van den Heuvel et al., 1994). Overproduction of GroEL is a characteristic of endosymbionts and pathogens in the intracellular environment (Baumann et al., 1995; Hogenhout et al., 1998). GroEL has been localized in maternal and embryonic endosymbionts by immunohistochemistry (Fukatsu and Ishikawa, 1992b). Electron micrographs indicate that the purified *Buchnera* GroEL has the characteristic double-ring appearance observed with the *E. coli* protein (Hara and Ishikawa, 1990; Filichkin et al., 1997). In addition, it has ATPase activity and in the presence of *E. coli* GroES and ATP could reconstitute denatured *Rhodospirillum rubrum* ribulose-1,5-biphosphate carboxylase (Kakeda and Ishikawa, 1991). *Buchnera* GroEL is able to complement *E. coli* mutants (Ohtaka et al., 1992).

The *Buchnera groESL* operon organization resembles that of *E. coli* (Ohtaka et al., 1992; Hassan et al., 1996; Hogenhout et al., 1998). Upstream of *groES* are nucleotide sequences characteristic of the -35 and -10 regions of σ^{32} promoters. A message of 2.1 kb (containing both *groES* and *groEL*) is made by the endosymbiont using only this promoter (Sato and Ishikawa, 1997a). It is not understood why GroES is barely detectable in the endosymbiont, in contrast to the high quantities of GroEL (Kakeda and Ishikawa, 1991; Fukatsu and Ishikawa, 1993). The genes for σ^{32} (*rpoH*) as well as *dnaKJ* have been cloned and sequenced (Sato and Ishikawa, 1997a, b). The latter are also transcribed solely from a σ^{32} promoter. In *E. coli* as well as other organisms, transcription of the *groESL* operon and the *dnaKJ* operon are in part of the σ^{32} regulon and their synthesis is increased by heat shock (Gross, 1996). It would appear that this mode of regulation is modified in *Buchnera* (Sato and Ishikawa, 1997a, b). Synthesis of *groESL* and *dnaKJ* messenger RNA is constitutive and is not increased by heat shock. This conclusion is supported by the observation that there is no increase in the level of total GroEL in aphids shifted from a temperature of 23°C to 33°C for a period of 1 d (Baumann et al., 1996).

Pathogenicity Aphids are major pests of agricultural plants (Blackman and Eastop, 1984). Although large populations of aphids can cause plant debilitation due to nutrient consumption, perhaps the major economic effect of aphids on agriculture is due to their transmission of plant viruses. Recently, *Buchnera*-derived GroEL has been implicated in the survival of luteoviruses in the hemolymph (van den Heuvel et al., 1994; Filichkin et al., 1997; Hogenhout et al., 1998). These viruses replicate in the plant and are ingested by aphids when they feed on phloem sap. Subsequently they are transported from the digestive tract into the hemolymph and from there into the salivary gland for transmission to plants via salivary secretions. The viruses are retained in an infective form (without replication) in the hemolymph throughout the life span of the aphid. There is evidence that the GroEL that is found in the hemolymph coats the virus particles and protects them from host defenses. A region in *Buchnera* GroEL has been identified that is essential for binding to the virus (Hogenhout et al., 1998), and similarly a portion of a viral capsid protein has been identified as the region to which the endosymbiont GroEL binds (van den Heuvel et al., 1997).

Antibiotic and drug sensitivity A variety of antibiotics have been used to eliminate endosymbionts, resulting in a reduction of weight gain of the aphid and the loss of reproductive potential. These antibiotics include chloramphenicol, chlortetracyline, neomycin, penicillin, rifampicin, and streptomycin.

Additional symbionts Many species of aphids also contain rod-shaped procaryotic endosymbionts designated as the secondary (S)-endosymbionts (Buchner, 1965; Houk and Griffiths, 1980; Fukatsu and Ishikawa, 1993). These organisms are usually absent from bacteriocytes and are found in vesicles within the sheath cells that surround the bacteriome. The S-endosymbiont from the aphid *A. pisum* is a member of the *Enterobacteriaceae* (Unterman et al., 1989). In this organism, the 16S rDNA is upstream of 23S rDNA (Unterman et al., 1989; Unterman and Baumann, 1990). The S-endosymbiont of *A. pisum* is dispensable (Chen and Purcell, 1997) since strains lacking this endosymbiont have been found in nature. The S-endosymbiont can be introduced into such strains by injection of hemolymph from strains of *A. pisum* that contain the S-endosymbiont. Some aphids may also contain a rod-shaped rickettsia closely related to *Rickettsia bellii* (Chen et al., 1996).

Although most species of aphids appear to contain bacteriocytes with *Buchnera*, some species of the tribe Cerataphidini lack both (Fukatsu and Ishikawa, 1992a; Fukatsu et al., 1994). These aphids instead contain, in their body cavity, a yeast-like symbiont that based on its 18S rDNA was found to belong to the subphylum Ascomycotine of the class Pyrenomycetes (Fukatsu and Ishikawa, 1996). These symbionts were related to those of planthoppers.

Enrichment and Isolation Procedures

Endosymbiont-enriched preparations have been obtained using methods previously described (Ishikawa, 1982; Harrison et al., 1989; Sasaki and Ishikawa, 1995). The endosymbionts require high osmolarity for the retention of their structure. The best criteria of purity have involved examination of the purified preparations by electron microscopy, which also allows determination of whether the endosymbionts are still within host-derived vesicles.

Both the aphids and the endosymbionts have a similar mol% G + C DNA content (Ishikawa, 1987; Unterman and Baumann, 1990), and consequently endosymbiont DNA cannot be separated from host DNA by CsCl density gradient centrifugation. For the routine purification of *Buchnera* from *S. graminum*, to obtain starting material for the preparation of endosymbiont-

enriched DNA, the method of Sasaki and Ishikawa (1995) has been used. All of the reagents and equipment are kept on ice and the procedures are performed as rapidly as possible. Approximately 2–3 g (wet weight) aphids are transferred to a 1.5 cm diameter tissue grinder. Ten milliliters of buffer A[1] is added and the aphids are ground with a loose-fitting plunger for 5 min and the preparation passed through a double layer of a nylon mesh to remove large particulate material. The filtrate is brought to a volume of about 100 ml with buffer A and then quickly passed through a 100-μm nylon filter (Spectrum Medical Industries, Inc., Houston, Texas, USA), followed by filtration through 20-μm and 10-μm nylon filters. Only slight vacuum pressure is applied during the last two filtration steps. The volume is made up to approximately 120 ml with buffer A and 30-ml aliquots are centrifuged in a swinging bucket rotor for 6 min at 1500 × g. The pellets are gently resuspended in 1.25 ml of buffer A and used for DNA purification (Unterman et al., 1989; Munson et al., 1991a). The DNA obtained from such preparations is endosymbiont-enriched 13- to 15-fold relative to the DNA obtained from the whole aphid (Baumann et al., 1997). Further purification of the endosymbiont preparation can be obtained by centrifugation through 10–90% Percoll gradients (Pharmacia Biotech, Uppsala, Sweden) as described by Ishikawa (1982).

Maintenance Procedures

Established lines of *S. graminum*, the aphid that contains the type strain of *B. aphidicola*, can be readily grown on wheat or barley at 23–24°C with 1500 foot candles illumination and a photoperiod of 16 h light and 8 h dark. Seeds are planted in rich soil, and, after 5–6 d, the seedlings are inoculated with aphids. The inoculum is obtained by cutting aphid-infested plants close to the roots and shaking them over the seedlings to dislodge the aphids. New seedlings are inoculated every 7–10 d.

Procedures for Testing Special Characters

Buchnera is somewhat unusual in that its rRNA genes are organized into two transcription units (Baumann et al., 1995). Consequently, 16S rDNA is not upstream of 23S rDNA. In eight strains of *Buchnera*, encompassing the diversity presented in Fig. BXII.γ.197a, *aroE* has been found to be upstream of 23S rDNA (Rouhbakhsh and Baumann, 1995). This property has been used for the identification of *Buchnera* using oligonucleotide primers complementary to *aroE* and 16S rDNA and PCR (Rouhbakhsh et al., 1994). This and other PCR-based identification methods are discussed by Rouhbakhsh et al. (1994). It should be noted that the S-endosymbiont found in some aphids has 16S rDNA upstream of the 23S rDNA (Unterman and Baumann, 1990).

Differentiation of the genus *Buchnera* from other genera

Since different evolutionary lineages of nonculturable endosymbionts are found within aphids, carpenter ants, and tsetse flies, their initial putative identification is at the level of the insect host (Fig. BXII.γ.196). In *Wigglesworthia* (endosymbionts of tsetse flies), 16S rDNA is upstream of 23S rRNA and this is a useful differential character (Aksoy, 1995a, b). In the carpenter ant endosymbionts the 16S rDNA is not upstream of 23S rDNA, and it appears that the rRNA genes are organized into at least two transcription units (C. Elsishans and R. Gross, personal communication). It is not known if in carpenter ant endosymbionts *aroE* is upstream of the 23S rDNA, as is the case in *Buchnera*. The members of the *Enterobacteriaceae* are mostly free-living, readily identifiable bacteria with their rRNA genes arranged in the order 16S–23S–5S.

Taxonomic Comments

There are over 4000 species of aphids (Blackman and Eastop, 1984), of which only 28 have been characterized by molecular methods. Consequently, our conclusions concerning *Buchnera* are based on a very small sample of aphid species. 16S rDNA has been useful for showing the monophyletic origin of the aphid symbiosis. It appears also to be useful for the differentiation of major aphid subgroups, as for example the *Aphididae* and possibly other families (Fig. BXII.γ.197a). 16S rDNA, however, is far too conserved for the elucidation of relationships between endosymbionts of closely related aphids. We have had some success with the use of a portion of *trpB* for this purpose (Fig. BXII.γ.197b). However, other informational molecules should also be tried.

The name *Buchnera aphidicola* as currently used designates the whole aphid endosymbiont lineage (Fig. BXII.γ.197a). The 16S rDNA sequence difference between *Buchnera* from *S. graminum* and *Buchnera* from *S. chinensis* (Sg and Sc in Fig. BXII.γ.197a) is approximately the same as that between *E. coli* and *Proteus vulgaris*. This clearly indicates that in subsequent studies *Buchnera* should be subdivided into new species. For this purpose, it is necessary to study a molecule that is less conserved than the 16S rDNA, and it is also necessary to know the range of variation within the endosymbionts of a single aphid species. In addition, since there is co-speciation between the host and the endosymbiont, the phylogeny of the host should also be elucidated to serve as an aid in the recognition of new endosymbiont species.

List of species of the genus Buchnera

1. **Buchnera aphidicola** Munson, Baumann and Kinsey 1991b, 567[VP]

a.ph' di.co.la. M.L. fem. n. *aphidicola* aphid dweller.

The characteristics are those described for the genus. Morphological features are depicted in Figs. BXII.γ.194 and BXII.γ.195.

The mol% G + C of the DNA is: 27 (determined from the nucleotide sequence of over 100 kb of DNA).

Type strain: Endosymbiont of the aphid *Schizaphis graminum*.

GenBank accession number (16S rRNA): M63246.

1. Buffer A contains 0.25 M sucrose, 35 mM Tris-HCl (pH 7.6), 25 mM KCl, 10 mM $MgCl_2$, and 1 mM dithiothreitol (Ishikawa, 1982).

Genus VI. **Budvicia** *Aldová, Hausner, and Gabrhelová* in *Bouvet, Grimont, Richard, Aldová, Hausner and Gabrhelová 1985, 63*[VP]

J.J. Farmer III

Bud.vi' ci.a. L. fem. n. *Budvicia* derived from Budvicium, the Latin name of the city České Budějovice where the bacterium was first isolated.

Small, straight, rod-shaped cells, nonsporeforming, nonencapsulated, and Gram negative, conforming to the general definition of the family *Enterobacteriaceae*. Contains the enterobacterial common antigen. **Motile, producing peritrichous flagella when grown at 22°C; less motile at 36°C.** Grows on laboratory media including MacConkey agar. Grows slowly on nutrient agar, forming colonies only about 0.1 mm at 24 h, 36°C; colonies are five times larger when grown at 30°C for 24 h. More active biochemically at 25°C than 36°C. Oxidase negative, reduce nitrate to nitrite. **Positive for: H_2S production, urea hydrolysis, and fermentation of glucose, L-arabinose, L-rhamnose, D-xylose, and D-galactose.**

Negative for indole production, Voges–Proskauer, citrate utilization (Simmons), phenylalanine deaminase, lysine decarboxylase, arginine dihydrolase, ornithine decarboxylase, growth in the presence of cyanide (KCN test), malonate utilization, esculin hydrolysis, gelatin hydrolysis (22°C), lipase (corn oil), DNase, and the fermentation of sucrose, dulcitol, salicin, adonitol, *myo*-inositol, D-sorbitol, raffinose, maltose, trehalose, cellobiose, α-methyl-D-glucoside, erythritol, melibiose, glycerol, and D-mannose.

Utilize 29 of 83 carbon sources tested. **Grow at 4°, 10°, 22°, 32°, and 37°C, but not at 42°C.** Complex growth factor requirement: **absolute requirement for nicotinic acid**; other vitamins and amino acids stimulate growth. Susceptible to colistin, nalidixic acid, sulfadiazine, gentamicin, streptomycin, kanamycin, chloramphenicol, and carbenicillin (disk diffusion method on Mueller-Hinton agar); **resistant to penicillin, ampicillin, and cephalothin**. **Isolated from drinking and environmental water** in Europe, and from fecal specimens in United States. **No evidence that it is a pathogen for plants or animals.**

The mol% G + C of the DNA is: 46 ± 1 (Bouvet et al., 1985); 51–54 (Aldová et al., 1983).

Type species: **Budvicia aquatica** Aldová, Hausner, and Gabrhelová *in* Bouvet, Grimont, Richard, Aldová, Hausner and Gabrhelová 1985, 63.

Further descriptive information

Guide to the literature Since the genus name was first published in 1983, there have been a few reports in the literature. "HG group" should be included in computer literature searches to retrieve early references. A search from 1983 to May 1999 yielded only seven citations in MEDLINE and 12 citations in BIOSIS. Most are about the organism (Aldová et al., 1983, 1984; Bouvet et al., 1985), comparative taxonomic studies (Bouvet and Grimont, 1987a), or water bacteriology (Hausner et al., 1986; Schubert and Groeger-Söhn, 1998).

Sources Most isolates of *Budvicia* have been from various types of water: wells, rivers and streams, swimming pools, conduits, environmental, and sewage. Hausner et al. (1986) isolated 170 strains of *B. aquatica* from 21,300 water samples, mainly from wells and water mains. One isolate was from the digestive tract of a shrew in Spain (Bouvet et al., 1985).

B. aquatica has also been isolated from human feces in United States (Enteric Reference Laboratory, CDC, unpublished). However, there is no evidence that *B. aquatica* causes diarrhea or infections of the intestinal tract. Apparently, it has not been isolated from extraintestinal human clinical specimens.

Bacteriocin-like agents Strains of *Budvicia* produce bacteriocin-like agents that Šmarda (1987) termed aquaticins.

Isolation, identification, culture preservation, phenotypic characterization Strains of *Budvicia* are not difficult to grow, and are typical *Enterobacteriaceae* in most respects. Strains grow slowly on nutrient agar, forming colonies only about 0.1 mm at 24 h at 36°C, but about five times larger when grown at 30°C for 24 h (Bouvet et al., 1985). Similarly, the biochemical reactions may be different at the two temperatures; and strains may be more active at 25°C. Schubert and Groeger-Söhn (1998) described a method for its detection and quantification in water and sewage samples. See the chapter on the family *Enterobacteriaceae* in this *Manual* for general information on growth, plating media, working and frozen stock cultures, media and methods for biochemical testing, identification, computer programs, and antibiotic susceptibility.

Biochemical reactions and differentiation from other *Enterobacteriaceae* Table BXII.γ.193 in the chapter on the family *Enterobacteriaceae* gives the results at 36°C for *Budvicia* strains in 47 biochemical tests normally used for identification (Farmer, 2003). There are no genus- or species-specific tests or sequences for the identification of *Budvicia*. The best approach is to do a complete set of phenotypic tests (growth on plating media, biochemical tests, antibiogram, etc.) and compare the results with all the other named organisms in the family *Enterobacteriaceae*. This approach is described in more detail in the chapter on the family *Enterobacteriaceae*. The biochemical results of a test strain can be compared to all the organisms listed in Table BXII.γ.193 of the chapter on the family *Enterobacteriaceae*. Several computer programs greatly facilitate analyzing the results. Bouvet et al. (1985) point out that strains of *B. aquatica* could be misidentified as H_2S-positive strains of *Yersinia*, *Citrobacter*, or *Salmonella*.

Taxonomic Comments

Discovery, history, nomenclature, and type strains In 1976 the first strain of an unusual H_2S-producing strain of *Enterobacteriaceae* was isolated at the Public Health Laboratory in České Budějovice, Czechoslovakia (Aldová et al., 1983). From 1976 to 1983, 27 additional strains were isolated from water samples in three different areas of Bavaria. In 1983 Aldová et al. described this collection of strains, which had been given the vernacular name "HG group". All the data indicated that this was a new group that was distinct from all of the described genera and species of *Enterobacteriaceae*. Throughout the paper Aldová et al. (1983) used the term "HG group" for the new organism; however, at the end of the paper there was a separate section with the heading "Note", which stated that after the manuscript had been submitted DNA–DNA hybridization data became available from the laboratory of P.A.D. Grimont of the Institute Pasteur confirming that the group was a new genus of *Enterobacteriaceae*. In this note they stated: "The authors accordingly propose for this genus the name *Budvicia* (from the ancient Latin name 'Budvicium' for the city of České Budějovice where the microorganism was first isolated) and for its only species the name *Budvicia aquatica*. The epithet, as is obvious, is derived from the Latin adjective 'aquaticus'."

It is clear from this paragraph that a formal nomenclatural proposal was actually made. However, since no type strain was designated for *B. aquatica*, the names *Budvicia* and *Budvicia aquatica* were not "validly published" (see the *Bacteriological Code*, pages 28–29), and thus are illegitimate names. This situation was

apparently rectified when the names *Budvicia* Aldová, Hausner, Gabrhelová, Schindler, Petráš and Braná 1985a and *Budvicia aquatica* Aldová, Hausner, Gabrhelová, Schindler, Petráš and Braná 1985a gained standing in nomenclature and were validly published in Validation List 17 in the April 1985 issue of the IJSB (see page 223). Footnote f of Validation List 17 states that the type strain of *Budvicia aquatica* is 20186 (CNCTC 350); "Personal communication to the editor of the IJSB". In 1984, Aldová et al. had published a second paper *that* specifically defined this as the type strain. A sentence on page 234 of Aldová et al. (1984) stated: "As the type strain, we propose strain No. 20186 of the National Dysentery Reference Laboratory, which has been deposited at the Czechoslovak National Collection of Type Cultures, Prague under No. M 350."

However, the 1984 paper of Aldová et al. was not listed in the Literature Cited section of Validation List 17. Validation List 17 would have ended a slightly confusing matter; however, in January, 1985 there was a new set of proposals for *Budvicia* and *Budvicia aquatica*. Bouvet et al. published a paper in the *International Journal of Systematic Bacteriology* proposing *Budvicia* and *Budvicia aquatica* as a new genus and species, and their species appeared to be based on a different type strain. This latter paper made a confusing situation even more confusing. In addition, they compounded the confusion by proposing an unconventional name citation (see Nomenclatural problem 3, below). These four conflicting proposals (Aldová et al., 1983, 1984, 1985a; Bouvet et al., 1985) create four nomenclatural problems that require analysis and discussion.

Nomenclatural problem 1 Priority of *Budvicia* Bouvet, Grimont, Richard, Aldová, Hausner and Gabrhelová 1985 over *Budvicia* Aldová, Hausner, Gabrhelová, Schindler, Petráš and Braná 1985a. The first name clearly has priority because it was validly published first (as an article in the *International Journal of Systematic Bacteriology*, January 1985, pages 60–64). The second name was published in the next issue (April 1985) in Validation List 17 (page 223).

Nomenclatural problem 2 Priority of *Budvicia aquatica* Bouvet, Grimont, Richard, Aldová, Hausner and Gabrhelová 1985 whose type strain is 20186HG01 (ATCC 35567) over *Budvicia aquatica* Aldová, Hausner, Gabrhelová, Schindler, Petráš and Braná 1985a whose type strain is 20186 (CNCTC 350). The first name has priority for the same reason given above.

Nomenclatural problem 3 Are *Budvicia aquatica* Bouvet, Grimont, Richard, Aldová, Hausner and Gabrhelová 1985 and *Budvicia aquatica* Aldová, Hausner, Gabrhelová, Schindler, Petráš and Braná 1985a objective or subjective synonyms? The two species would be objective synonyms if they have the same type strain, but would be subjective synonyms if they have different type strains. The type strains were published with different, but similar, strain numbers (20186HG01 vs 20186). Whether these strain numbers are the same or different is not clear from any of the published papers.

Nomenclatural problem 4 Author citations for *Budvicia* and *Budvicia aquatica*. In their original paper in the *International Journal of Systematic Bacteriology* Bouvet et al. (1985) stated: "To recognize the priority of three authors in the delineation of the new genus and species, we propose the following citation of names: *Budvicia* Aldová, Hausner, and Gabrhelová *in* Bouvet, Grimont, Richard, Aldová, Hausner and Gabrhelová 1985, and *Budvicia aquatica* Aldová, Hausner, and Gabrhelová *in* Bouvet, Grimont, Richard, Aldová, Hausner and Gabrhelová 1985."

It seems confusing and a danger to "stability in nomenclature" to have a name citation that disagrees with the authorship of the original paper. The conventional style for author citations as specified in the Bacteriological Code has been followed here, and the reader is referred to the irregular citation proposed by Bouvet et al. (1985). However, in the chapter on *Tatumella*, an

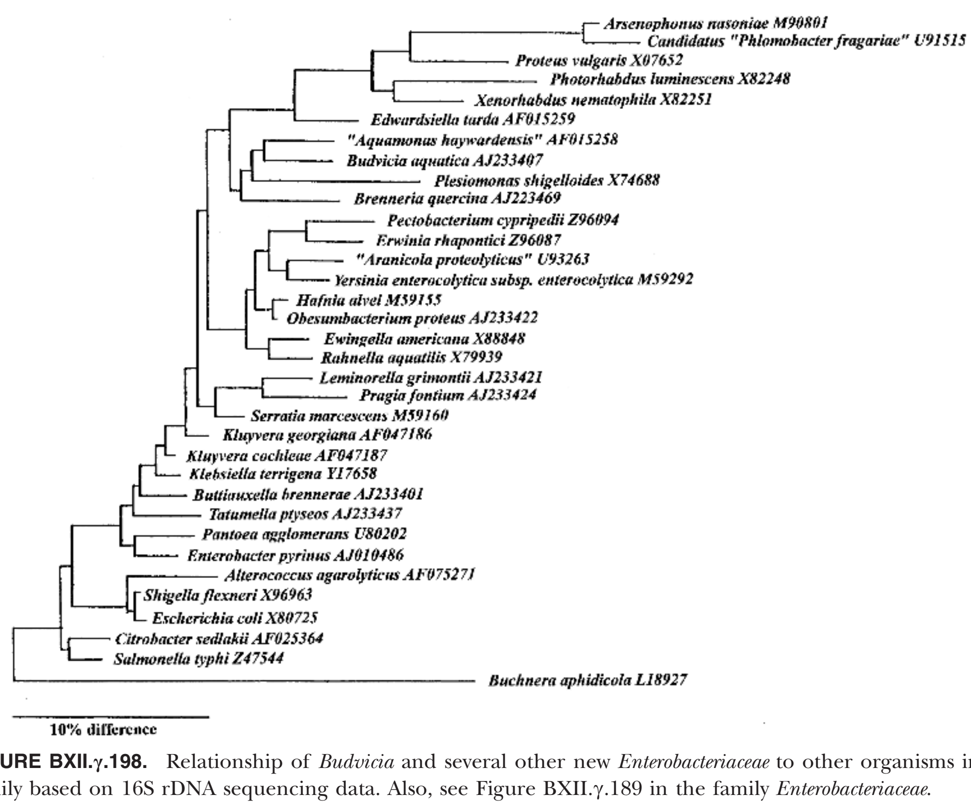

FIGURE BXII.γ.198. Relationship of *Budvicia* and several other new *Enterobacteriaceae* to other organisms in the family based on 16S rDNA sequencing data. Also, see Figure BXII.γ.189 in the family *Enterobacteriaceae*.

irregular name citation was also used. For consistency, the irregular author citation given by Bouvet et al. (1985) was used in this chapter on *Budvicia*.

Interestingly, this is a point that can cause instability in nomenclature. Because an "authors' proposal for an unorthodox name citation" is not specifically covered in the Bacteriological Code, remedial action in the form of a rule modification or Opinion of the Judicial Commission will be needed to guide future writers.

Phylogeny based on DNA–DNA hybridization and 16S rRNA sequencing Based on the DNA–DNA hybridization data *Budvicia* is a distinct and well-defined genus of *Enterobacteriaceae* with its one species *Budvicia aquatica* (Bouvet et al., 1985). None of the other genera of *Enterobacteriaceae* are closely related. Fig.BXII.γ.198 is a tree based on 16S rDNA sequencing that confirms this relationship. The organism on the same branch as *B. aquatica* is a new H_2S producing *Enterobacteriaceae* that will be named *Aquimonas* (originally listed as *Aquamonas* in the GenBank database of sequences). This tree should be compared with the tree published by Spröer et al. (1999), which also shows the distinctness of *Budvicia*. However, this latter tree has *Pragia* and *Leminorella*, two other H_2S-producing genera of *Enterobacteriaceae*, on the same branch.

Schindler et al. (1992) agreed that *Budvicia* strains are distinct from other H_2S-producing *Enterobacteriaceae* based on SDS-PAGE protein patterns.

List of species of the genus Budvicia

1. **Budvicia aquatica** Aldová, Hausner, and Gabrhelová *in* Bouvet, Grimont, Richard, Aldová, Hausner and Gabrhelová 1985, 63^{VP}

a.qua' ti.ca. L. fem. adj. *aquatica* living in water; named to show the aquatic habitat of the organism, since all but one of the original strains were isolated from water.

The characteristics are as previously described for the genus. Biochemical characteristics of the species are given in Table BXII.γ.193 in the chapter on the family *Enterobacteriaceae*. Isolated from well water, rivers and streams, swimming pools, water conduits, environmental water, sewage, the digestive tract of a shrew, and from human fecal specimens in United States (Enteric Reference Laboratory, CDC, unpublished). There is no evidence that *B. aquatica* causes diarrhea, infections of the intestinal tract, or extraintestinal infections.

The mol% G + C of the DNA is: 46 ± 1 (T_m) (Bouvet et al., 1985); 51–54 (T_m and UV spectrophotometry) (Aldová et al., 1983).

Type strain: 20186HG01, ATCC 35567, Eb 13/82, CDC 0440-84, CNCTC 20186, DSM 5075.

GenBank accession number (16S rRNA): AJ233407.

Additional Remarks: The ATCC also lists two other strains ATCC 35566 (Eb 4/81, CNCTC 21930, M 325) and ATCC 51341 (85-01-010).

Genus VII. Buttiauxella *Ferragut, Izard, Gavini, Lefebvre and Leclerc 1982, 266^{VP} (Effective publication: Ferragut, Izard, Gavini, Lefebvre and Leclerc 1981, 40)*

Peter Kämpfer

But.ti' aux' el.la. M.L. dim. ending *-ella*; M.L. fem. n. *Buttiauxella* named after René Buttiaux, a French microbiologist for his numerous contributions to the taxonomy of *Enterobacteriaceae*.

Straight rods, 0.5–0.7 × 2–3 µm, conforming to the general definition of the family *Enterobacteriaceae*. **Gram negative, motile by peritrichous flagella.** Facultatively anaerobic. Chemoorganotrophic. Psychrotolerant, growing at 4°C. D-Glucose is fermented with the production of acid and gas. Nitrate is reduced to nitrite. Oxidase negative, catalase positive. **Most strains are methyl red positive**. **The majority of strains are indole negative**. **Acids are produced from various carbohydrates, including L-arabinose, cellobiose, maltose, D-mannose, L-rhamnose, D-xylose, and salicin**. 16S rDNA sequence analysis of the type strain of *Buttiauxella agrestis* clearly places the genus in the family *Enterobacteriaceae* within the *Gammaproteobacteria*. Often isolated from fresh water, but also found in soil, and especially in the intestines of snails and slugs from various regions in the world.

The mol% G + C of the DNA is: 47–51.

Type species: **Buttiauxella agrestis** Ferragut, Izard, Gavini, Lefebvre and Leclerc 1982, 266, emend. Müller, Brenner, Fanning, Grimont and Kämpfer 1996, 60 (Effective publication: Ferragut, Izard, Gavini, Lefebvre and Leclerc 1981, 40).

Further descriptive information

Based on 16S rDNA sequence analysis of the type strain, *B. agrestis* was most similar to the type strain of *Klebsiella planticola* (97.9%). Analysis of 16S rDNA of the type strains of the seven species revealed a very high degree of phylogenetic relatedness (99.1–99.7% similarity) (Spröer et al., 1999). The phenotypic description of the genus *Buttiauxella* is largely based on the studies of Gavini et al. (1976b), Ferragut et al. (1981), Farmer (1984b), Farmer et al. (1985a), Brenner (1992a), and Müller et al. (1996). Based on DNA–DNA hybridization it was obvious that the *Buttiauxella* strains comprised seven closely related species, which were very difficult to differentiate phenotypically. The subdivision of the genus *Buttiauxella* is described below (seeTaxonomic Comments).

Cells are straight rods, 0.5–0.7 × 2–3 µm, and can occur singly or in pairs. They are motile at 36°C by peritrichous flagella. *Buttiauxella* strains grow readily on many common media; no growth requirements have been described. A nutrient-rich medium (e.g., Tryptone–Soy agar, sheep-blood agar, or nutrient agar) gives best results. Optimal growth occurs at temperatures ranging from 25°C to 35°C, often yielding better growth than incubation at 37°C. The majority of strains are psychrotolerant, growing (slowly) at 4°C, but not at 41°C.

All members of the genus *Buttiauxella* produce a positive β-galactosidase reaction (ONPG test), although not all produce acid from lactose. The β-glucuronidase test is negative for all

[a]Data adapted from Müller et al. (1996).

[b]Symbols: +, positive for 90–100% of strains; [+], positive for 75–89% of strains; d, positive for 25–74% of strains; [−], positive for 11–24% of strains; −, positive for 0–10% of strains. All reactions, unless otherwise stated, were done at 36° ± 1°C and read after 48 h.

[c]All of the strains studied were Gram-negative, oxidase-negative, catalase-positive, D-glucose-fermenting, nitrate-reducing, rod-shaped organisms. All strains grew on MacConkey agar and on Endo agar at 30°C. With few exceptions, all of the strains were positive in standard tests for motility, acid and gas production from D-glucose, fermentation of D-mannitol, salicin, L-arabinose, L-rhamnose, maltose, D-xylose, trehalose, cellobiose, D-mannose, galactose, gentiobiose, D-ribose, and arbutin, esculin hydrolysis, and *o*-nitrophenyl-β-D-galactopyranoside (β-galactosidase) test. They were all negative for production of hydrogen sulfide on triple sugar iron, Christensen urease activity, gelatin liquefaction (at 22°C), lipase activity (Tween 80 and corn oil), DNase activity, and production of a yellow pigment, and did not ferment 2-deoxy-D-glucose, 2-deoxy-D-ribose, erythritol, α-D-fucose, D-lyxose, and xylitol.

Almost all of the strains utilized the following compounds as sole carbon and energy sources: *N*-acetyl-D-glucosamine, D-alanine, L-alanine, L-arabinose, arbutin, DL-asparagine, D-cellobiose, D-fructose, D-galactose, D-galacturonate, gentiobiose, D-gluconate, D-glucosamine, D-glucuronate, L-glutamine, L-glutamate, DL-glycerate, glycerol, 4-hydroxybenzoate, 2-ketogluconate, D-lactate, DL-lactate, maltose, maltotriose, mannitol, D-mannose, methyl-α-galactoside, methyl-β-galactoside, methyl-β-D-glucoside, mucate, oxaloacetate, palatinose, protocatechuate, pyruvate, quinate, L-rhamnose, D-ribose, D-saccharate, salicin, L-serine, starch, D-trehalose, and D-xylose.

Almost all of the strains were unable to utilize the following compounds as sole carbon and energy sources: acetamide, acetamidocaprate, *N*-acetyl-DL-methionine, *N*-acetyl-L-proline, *cis*-aconitate, *trans*-aconitate, adipate, β-alanine, allantoin, altrose, DL-2-aminoadipate, 2-aminobenzoate, 3-aminobenzoate, 4-aminobenzoate, DL-2-aminobutyrate, DL-3-aminobutyrate, 4-aminobutyrate, DL-2-aminoisobutyrate, DL-3-aminoisobutyrate, 5-aminovalerate, aminoxyacetate, amygdalin, anthranilate, L-arabitol, arabonate, D-arginine, D-asparagine, azelate, benzoate, betaine, 1-butanol, 2-butanol, *n*-butyrate, cadaverine, caprate, caprylate, carni-tine, carnosine, L-citrulline, citraconate, L-cysteinate, dextran, DL-2,4-diaminobutyrate, diaminopimelate, 2,3-diaminopropionate, dimethylglycine, *m*-erythritol, ethanol, ethanolamine, ethylamine, D-fucose, D-glutamate, glutarate, glycinamide, glycogen, glycolate, glycyrrhizinate, 1-hexanol, 1,6-hexandiol, hexylamine, hippurate, histamine, D-histidine, L-histidine, L-homoserine, DL-3-hydroxybutyrate, 4-hydroxybutyrate, DL-2-hydroxycaprate, DL-2-hydroxyisobutyrate, L-2-hydroxyisocaprate, 2-hydroxyisovalerate, DL-δ-hydroxylysine, 2-hydroxyphenylacetate, 4-hydroxyphenylglycine, DL-hydroxyproline, 2-hydroxyvalerate, HQ-β-glucuronide, heptanoate, indole-3-acetate, isobutyrate, isophthalate, itaconate, 2-ketoglutarate, 2-ketoisocaprate, D-leucine, L-leucine, levulinate, D-lysine, D-malate, maleate, D-mandelate, L-mandelate, D-mannoheptulose, D-melezitose, mesaconate, mesoxalate, D-methionine, L-methionine, DL-methioninesulfone, methyl-α-D-glucoside, α-methyl-D-mannoside, β-methyl-D-xyloside, L-norleucine, D-norvaline, L-norvaline, 1,8-octandiol, D-ornithine, phenoxyacetate, D-phenylalanine, phenylglycine, phenyllactate, phosphoenolpyruvate, phthalate, pimelate, poly-D-galactomannan, polygalacturonate, D-proline, propionate, protocatechuate, putrescine, salicylamide, salicylate, sarcosine, sorbate, L-sorbose, spermine, suberate, D-tartrate, *meso*-tartrate, tartronate, taurine, thiamine, tricarballylate, trigonelline, tropate, tryptamine, D-tryptophan, L-tryptophan, tyramine, L-tyrosine, ureidosuccinate, *n*-valerate, isovalerate, L-valine, xylitol, and L-xylose.

The strains varied in their ability to utilize the following compounds as sole sources of carbon and energy, and these characteristics could not be used to differentiate hybridization groups: D-alanine, L-asparagine, L-aspartate, benzoate, fumarate, D-glucarate, D-glucosaminate, glycerate, glycerophosphate, glycine, glyoxylate, 4-hydroxybenzoate, 4-hydroxyphenylacetate, inulin, DL-isocitrate, DL-isoleucine, 2-ketoglutarate, L-lactate, D-lyxose, L-lyxose, L-malate, L-mannose, phenylpyruvate, D-serine, spermidine, succinate, L-tartrate, L-threonine, and D-turanose.

B. agrestis and *B. izardii* could not be distinguished on the basis of the results of any single test. These groups had to be distinguished on the basis of their overall biochemical profiles. *B. gaviniae* and *B. noackiae* could also not be separated on the basis of the results of a single test, but could be differentiated on the basis of their *N*-acetyl-L-glutamine, adonitol, D-arabitol, L-fucose, mucate, and tartrate reactions. As stated in the text, these two pairs of hybridization groups exhibited the highest levels of interspecies DNA relatedness.

[d]Ut, utilization test; Acid, acidification test; Alcal, alkalinization test.

strains. Hydrogen sulfide formation, Voges–Proskauer, urease, and DNase tests are negative for all strains.

The reduction of nitrous oxide to dinitrogen has been reported in some strains of *B. agrestis* (Kaldorf et al., 1993). Various carbon sources, including carbohydrates, organic acids, and amino acids are utilized as sole sources of carbon (Gavini et al., 1976b; Ferragut et al., 1981; Müller et al., 1996; Table BXII.γ.210).

Isoprenoid quinone Q-8 is the predominant quinone type and a small amount of the menaquinone MK-8 is present in *B. agrestis* ATCC 33320^{T} (P. Kämpfer, unpublished results). The fatty acid composition as determined by gas chromatographic analysis of 66 strains representing all species (Kämpfer et al., 1997) differed only slightly. All strains contained the fatty acids $C_{14:0}$, $C_{16:0}$, $C_{17:0\ cyclo}$, summed feature ($C_{16:1\ isoI}$ and/or $C_{14:0\ 3OH}$), summed feature ($C_{16:1\ \omega7c}$ and/or $C_{15:0\ iso\ 2OH}$), and summed feature ($C_{18:1\ \omega7c}$, $C_{18:1\ \omega9t}$, and/or $C_{18:1\ \omega12t}$) (Kämpfer et al., 1997), a fatty acid profile typical for the family *Enterobacteriaceae*.

Antimicrobial susceptibility data are summarized by Freney et al. (1988). Members of the genus *Buttiauxella* (13 strains) were usually sensitive to aminoglycosides (gentamicin, tobramicin, and amikacin), doxocycline, and trimethoprim, but resistant to chloramphenicol. Susceptibility to ampicillin, aminoxycillin-clavulanic acid, and tiracillin was observed. Cephalothin and cefoxitin were inactive. *Buttiauxella* produces enterobacterial common antigen (Böttger et al., 1987).

Pathogenicity of *Buttiauxella* for humans and animals has not been documented. Only one *B. agrestis* strain in the study of Müller et al. (1996) was from a human clinical specimen. Farmer et al. (1985a) described seven strains of Enteric Group 59 (now *Buttiauxella noackiae*) originating from sputum and a foot wound. *Buttiauxella* is widely distributed in nature, may be isolated from foods and is occasionally isolated from human sources. Although the natural habitat of *Buttiauxella* was originally thought to be water, the majority of strains have been isolated from the intestines of snails and slugs (Müller et al., 1996).

Enrichment and Isolation Procedures

The cultivation media used for the isolation of *Buttiauxella* are those regarded useful for other members of the family *Enterobacteriaceae*. No specific selective medium has been reported for *Buttiauxella* species. Because of the relatively low clinical significance and the presence of *Buttiauxella* in various habitats, the selective isolation of *Buttiauxella* is rarely required. In most cases, organisms belonging to the genus *Buttiauxella* are isolated with differential media not inhibitory for *Enterobacteriaceae*, such as MacConkey agar, bromothymol blue lactose agar, or phenol red lactose agar. *Buttiauxella* strains grow readily on ordinary nutrient-rich media, and no growth requirements have been described.

Maintenance Procedures

Buttiauxella strains can be maintained in tryptone soy agar stabs or on nutrient agar when kept at room temperature in the dark. They can be preserved by storage in broth containing 10% glycerol or in calf or bovine serum at −80°C. Lyophilization seems to be the best procedure for preservation.

Differentiation of the genus *Buttiauxella* from other genera

No single distinguishing feature is useful for the differentiation of *Buttiauxella* from the other genera of *Enterobacteriaceae* (Table BXII.γ.193 in *Enterobacteriaceae*). Biochemically and based on DNA–DNA hybridization data, *Buttiauxella* are most similar to the genus *Kluyvera*. (Gavini et al., 1983a; Farmer et al., 1985a; Müller et al., 1996); however, the levels of DNA similarity between members of the genera *Buttiauxella* and *Kluyvera* and more than 50 other species belonging to the family *Enterobacteriaceae* were between 15% and 36% (Gavini et al., 1983a; Müller et al., 1996), indicating the separate position of these two genera. In addition, the mol% G + C ratios of *Buttiauxella* and *Kluyvera* are quite different, with values ranging from 47–51% for *Buttiauxella* and 54–58% for *Kluyvera* (Ferragut et al., 1981; Gavini et al., 1983a). *Buttiauxella* and *Kluyvera* exhibit similar fatty acid patterns, but all strains of *K. ascorbata*, *K. cryocrescens*, and *K. georgiana* produced the summed feature $C_{18:1\ \omega7c}$, $C_{18:1\ \omega9c}$, and/or $C_{18:1\ \omega12t}$ in higher amounts (>20% of all fatty acids) than any strain of *Buttiauxella* (Kämpfer et al., 1997). Although *K. georgiana* produced this feature also in amounts >20%, this species can be separated from all *Buttiauxella* species by its high amounts of 15:0 (>8%), which is not found in *Buttiauxella* (Kämpfer et al., 1997). Further physiological and biochemical characters that are helpful for differentiation of the two genera are given in Table BXII.γ.211.

Taxonomic Comments

Based on a numerical taxonomic study of *Enterobacteriaceae*, Gavini et al. (1976b) defined a new group of strains within the family and gave it the vernacular name "group F". Originally these 17 strains isolated from water and unpolluted soils were regarded to be similar to the genus *Citrobacter* because of their negative indole and Voges–Proskauer reactions and their positive citrate and methyl red tests. Subsequently, Ferragut et al. (1981) used DNA–DNA hybridization to compare strains of group F to each other and to named species of *Enterobacteriaceae*. Based on DNA similarity of 82–96% within group F and its low level of DNA similarity to other *Enterobacteriaceae*, they proposed the new genus *Buttiauxella* with one species *Buttiauxella agrestis*. The names *Buttiauxella* and *B. agrestis* were effectively published, but were not validated in the *International Journal of Systematic Bacteriology* before January 1, 1980. They did not appear on the Approved Lists of Bacterial Names (Skerman et al., 1980), but both names have now been validly published (Ferragut et al., 1982) and have standing in nomenclature. Four additional "group F" strains were only 62–66% related to *B. agrestis*. Based on phenotypic differences, three of these strains were placed in a group that was given the name Enteric Group 63, and the remaining strain was designated as Enteric Group 64 (Farmer et al., 1985a). In 1981, another group of strains, phenotypically similar to *Pantoea agglomerans* (formerly *Enterobacter agglomerans*), except for a positive arginine dihydrolase reaction, was reported and named Enteric Group 59 (Farmer et al., 1985a). Eight isolates, originating from sputum (6), a foot wound (1), and ham (1), were studied.

Between 1984 and 1988, Müller et al. (1995a, b, 1996)

[b]Symbols: +, positive for 90–100% of strains; [+], positive for 75–89% of strains; d, positive for 25–74% of strains; [−], positive for 11–24% of strains; − positive for 0–10% of strains.

[c]Except for *K. cochleae*.

screened the intestinal contents of snails and slugs for the presence of *Enterobacteriaceae* and, in addition to *Rahnella* isolates and the infrequently seen species *Ewingella americana* and *Serratia fonticola*, found many strains belonging to the genera *Buttiauxella* and *Kluyvera*.

Two hundred and nineteen strains belonging to the genera *Buttiauxella* and *Kluyvera* were subjected to an extensive DNA similarity study. The results indicated that the strains belonging to the genus *Buttiauxella* comprised seven closely related hybridization groups. One of these (hybridization group 1) corresponded to *B. agrestis*. Hybridization groups 2 through 7 were described as the new species: *B. ferragutiae* (formerly Enteric Group 63), *B. gaviniae* (formerly Enteric Group 64), *B. brennerae*, *B. izardii*, *B. noackiae* (formerly Enteric Group 59), and *B. warmboldiae* (Müller et al., 1996). The levels of similarity obtained for members of the seven species were generally between 45% and 65%, a good indication that all of these groups belong to a single genus. The hybridization groups that exhibited the highest levels of intergeneric similarity were hybridization groups 1 (*B. agrestis*) and 5 (*B. izardii*) and hybridization groups 3 (*B. gaviniae*) and 6 (*B. noackiae*). The relative binding ratios obtained from DNA–DNA hybridization studies between the *Buttiauxella* species are given in Table BXII.γ.212. The levels of DNA similarity between members of the *Buttiauxella* and *Kluyvera* species were generally between 15% and 30% (Müller et al., 1996).

Acknowledgments

I thank Don J. Brenner for his helpful comments and critical reading of this chapter, Hans E. Müller for interesting discussions and for furnishing strains, and W. Ludwig for critical comments and his experience in 16S rDNA sequence analyses.

List of species of the genus Buttiauxella

1. **Buttiauxella agrestis** Ferragut, Izard, Gavini, Lefebvre and Leclerc 1982, 266[VP], emend. Müller, Brenner, Fanning, Grimont and Kämpfer 1996, 60 (Effective publication: Ferragut, Izard, Gavini, Lefebvre and Leclerc 1981, 40.)
a.gres' tis. L. masc. n. *ager, agri*; adj. *agrestis* living in the fields, so named because all original strains were isolated from unpolluted soils and water.

B. agrestis was called DNA hybridization group 1 in the study of Müller et al. (1996). All 30 strains studied by Müller et al. (1996) were ≥73% DNA-related in 60°C reactions (range 73–100%). In the original description (Ferragut et al., 1981), which was based on the 17 strains originally described by Gavini et al. (1976b), it was observed that 60% of *B. agrestis* strains were malonate positive. In the study of Müller et al. (1996), 96% of the strains were malonate positive. Biochemical tests that are useful for differentiating *B. agrestis* from other *Buttiauxella* species are given in Table BXII.γ.210. The arginine dihydrolase, fucose, glycerol, lactose, melibiose, ornithine decarboxylase, palatinose, and D-sorbitol tests are helpful. Clinical significance, if any, is unknown. Isolated from mollusks, as well as water, soil, and human materials.

The mol% G + C of the DNA is: 47–50 (T_m).
Type strain: ATCC 33320, CDC 1176-81, CUETM 77-167, DSM 4586.
GenBank accession number (16S rRNA): AJ233400.

2. **Buttiauxella brennerae** Müller, Brenner, Fanning, Grimont and Kämpfer 1996, 62[VP]
bren' ner.ae. M.L. fem. gen. n. *brennerae* of Brenner, in honor of Frances W. Hickman-Brenner, an American microbiologist, for her contributions to the study of many genera of the *Enterobacteriaceae*.

Biochemical characteristics are shown in Table BXII.γ.210. Tests that can be used to differentiate *B. brennerae* from other *Buttiauxella* species are the L-arabinose, arginine dihydrolase, fucose, *myo*-inositol, 5-ketogluconate, lysine decarboxylase, and malonate. Clinical significance, if any, is unknown. Isolated from mollusks.

The mol% G + C of the DNA is: ~50 (T_m).
Type strain: ATCC 51605, DSM 9396.
GenBank accession number (16S rRNA): AJ233401.

3. **Buttiauxella ferragutiae** Müller, Brenner, Fanning, Grimont and Kämpfer 1996, 60[VP]
fer' ra.gut.i.ae. M.L. fem. gen. n. *ferragutiae* of Ferragut, in honor of Carmen Ferragut, a French microbiologist, for

[b]Results are expressed as percentages, figures in parentheses indicate the range of similarity.

her contribution to the study of the genus *Buttiauxella*, previously called Enteric Group 63.

Biochemical characteristics are shown in Table BXII.γ.210. Positive lysine decarboxylase and D-sorbitol tests and negative ketogluconate and malonate tests can clearly differentiate this species from all other *Buttiauxella* species. Clinical significance, if any, is unknown.

Isolated from water and soil.

The mol% G + C of the DNA is: 48–50 (T_m).

Type strain: ATCC 51602, CDC 1180-81, CUETM 78-31, DSM 9390.

GenBank accession number (16S rRNA): AJ233402.

4. **Buttiauxella gaviniae** Müller, Brenner, Fanning, Grimont and Kämpfer 1996, 62[VP]
ga.vin'i.ae. M.L. fem. gen. n. *gaviniae* of Gavini, in honor of Françoise Gavini, a French microbiologist, for her contributions to the study of the genus *Buttiauxella*, previously called Enteric Group 64.

Biochemical characteristics are shown in Table BXII.γ.210. Positive arginine dihydrolase, 5-ketogluconate, and palatinose reactions and negative ornithine decarboxylase and raffinose reactions are useful in differentiating *B. gaviniae* from other *Buttiauxella* species. A combination of reaction results is necessary to differentiate this species from *Buttiauxella noackiae*. Clinical significance, if any, is unknown. All but one strain were isolated from mollusks.

The mol% G + C of the DNA is: ~51 (T_m).

Type strain: ATCC 51604, DSM 9393.

5. **Buttiauxella izardii** Müller, Brenner, Fanning, Grimont and Kämpfer 1996, 62[VP]
iz.ard'i.i. M.L. masc. gen. n. *izardii* of Izard, in honor of Daniel Izard, a French microbiologist, for his contribution to the study of the genus *Buttiauxella*.

Biochemical characteristics are shown in Table BXII.γ.210. No single biochemical characteristic differentiates *B. izardii* from *B. agrestis*, but a combination of several characteristics differentiates these taxa. Useful differential biochemical tests are the L-arabinose, citrate, fucose, *myo*-inositol, ornithine decarboxylase, and raffinose. Clinical significance, if any, is unknown. Isolated from mollusks.

The mol% G + C of the DNA is: ~50 (T_m).

Type strain: ATCC 51606, DSM 9397.

GenBank accession number (16S rRNA): AJ233404.

6. **Buttiauxella noackiae** Müller, Brenner, Fanning, Grimont and Kämpfer 1996, 62[VP]
no.ack'i.ae. M.L. fem. gen. n. *noackiae* of Noack, in honor of Katrin Noack, who phenotypically characterized the *Buttiauxella* strains, previously called Enteric Group 59.

Biochemical characteristics of 15 strains isolated from snails are shown in Table BXII.γ.210. These characteristics are almost identical to those described for Enteric Group 59; the only exception is the result of the lactose test. All snail isolates lack a yellow pigment and are lactose negative, but seven of the eight Enteric Group 59 strains isolated from humans and food were shown to be lactose positive (Farmer et al., 1985a). It is possible that there is a correlation between the ability to split and metabolize lactose and the ability to survive in humans. Tests that are useful in differentiating *B. noackiae* from other *Buttiauxella* species are the *N*-acetyl-L-glutamine, L-arginine dihydrolase, melibiose, and L-ornithine decarboxylase. A combination of several characteristics is necessary to differentiate *B. noackiae* from other *Buttiauxella* species.

Isolated from mollusks, human sputum, human wounds, and food. Clinical significance, if any, is unknown.

The mol% G + C of the DNA is: ~50 (T_m).

Type strain: ATCC 51607, DSM 9401.

GenBank accession number (16S rRNA): AJ233405.

7. **Buttiauxella warmboldiae** Müller, Brenner, Fanning, Grimont and Kämpfer 1996, 62[VP]
warm'bold.i.ae. M.L. fem. gen. *warmboldiae* of Warmbold, in honor of Sabine Warmbold, who isolated most strains of the new *Buttiauxella* species at the Staatliches Medizinaluntersuchungsamt Braunschweig.

Biochemical characteristics are shown in Table BXII.γ.210. *Myo*-inositol is utilized and acid is produced by freshly isolated strains for many months, in contrast to all other species belonging to the genus *Buttiauxella*. However, these characteristics are lost after some years of storage; therefore, they are not constitutive. Other biochemical tests that are useful in differentiating *B. warmboldiae* from other *Buttiauxella* species are the L-arabinose, arginine dihydrolase, citrate, fucose, KCN, malonate, maltitol, ornithine decarboxylase, and palatinose. This species is the species that is the most distant from all other *Buttiauxella* species and has the lowest level of DNA–DNA similarity to other *Buttiauxella* species. Clinical significance, if any, is unknown. Isolated from snails.

The mol% G + C of the DNA is: ~52 (T_m).

Type strain: ATCC 51608, DSM 9404.

GenBank accession number (16S rRNA): AJ233406.

Genus VIII. **Calymmatobacterium*** *Aragão and Vianna 1913, 221*[AL]

GEORGE H. BROWNELL

Ca.lym.ma.to.bac.te'ri.um. Gr. n. *calymma* mantle, sheath; Gr. dim. neut. n. *bakterion* a small rod; M.L. neut. n. *Calymmatobacterium* the sheathed rodlet.

Pleomorphic rods, 0.5–1.5 × 1.0–2.0 µm, with rounded ends. Occur singly or in clusters. **The cells exhibit single or bipolar condensation of chromatin. Capsules are present.** Gram negative. Nonmotile. The exudate from infected tissues, when stained by Wright's stain or by Giemsa stain, demonstrates **characteristic intracellular organisms in the cytoplasm of large mononuclear phagocytes** ("Donovan bodies"). Can be cultivated *in vivo* in the yolk sac of embryonated chicken eggs, peripheral blood mononuclear cells, and human epithelial (HEp-2) monolayers, or *in vitro* on special egg yolk-containing media; has not been reproducibly cultivated in bacteriologic media. Optimum growth temperature, 37°C. Pathogenic for humans, causing **Donovanosis (granuloma inguinale).**

**Editorial Note:* The type species of the genus *Calymmatobacterium* has been transferred to *Klebsiella* as *Klebsiella granulomatis* (Aragão and Vianna 1913) Carter, Bowden, Bastian, Myers, Sriprakash and Kemp 1999.

The mol% G + C of the DNA is: not known.

Type species: **Calymmatobacterium granulomatis** Aragão and Vianna 1913, 221.

Further descriptive information

In diseased tissue smears stained by Wright's method, *C. granulomatis* occurs within the cytoplasm of large mononuclear monocytes as blue to purple pleomorphic rods surrounded by pink capsules (Fig. BXII.γ.199). The organism may occasionally be observed free in extracellular spaces. The single or bipolar condensation of chromatin gives rise to characteristic "safety-pin" forms. The ultrastructure of the intracellular organisms has been described by Davis and Collins (1969), Dodson et al. (1973), Kuberski et al. (1980), Chandra et al. (1989), Chandra and Jain (1991), and Kharsany et al. (1997). Electron micrographs reveal encapsulated bacilliforms with characteristic Gram-negative cell walls. The presence of fimbriae-like structures have been reported by some investigators: Kuberski et al. (1980), Chandra et al. (1989), and Chandra and Jain (1991).

Calymmatobacterium granulomatis has been clinically proven to be the causal agent of granuloma inguinale (Dienst et al., 1938). The disease is often referred to as donovanosis because initial lesions have been diagnosed in skin areas other than the genital region. Most researchers support the contention that donovanosis is not necessarily a venereal disease but is an infection resulting from intimate contamination and poor hygiene. Infection

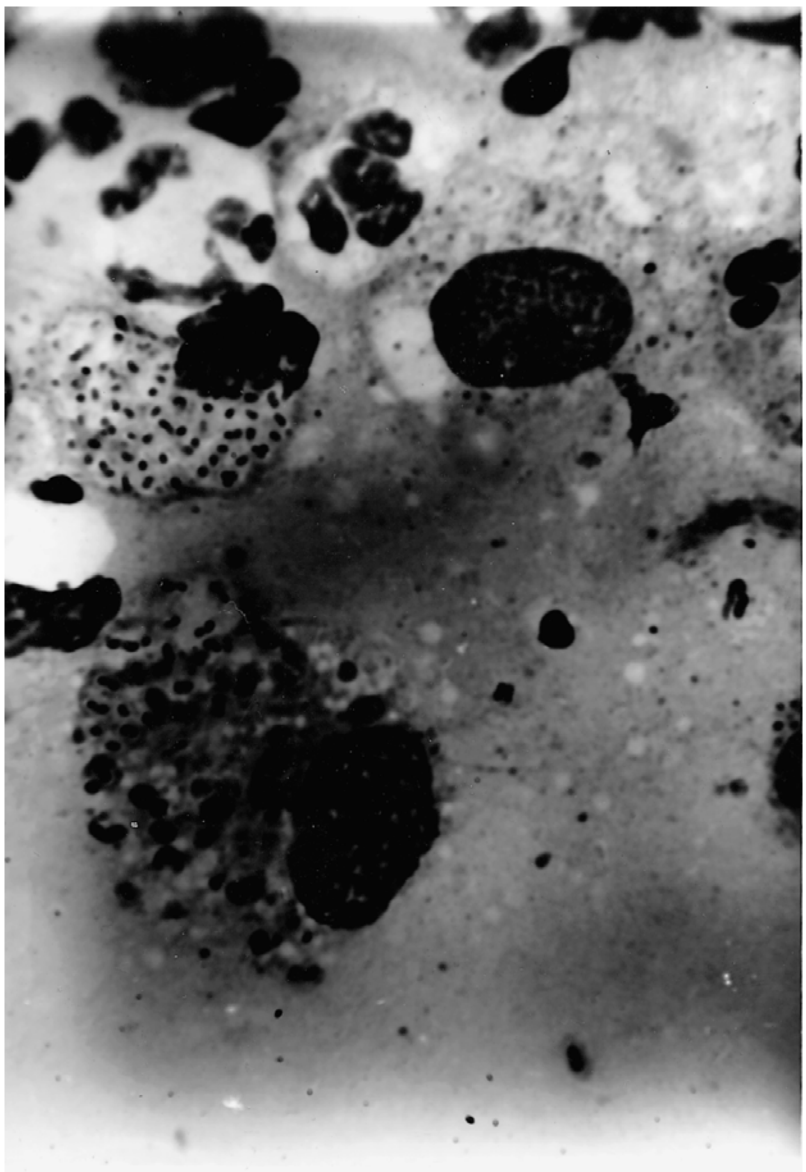

FIGURE BXII.γ.199. Large mononuclear phagocytes filled with *C. granulomatis*. Wright's stain ($\times$ 675). (Reproduced with permission from R.B. Dienst and G.H. Brownell in M.P. Starr et al. (Eds.) *The Prokaryotes: a Handbook on Habitats, Isolation and Identification of Bacteria*. p. 1410, 1981, ©Springer-Verlag, New York.)

is usually seen as a chronic, granulomatous, genital ulcerative disease. Donovanosis is an uncommon disease found in specific geographical regions including northern and central Australia, New Guinea, parts of central and south Africa, southeast India, the Caribbean, and parts of South America. The organism is pathogenic only for humans and infection cannot be produced in laboratory animals.

There are no protective antibodies produced by a patient infected with *C. granulomatis*. Once the infection occurs, the disease persists chronically and may spread through the lymphatics to all tissue unless treated with antibiotics. The patient does produce specific sensitizing antibodies as shown by skin testing (Chen et al., 1949). Antibodies can be detected in the serum of patients by complement-fixation procedures (Anderson et al., 1945b; Dulaney and Packer, 1947; Goldberg et al., 1953). The test antigens used in these techniques have included pus from granulomatous lesions, whole or ruptured *C. granulomatis*, or boiled or extracted egg yolk medium following growth of the organism. Immunological studies first noted a relationship between strains of *C. granulomatis* and *Klebsiella pneumoniae* (Packer and Goldberg, 1950). An indirect immunofluorescence test for granuloma inguinale was reported by Freinkel et al. (1992). The antigen consisted of paraffin-embedded tissue sections from lesions containing Donovan bodies. Unabsorbed sera at dilutions of 1:160 were reported to be 100% sensitive and 98% specific. After absorption with *K. pneumoniae* antigen, sera from proven granuloma inguinale patients remained reactive but at lower titers. Antigens obtained from newly reported culture methods well undoubtedly lead to more effective serological tests. (Carter et al., 1997; Kharsany et al., 1997).

Enrichment and Isolation Procedures

At present, the only sources for *C. granulomatis* are the lesions of donovanosis, although new culture methods may soon provide reference strains. An organism was reportedly isolated from human feces (Goldberg, 1962) that had antigenic similarities to *C. granulomatis*. Early reports of the cultivation of *C. granulomatis* in cell-free media include the yolk of embryonated eggs (Anderson, 1944), fresh yolk medium (Dienst et al., 1948), Locke-yolk Dulaney slants (Dulaney et al., 1948), and egg yolk replaced by lactalbumin hydrolysate (Goldberg, 1959). Reports of the successful culturing of *C. granulomatis* in peripheral blood mononuclear cells (Kharsany et al., 1997) or, more conveniently, human epithelial (HEp-2) cells (Carter et al., 1997), should provide the materials that can provide fundamental information about this species that to date is unknown.

The following procedure is given by Morse (1980). The ulcerative lesions are cleansed with sterile, saline-soaked gauze before obtaining samples, in order to decrease contamination and remove tissue debris. Samples of tissue are removed by scraping or by means of a biopsy punch from beneath the border of the lesion, and small cleansed pieces of tissue are minced into small particles. Inoculation is made into the yolk sacs of 5-day-old embryonated eggs. After incubation for 72 h, the organisms can be detected in the yolk sac fluid.

C. granulomatis can also be isolated and grown *in vitro*. For example, a pure culture was isolated by Dienst et al. (1948) by inoculating fresh egg medium exudate aspirated from a pseudobubo of a patient. This isolate was reported to be subcultured and maintained in the same culture medium, and examination of the subcultures revealed large numbers of encapsulated organisms consistent with the morphology of *C. granulomatis*. Dienst et al. (1948) indicated that several factors were important for isolation and cultivation: (a) maintenance of a low oxidation-reduction potential, (b) the requirement for a growth factor found in egg yolk, and (c) use of semisolid media containing 0.12% agar.

Dulaney slants have also been used for isolation and cultivation of *C. granulomatis* (Dulaney et al., 1948). After inoculation of lesion material onto a Dulaney slant, Locke's fluid is added to cover three-quarters of the slant, and the tubes are then incubated in a vertical position for 48–72 h (Morse, 1980). A semisynthetic medium has been devised by Goldberg (1959) for cultivation of laboratory strains of *C. granulomatis*. In this medium, the requirement for egg yolk is replaced by lactalbumin hydrolysate or by papaic digest of soy meal USP.

Recent efforts to culture *C. granulomatis* from biopsy material using these cell-free growth media suggest that they are unreliable. The recommended procedure is therefore the use of fresh monocytes (Kharsany et al., 1996, 1997) or the technically less demanding HEp-2 cell line. The latter employs standard *Chlamydia* culturing procedure (Carter et al., 1997).

Because diagnosis is still based on the observations of *C. granulomatis* in stained biopsy specimens and because of unreliable culture methods, this organism is a prime candidate for PCR primer targeting identification. Using PCR primers designed to target the *pho*E gene encoding for porin protein among klebsiellae and other enterobacteria, Bastian and Bowden (1996) reported amplification of *pho*E gene fragments from biopsy material showing Donovan bodies. The amplified sequences showed close correlation to those from *K. pneumoniae*, *K. rhinoscleromatis*, and *K. ozaenae*, and considerable divergence from corresponding sequences of other enterobacteria analyzed. Using the *pho*E gene primers in combination with primers for *Klebsiella scr*A (sucrose transport gene), reportedly absent in *C. granulomatis*, Carter et al. (1997) obtained *pho*E-positive and *scr*A-negative amplification from original clinical swab material as well as HEp-2 cell cultured isolates. Specific *C. granulomatis* primers have not yet been reported.

Differentiation of the genus *Calymmatobacterium* from other genera

As of this printing, the examination of diseased tissue smears stained by Wright's blood stain or Giemsa stain remains the simplest procedure for identification for *C. granulomatis*. The characteristic appearance of the intracellular organisms (Fig. BXII.γ.199) is specific for the diagnosis of donovanosis. Species-specific PCR primers as well as immunofluorescence tests should soon be available.

Taxonomic Comments

The coccobacillary microorganisms first observed by Donovan (1905) were frequently referred to as "Donovan bodies" when seen in tissue smears from patients with granulomatis lesions in the inguinal region. The Donovan bodies were later called *Calymmatobacterium granulomatis* by Aragão and Vianna (1913). When Anderson et al. (1945a) first isolated the organisms by yolk sac inoculation, they termed the etiologic agent of granuloma inguinale *"Donovania granulomatis"*; however, the name *"Donovania"* did not have priority over *Calymmatobacterium*.

In the first edition of *Bergey's Manual of Systematic Bacteriology*, the genus was not assigned to any family. It has been suggested that it should be placed in the family *Enterobacteriaceae* (Rake, 1948), and this relationship is supported (based on very limited

PCR-generated fragment analysis with "*Klebsiella*-like" sequences) by Bastian and Bowden (1996). Kharsany et al. (1997) observed no cross-reactivity with sera from patients showing Dovonan bodies and laboratory reference strains of *K. pneumoniae*, *K. oxytoca*, or *Enterobacter aerogenes*. Thus, the taxonomic relationships of *Calymmatobacterium* to other bacterial genera are not yet understood, and in the present edition of the *Manual* it seems desirable not to ally the genus with any established family, although it must be noted that the type strain was recently transferred to the genus *Klebsiella* as *Klebsiella granulomatis* (Carter et al., 1999).

List of species of the genus Calymmatobacterium

1. **Calymmatobacterium granulomatis** Aragão and Vianna 1913, 221[AL]
gran.u.lo' ma.tis. L. dim. n. *granulum* a small grain; Gr. suff. *-oma* a swelling or tumor; M.L. n. *granuloma* a granuloma; M.L. gen. n. *granulomatis* of a granuloma.

The characteristics are as described for the genus and as depicted in Fig. BXII.γ.199.

The mol% G + C of the DNA is: not known.

Type strain: no strain extant.

Genus IX. **Cedecea** *Grimont, Grimont, Farmer and Asbury 1981a, 325*[VP] *(Enteric Group 15 Farmer, Grimont, Grimont and Asbury 1980b, 295)*

J.J. Farmer III

Ce.de' ce.a. M.L. fem. n. *Cedecea* formed from the abbreviation CDC. The named was coined by P.A.D. Grimont and F. Grimont for the Centers for Disease Control, Atlanta, Georgia, where the organisms were originally recognized as a new group and named Enteric Group 15.

Rod-shaped cells 0.6–0.7 × 1.3–1.9 µm, conforming to the general definition of the family *Enterobacteriaceae*. Gram negative. Motile, with five to nine peritrichous flagella. Grow at 15°, 20°, and 37°C. Facultatively anaerobic. **Catalase positive, strong and rapid.** Oxidase negative. Nonpigmented. Reduce nitrate to nitrite.

Positive for methyl red, Voges–Proskauer, citrate utilization (Simmons), motility at 36°C, growth in the presence of cyanide (KCN test), malonate utilization, D-glucose fermentation, and the fermentation of D-mannitol, salicin, maltose, trehalose, cellobiose, melibiose, D-arabitol, D-mannose, and D-galactose. Many strains produce visible gas during fermentation. Lipase (corn oil, Tween 40, Tween 60, Tween 80, and tributyrin) is positive, but gelatin hydrolysis, DNase, chitinase, polygalacturonase, and amylase are negative. Utilize 24 of 97 carbon sources.

Negative for indole production, H_2S production (TSI), urea hydrolysis, phenylalanine deaminase, lysine decarboxylase and the fermentation of dulcitol, adonitol, *myo*-inositol, D-sorbitol, L-arabinose, L-rhamnose, α-methyl-D-glucoside, erythritol, melibiose, glycerol, and mucate.

Susceptible to nalidixic acid, sulfadiazine, trimethoprim, gentamicin, streptomycin, kanamycin, tobramycin, amikacin, tetracycline, minocycline, chloramphenicol, carbenicillin, and furantoin (disk diffusion method on Mueller-Hinton agar); **resistant to colistin, polymyxin, penicillin, ampicillin, and cephalothin**.

Isolated from human clinical specimens that are normally sterile such as blood, urine, gallbladder, and lung tissue; also isolated from other clinical specimens such as throat, sputum, ulcers, and wounds. **An opportunistic pathogen that occasionally causes extraintestinal human infections**, or colonizes body surfaces. Isolated from water, ticks, and insects. A **rarely isolated genus of a *Enterobacteriaceae*.** No 16S rRNA sequences of *Cedecea* strains have been reported.

The mol% G + C of the DNA is: 48–52.

Type species: **Cedecea davisae** Grimont, Grimont, Farmer and Asbury 1981a, 325.

Further descriptive information

Literature Since the genus was described in 1981 there have been a few reports in the literature; 11 reports cataloged in MEDLINE and 27 cataloged in BIOSIS. These have described the genus in human clinical specimens and infections, its isolation from natural sources, and its basic physiology-metabolism.

Infections in humans Most of the original isolates of *Cedecea* in the CDC collection were from human respiratory tract specimens, so it was difficult to assess clinical significance (Farmer et al., 1980b). However, a few isolates were from body sites that are normally sterile. Since the original description in 1981, there have been several case reports that suggest clinical significance. The first case of bacteremia due to a strain of *Cedecea* was caused by *Cedecea neteri* (Farmer et al., 1982) and led to the naming of this organism, which was previously without a scientific name ("*Cedecea* species 4"). Other cases of bacteremia have now been described (Perkins, et al., 1986; Aguilera et al., 1995). Several other cases have been described in which a *Cedecea* strain was isolated from a body site that is normally sterile, or thought to be clinically significant (Bae et al., 1975; Hansen and Glupczynski, 1984; Coudron and Markowitz, 1987; Anon et al., 1993). Infections due to *Cedecea* have usually been in elderly hospital patients with debilitating conditions such as heart disease, diabetes, alcoholism, and renal insufficiency. A few isolates have been from human feces, but there is no evidence that any *Cedecea* species causes diarrhea or intestinal infections.

Possible origin of the *Cedecea* strains in human clinical specimens Originally there was little information on this point. Strains of *Cedecea* have now been isolated from well water, ticks, and insects (Jang and Nishijimi, 1990; Kaaya and Okech, 1990; Pellegrini et al., 1992), which may be natural reservoirs and lead to exposure of humans. Berkowitz and Metchock (1995) described bacteria in the feces of hospitalized children that are resistant to third-generation cephalosporins. Antibiotic usage is common in hospitals and selects for strains that have intrinsic or acquired resistance. Since *Cedecea* strains have high intrinsic resistance to penicillin, ampicillin, and the cephalosporin antibiotic cephalothin, they probably have a selective advantage in the feces of hospitalized patients. The reduction of the normal host flora by antibiotic usage could favor the growth and selection

of *Cedecea* strains, which might then colonize certain body sites, and under the right conditions cause infection.

Additional studies and more case reports are needed to better define the pathogenic potential of the five species in the genus. The clinical significance of a *Cedecea* is probably as an infrequent colonizer or infrequent opportunistic pathogen, particularly in older people who are debilitated. More information is needed on ecology, epidemiology, and how humans are exposed to and acquire the organism.

Bacteriology Strains of *Cedecea* grow well on media normally used in enteric bacteriology. Colonies on nutrient agar are about 1.5 mm (24 h, 37°C). They are typical *Enterobacteriaceae* in most of their properties. See the chapter on the family *Enterobacteriaceae* for general information on growth, plating media, working and frozen stock cultures, media, and methods for biochemical testing, identification, and antibiotic susceptibility. Also see Table BXII.γ.193 in the chapter on the family *Enterobacteriaceae*, which gives the percentage positive for the five *Cedecea* species on 47 biochemical tests done at the Enteric Reference Laboratories at the Centers for Disease Control (CDC) with standard media and methods (Farmer, 1995). These tests and computer analysis have proved useful for identification and for differentiating strains of *Cedecea* from other species in the family. Table BXII.γ.213 lists phenotypic tests that are useful for differentiating and identifying the five species of *Cedecea*. Additional descriptive material, including the results for 97 carbon source utilization tests, can be found in the original description of the genus (Grimont et al., 1981a). Chester and Moskowitz (1987) found that *Cedecea* strains produce catalase, and that the catalase reaction was very strong and rapid and could be useful as a screening test.

Taxonomic Comments

History and discovery *Cedecea* was proposed as a new genus in *Enterobacteriaceae* in 1980 (Farmer et al., 1980b; Grimont et al., 1981a). In 1977 it was first recognized and named "Enteric Group 15" as a diagnostic culture was being studied at the CDC. The laboratory's STRAIN MATCHER computer program indicated a group of over a dozen other cultures that were very similar to the diagnostic culture, and all had been reported "unidentified". The strains were lipase-positive (corn oil) and resistant to the antibiotics colistin and cephalothin. Among *Enterobacteriaceae*, these properties are unique to the genus *Serratia*, but the new group differed from *Serratia* because it was negative for DNase and gelatin hydrolysis. Originally, Enteric Group 15 was thought to be a uniform group of strains that would probably be a new species of *Serratia*, intermediate between the "typical" *Serratia* (DNase positive, lipase positive, gelatinase positive) and *Serratia fonticola*, which is negative for all three of these tests (Farmer et al., 1980b). Strains of Enteric Group 15 were sent to the Grimonts in France (Farmer et al., 1980b; Grimont et al., 1981a), who used phenotypic characterization and DNA–DNA hybridization (SI nuclease method) to characterize them. Fifteen strains of Enteric Group 15 were more closely related (Fig. BXII.γ.200) to each other (32–100%) than to strains of the six named *Serratia* species (6–10%) or to other *Enterobacteriaceae* (1–23%). Originally, Enteric Group 15 was defined as a single group of 17 strains, but further study indicated five different DNA hybridization groups (Fig. BXII.γ.200) that were also phenotypically distinct (Table BXII.γ.213). In the original paper proposing the genus *Cedecea*, the two largest hybridization groups were named *C. davisae* and *C. lapagei*. The name *Cedecea neteri* was later given to DNA hybridization group 4 (Farmer et al., 1982). The original vernacular names "*Cedecea* species 3" and "*Cedecea* species 5" are still being used for the two other DNA hybridization groups until more strains are available, or there is a compelling reason to name them (see Other Organisms, below).

List of species of the genus Cedecea

1. **Cedecea davisae** Grimont, Grimont, Farmer and Asbury 1981a, 325[VP]
da' vi.sae. M.L. gen. n. *davisae* named to honor Betty Davis, the American bacteriologist of the Enteric Bacteriology Laboratories, Centers for Disease Control and Prevention, Atlanta, Georgia, who made many contributions to the biochemical and serological identification of *Enterobacteriaceae* and *Vibrionaceae*.

TABLE BXII.γ.213. Differentiation of the three named and two unnamed *Cedecea* species

Test or property	*Cedecea davisae*	*Cedecea lapagei*	*Cedecea neteri*	*Cedecea* species 3	*Cedecea* species 5
Ornithine decarboxylase	95[a]	0	0	0	50
Sucrose fermentation	100	0	100	50	100
D-Sorbitol fermentation	0	0	100	0	100
Raffinose fermentation	10	0	0	100	100
D-Xylose fermentation	100	0	100	100	100
Melibiose fermentation	0	0	0	100	100
Malonate utilization	91	100	100	0	0
Thiamin required for growth[b]	100	0	0	0	0
Growth at 5°C[b]	100	0	0	0	0

[a]For the first seven tests each number gives the percentage positive after 2 d incubation at 36°C and is based on the data summarized by Farmer (1999). The vast majority of these positive reactions occur within 24 h. Reactions that become positive after 2 d are not considered.

[b]The results for thiamin requirement and growth at 5°C are from Grimont et al. (1981a).

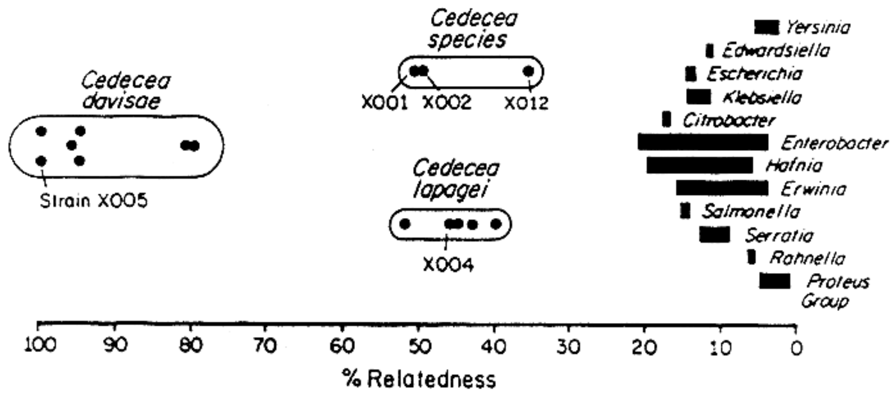

FIGURE BXII.γ.200. Relatedness by DNA–DNA hybridization of the *Cedecea davisae* type stain (X005) to 14 other *Cedecea* strains and to other genera of *Enterobacteriaceae*. Strain X004 is the type strain of *Cedecea lapagei*; X002 is the type strain of *Cedecea neteri*; X001 is the reference strain of "*Cedecea* species 3"; and X012 is the reference strain of "*Cedecea* species 5". (Redrawn with permission from J.J. Farmer III, P.A.D. Grimont, F. Grimont, and M.A. Asbury.)

The characteristics are as given for the genus. All strains require thiamin (0.01 μg/ml) for growth in minimal media and one strain also requires *p*-aminobenzoic acid (Grimont et al., 1981a). Most strains grow at 5°C, unlike the other *Cedecea* species. See Table BXII.γ.193 in the chapter on the family *Enterobacteriaceae* for a more complete phenotypic description based on the results of 47 biochemical tests. One strain produces a strong distinct aroma, the "odor of *Serratia odorifera*", which is apparently due to the pyrazine compound 3-sec-butyl-2-methoxypyrazine (Gallois and Grimont, 1985).

Isolated from human clinical specimens including blood, gallbladder, eye, urine, sputum, throat, wound, feces; probably a rare opportunistic pathogen or colonizer. Perkins et al. (1986) described a case of bacteremia in a 70-year-old woman with a history of heart disease and a diagnosis of bronchitis and chronic obstructive pulmonary disease. Other case reports have described pneumonia in an elderly diabetic with a heart condition (Bae et al., 1975) and a scrotal abscess in a patient with alcoholic liver disease (Bae and Sureka, 1983). Isolated from the cockroaches *Blatta germania* and *Blatta orientalis* (Pellegrini et al., 1992). The 16S rRNA sequence has not been determined.

The mol% G + C of the DNA is: 49–50 (T_m).

Type strain: ATCC 33431, CDC 3278-77, CIP 80.34.

Additional Remarks: The American Type Culture Collection includes four other human strains; two from sputum and one each from gallbladder and wound.

2. **Cedecea lapagei** Grimont, Grimont, Farmer and Asbury 1981a, 325[VP]
la.pa' ge.i. M.L. gen. n. *lapagei* named to honor the late Stephen Lapage, a British bacteriologist who made many contributions to the *Enterobacteriaceae*, bacterial systematics, and particularly as an editor of the Bacteriological Code.

The characteristics are as given for the genus. See Table BXII.γ.193 in the chapter on the family *Enterobacteriaceae* for a more complete phenotypic description based on the results of 47 biochemical tests. All five strains of *C. lapagei* are highly related by DNA–DNA hybridization, but strain 1554-75 had higher divergence values and differed from the other strains in phenotype (Grimont et al., 1981a).

Isolated from human respiratory tract (throat and sputum) and from ticks. Coudron and Markowitz (1987) described an isolate from lung tissue in a case report, but concluded that its etiological role was not proven. Appears to be a tick pathogen. Brun and Texeira (1992a, b) described genital tract infections of the tick species *Boophilus microplus* that resulted in "engorged females". The 16S rRNA sequence has not been determined.

The mol% G + C of the DNA is: 48–52 (T_m).

Type strain: ATCC 33432, CDC 0485-76, CIP 80.35.

Additional Remarks: The American Type Culture Collection includes four other strains, all from human sputum.

3. **Cedecea neteri** Farmer, Sheth, Hudzinski, Rose and Asbury 1983, 438[VP] (Effective publication: Farmer, Sheth, Hudzinski, Rose and Asbury 1982, 777.)
ne' te.ri. M.L. gen. n. *neteri* named to honor Erwin Neter, an American physician and microbiologist who made many contributions to our knowledge of the family *Enterobacteriaceae*, particularly the role of this family in human disease.

The characteristics are as given for the genus. Also see Table BXII.γ.193 in the chapter on the family *Enterobacteriaceae* for a more complete phenotypic description based on the results of 47 biochemical tests.

Isolated from human blood, sputum, and wound. Farmer et al. (1982) described a case of bacteremia with possible endocarditis in a 62-year-old man with vascular heart disease and recurrent fever and chills of 4 d duration. Anon et al. (1993) described a case of peritonitis after vigorous abdominal surgery in which *Cedecea neteri* was isolated along with *Escherichia vulneris*. Aguilera et al. (1995) described a case of bacteremia in a patient with systemic lupus erythematosus.

The mol% G + C of the DNA is: not reported.

Type strain: ATCC 33855, CDC 0621-75.

Additional Remarks: The American Type Culture Collection includes two other strains, one from human blood (the case report of Farmer et al., 1982) and one from sputum.

Other Organisms

1. "Cedecea species 3"

   The CDC collection has three strains of this organism, from blood, gallbladder, and sputum.

   The mol% G + C of the DNA is: not reported.

   Deposited strain: X001, CDC 4853-73.

2. "Cedecea species 5"

   The CDC collection has only one strain of this organism, from a human toe.

   The mol% G + C of the DNA is: not reported.

   Deposited strain: X012, CDC 3699-73.

The CDC collection has at least 11 other cultures from a variety of human clinical specimens that were reported "*Cedecea* species" because they had high computer identification scores as "genus *Cedecea*" and had characteristics typical for the genus. However, the phenotypic properties of these strains differed from the five *Cedecea* species described above. The data on the two unnamed *Cedecea* species and these 11 "*Cedecea* species" clearly indicate that there are additional species of *Cedecea*. Future studies are needed to better define this collection. There have been two case reports describing *Cedecea* strains that are phenotypically different from the five named species. Hansen and Glupczynski (1984) described a *Cedecea* isolate from a cutaneous ulcer with a purulent discharge in a 79-year-old diabetic with arthritis of both lower limbs. Cultures were positive on days 2, 5, and 43. The isolate was most like *Cedecea davisae* except that it was positive for acetate utilization and D-sorbitol fermentation. The isolate was lost before it could be confirmed by a reference laboratory. Magnum and Radisch (1982) described a *Cedecea* isolate from the postmortem heart blood of a 76-year-old alcoholic man with decubiti, anemia, metabolic acidosis, renal insufficiency, and urinary incontinence. This strain was most like *Cedecea* species 3 except it was Voges–Proskauer positive, fermented sucrose, and grew on acetate agar.

Two additional *Cedecea* species have been described, but they were given the vernacular names of "*Cedecea* species 3" and "*Cedecea* species 5" rather than scientific names (Farmer et al., 1980b; Grimont et al., 1981a). Thus, the two organisms do not have standing in nomenclature, but appear to be unnamed species of *Cedecea* based on DNA–DNA hybridization and phenotypic differences (Table BXII.γ.213). See Table BXII.γ.193 in the chapter on the family *Enterobacteriaceae* for a more complete phenotypic description of this organism based on the results of 47 biochemical tests.

Genus X. **Citrobacter** *Werkman and Gillen 1932, 173*[AL]

WILHELM FREDERIKSEN

Cit.ro.bac′ter. L. n. *citrus* lemon; M.L. n. *bacter* a small rod; M.L. masc. n. *Citrobacter* a citrate-utilizing rod.

Straight rods, ~1.0 μm × 2.0–6.0 μm. Occur singly and in pairs. Conform to the general definition of the family *Enterobacteriaceae*. Usually not encapsulated. Gram negative. Usually **motile by peritrichous flagella**. Facultatively anaerobic, having both a respiratory and a fermentative type of metabolism. Grow readily on ordinary media. Colonies on nutrient agar are generally 2–4 mm in diameter, smooth, low convex, moist, translucent or opaque, and gray with a shiny surface and entire edge. Mucoid or rough forms may occur occasionally. Oxidase negative. Catalase positive. Chemoorganotrophic. **Citrate can be utilized as a sole carbon source by most strains. Lysine is not decarboxylated.** Alginate and pectate are not decomposed. D-glucose is fermented with the production of acid and gas. The methyl red test is positive; the Voges–Proskauer test is negative. Occur in the feces of humans and some animals; probably normal intestinal inhabitants. Sometimes pathogenic and often isolated from clinical specimens as opportunistic pathogens. Can also be found in soil, water, sewage, and food.

The mol% G + C of the DNA is: 50–52 (T_m).

Type species: **Citrobacter freundii** (Braak 1928) Werkman and Gillen 1932, 173 (*Bacterium freundii* Braak 1928, 140.)

FURTHER DESCRIPTIVE INFORMATION

Members of *Citrobacter* may or may not ferment lactose promptly but nearly always produce β-galactosidase. L-arabinose, maltose, L-rhamnose, trehalose, D-xylose, D-mannitol, and D-sorbitol are fermented rapidly by the majority of strains. Erythritol and *myo*-inositol are rarely attacked.

Ornithine is decarboxylated by almost all strains of *C. koseri*, *C. amalonaticus*, *C. farmeri*, *C. braakii*, *C. sedlakii*, and *C. rodentium*, but not by *C. freundii*, *C. youngae*, and *C. werkmanii*. *C. koseri* and *C. rodentium* do not grow in media containing potassium cyanide (KCN) in contrast to the other species.

Strains of *C. koseri* ferment D-adonitol and D-arabitol, but strains of the other species do not. Malonate is utilized as a sole carbon source by most strains of *C. koseri*, *C. werkmanii*, *C. sedlakii*, and *C. rodentium*, but can be used by less than 15% of the strains of the other species.

The majority of strains of *C. freundii*, *C. youngae*, *C. braakii*, and *C. werkmanii* produce abundant H_2S in the butt of Kligler iron agar and triple-sugar iron agar.

Indole is produced by *C. koseri*, *C. amalonaticus*, *C. farmeri*, and *C. sedlakii* with few exceptions, but few strains of the other species give a positive indole test.

Based on 16S rRNA gene sequence, the genus *Citrobacter* clusters in the family *Enterobacteriaceae* within the *Gammaproteobacteria*. Its nearest relatives are members of the genera *Salmonella* and *Pantoea*.

DNA–DNA hybridization experiments (Brenner et al., 1993) using the hydroxyapatite method showed intraspecific relatedness almost always above 70%, with 5% or less divergence within related sequences, and interspecific relatedness from ~30% to ~70%. *C. farmeri* was closely related to *C. amalonaticus*; *C. youngae*, *C. braakii*, and *C. werkmanii* were related to each other and to *C. freundii* at the 50–70% level. The other interspecies relations were on a lower level (~30% to ~55%).

Some strains of *C. koseri* produce bacteriocins, and many can be induced to produce bacteriophages (Hamon et al., 1974; Markel et al., 1975).

The antigenic structure was developed around the so-called Bethesda-Ballerup group that was considered close to *Salmonella* (Kauffmann and Møller, 1940; West and Edwards, 1954). After its inclusion in *Citrobacter freundii*, the group formed the basis for the elucidation of the O- and H-antigen structure of this species, and its relation to other taxa, especially within the genus *Salmonella*; see Ewing (1986a) for a detailed description. The Vi antigen of *Salmonella* serovar Typhi (*S. typhi* or *S. enterica*, subsp. *enterica*, serovar Typhi) can be found in certain strains of *C. freundii*.

The antigenic structure of *C. koseri* was studied by several groups (Gross and Rowe, 1974, 1983; Popoff and Richard, 1975; Sourek and Aldová, 1976) resulting in three different O- and H-antigen serotyping systems. Sourek and Aldová (1976) also established an O-antigen scheme for *C. amalonaticus*, which they extended in 1988 (Sourek and Aldová, 1988). Van Oye et al. (1975) found that many strains of *C. amalonaticus* reacted in different *Shigella* sera.

Miki et al. (1996) reexamined the 90 reference strains listed in the scheme for *C. freundii* by West and Edwards (1954). They found that 40 of these strains belonged to *C. youngae* as defined by Brenner et al. (1993), 25 to *C. braakii*, 13 to *C. werkmanii*, and only three to the redefined *C. freundii*. Nine O-group-29 strains formerly allocated to the Ballerup group were all identified as *C. braakii*.

With modern typing systems there seems to be less place for serotyping of citrobacters for epidemiological purposes. Both multilocus enzyme electrophoresis (Woods et al., 1992), ribotyping (Papasian et al., 1996; El Harrif-Heraud et al., 1997), PCR methods (Woods et al., 1992; El Harrif-Heraud et al., 1997), and pulsed field gel electrophoresis (Papasian et al., 1996) have been applied, often to elucidate possible outbreaks of *C. koseri* meningitis/cerebral abscesses.

A 32-kDa outer membrane protein (OMP) was found to be a marker of virulence for *C. koseri* (Kline et al.,1988), and possibly a factor of virulence (Li et al., 1990).

Antibiotic sensitivity Strains of *Citrobacter* are naturally susceptible to sulfonamides, trimethoprim, aminoglycosides, chloramphenicol, tetracycline, nalidixic acid, fluoroquinolones, nitrofurantoin, polymyxins, and fosfomycin. Like other enterobacteria they are resistant to erythromycin and other macrolides, lincosamides, fusidic acid, and vancomycin. Resistance to one or more of the former group of antibiotics may be acquired, depending on circumstances, especially antibiotic usage policy in a broad sense.

Citrobacter strains are usually extremely susceptible to the fluoroquinolones. However, like many other enterobacteria they are prone to develop resistance, although this seems to occur rarely. The majority of strains are susceptible to the aminoglycosides, although less so to streptomycin than to newer aminoglycosides.

Almost all strains of *Citrobacter* produce a β-lactamase. *C. freundii* and *C. koseri* differ in the type of β-lactamase produced, *C. freundii* being resistant to cephalosporins and susceptible to carboxypenicillins, while *C. koseri* behave in the reverse way. Resistance to a broad range of newer β-lactam antibiotics may appear in both species; however, imipenem seems to remain active. See Frederiksen and Søgaard (1992) for a broader review of antibiotics and *Citrobacter*. El Harrif-Heraud et al. (1997) described a nosocomial outbreak where six identical strains of *C. koseri* produced an extended spectrum β-lactamase (ESBL), leaving susceptibility only to imipenem, latamoxef, and some combinations with clavulanic acid. The strains harbored a plasmid mediating a SHV-4 type lactamase.

Members of the genus *Citrobacter* occur not only in feces of humans and animals with no disorder but also in water, sewage, soil, and food. Isolates of *C. freundii* recovered from fish were compared with strains from various other sources by Toranzo et al. (1994), and a possible role as a fish pathogen discussed. Citrobacters are found in clinical bacteriology not only in stools but also in urine, sputum, and specimens from bacteremia, meningitis, otitis media, wounds, abscesses, the throat, and autopsies. Their role often seems to be that of an opportunistic pathogen. Cases of neonatal meningitis caused by *C. koseri* have been reported (Gwynn and George, 1973; Kline, 1988). Khashe and Janda (1996) found that an iron-scavenging mechanism such as induction of high molecular mass proteins (72–83 kDa) could be a virulence factor for *C. koseri*.

Although *C. freundii* was once considered an enteropathogen, it seems rather to be a normal inhabitant of the intestine (Sakazaki et al., 1960), but the role in diarrhea is dubious (Sedlák, 1973, Lipsky et al., 1980). In most instances the organism is probably a normal intestinal inhabitant, but some strains produce enterotoxins like many other enterobacteria, and may then act as intestinal pathogens (Guarino et al., 1987, 1989). Septicemia and other disseminated infections, e.g., osteomyelitis, occur with low frequency (Frederiksen and Søgaard, 1992).

C. rodentium has been found only in rodents; it was shown to be the cause of transmissible murine colonic hyperplasia, a disease of laboratory mice (Schauer and Falkow, 1993; Schauer et al., 1995).

Ecology As intestinal inhabitants of humans and animals, citrobacters are excreted into the environment and found in sewage, water, and soil. Apart from this, nothing is known about the ecological role of *Citrobacter* species in the environment.

Phylogenetic position On the basis of their 16S rDNA sequences, citrobacteria group within the *Gammaproteobacteria*, with *Escherichia*, *Erwinia*, *Salmonella*, and *Serratia* species as their nearest relatives.

Enrichment and Isolation Procedures

The majority of *Citrobacter* strains can grow in liquid enrichment media such as selenite broth and tetrathionate broth and on selective isolation media such as *Salmonella–Shigella* agar, deoxycholate–citrate agar, brilliant green agar, and bismuth sulfite agar. Colonies that ferment lactose slowly often resemble *Salmonella* colonies.

Maintenance Procedures

Stock cultures of *Citrobacter* strains may be maintained at room temperature in a semisolid medium containing 1.0% Bacto-casitone (Difco), 0.3% yeast extract, 0.5% NaCl, and 0.3% agar, pH 7.0. The cultures remain viable for up to a year without subculturing if they are sealed with a rubber stopper or a cork that has been soaked in hot paraffin wax. Strains may be preserved indefinitely by lyophilization. They can also be maintained for years as stab cultures in sealed tubes of meat extract agar.

Differentiation of the genus *Citrobacter* from other genera

The differentiation of *Salmonella* from lactose-negative *Citrobacter* proved difficult ever since the "Bethesda–Ballerup" group was recognized as belonging in the genus *Citrobacter*. The most useful tests to distinguish among these lactose-negative strains are lysine decarboxylase and growth in KCN medium. The greatest difficulties arise with the rare lactose/o-nitrophenyl-β-galactosidase (ONPG) positive *Salmonella* strains, the ONPG-negative *Citrobacter* strains (also rare), and, in addition, when H_2S positive *E. coli* are encountered. Table BXII.γ.214 gives some tests useful for differentiation and correct identification of such strains.

Taxonomic Comments

The genus *Citrobacter* was proposed by Werkman and Gillen (1932) for the citrate-utilizing "coli-aerogenes intermediates". The organisms were since described under several names, and *C. freundii* was called *"Escherichia freundii"* by Yale (1939a). The role of citrobacters as possible pathogens was first noticed by Kauffmann and Møller (1940), who described an organism called *"Salmonella ballerup"* that is presently classified in *C. freundii*. Later this biogroup of organisms was removed from the genus *Salmonella* and was called the Ballerup group (Bruner et al., 1949; Harhoff, 1949). Independently of the Ballerup group of organisms, Edwards et al. (1948) and Moran and Bruner (1949) studied a group of bacteria characterized by Barnes and Cherry (1946) and referred to it as the Bethesda group of bacteria. West and Edwards (1954) found that organisms of both the Bethesda and Ballerup groups were biochemically and serologically indistinguishable and combined the two groups into the Bethesda-Ballerup group. Moreover, West and Edwards (1954) and Møller (1954) called attention to the close biochemical relationship between members of the Bethesda-Ballerup group and strains of *"E. freundii"*. Accordingly, Kauffmann (1954) reclassified the Bethesda-Ballerup group into *"E. freundii"*, and later revived the genus *Citrobacter* for *"E. freundii"* (Kauffmann, 1956).

Frederiksen (1970) described a new species that he named *Citrobacter koseri*. Young et al. (1971) described a new genus, *Levinea*, which contained two species, *L. malonatica* and *L. amalonatica*. Ewing and Davis (1972a) published a paper on *Citrobacter diversus*, using the specific epithet "*diversum*" of Werkman and Gillen (1932) for a group of organisms that they considered to belong in *Citrobacter*. It became apparent that *C. koseri*, *L. malonatica*, and *C. diversus* were probably different names for the same species. DNA–DNA hybridization studies by Crosa et al. (1974) showed that *C. diversus* and *L. malonatica* belonged to one hybridization group and that this group and *C. freundii* and *L. amalonatica* were all related with binding ratios around 50–60%.

TABLE BXII.γ.214. The differentiation of H_2S positive *Citrobacter* from ONPG positive *Salmonella* and H_2S positive *Escherichia coli*[a]

Characteristic	*Citrobacter*	*Salmonella*	*E. coli*
Indole	d	–	+
Citrate	+	+	–
KCN (growth)	+	–	–
Lysine	–	+	+
Ornithine	d	+	d
Sucrose	d	–	d
Cellobiose	d	–	–
ONPG	+	+	+
H_2S (iron agar)	+	+	+

[a]For symbols, see standard definitions.

Thus, they all could be considered to belong in the genus *Citrobacter*, with no need for the genus *Levinea*.

Crosa et al. (1974) suggested moving *L. amalonatica* to *Citrobacter*, and Sakazaki et al. (1976), as a result of numerical taxonomy, suggested placing *L. amalonatica* in *Citrobacter* as a species separate from *C. freundii*. The name *C. amalonaticus* was formally proposed by Brenner and Farmer (1981, 1982). Macierevicz (1966) studied a group of organisms that were H_2S-negative and ornithine decarboxylase-positive and proposed the name "*Padlewskia*", without designating a specific epithet for the organisms of this genus. From the biochemical characteristics described it was probable that "*Padlewskia*" organisms and *C. amalonaticus* were identical. This was confirmed when strains from Macierevicz and from Young were compared by the author (unpublished observations).

Werkman and Gillen (1932) also proposed the species name *"Citrobacter intermedium"* (sic) for four of their strains. Frederiksen (1970) showed that the only extant strain, ATCC 6750, was a typical *C. freundii*. The name *"Citrobacter intermedius"*, therefore, was not included on the Approved Lists of Bacterial Names in 1980, and has no nomenclatural standing.

For a time there were three names—*C. koseri*, *L. malonatica*, and *C. diversus*—for the same species, all of which were on the Lists of Approved names. Frederiksen (1990) requested that the name *C. diversus* (Werkman and Gillen, 1932) be placed on the list of rejected names, because it was incorrectly used by Ewing and Davis (1972a), as the organism they described differed in at least eight characteristics from the organism described by Werkman and Gillen as *"Citrobacter diversum"* (sic), and is thus a nomen dubium. This request was granted by the Judicial Commission (1993). The epithet *malonatica* is a junior synonym and should not be used.

The concept of what should be called *C. freundii* was changed when Brenner et al. (1993) published a study showing that a number of atypical *Citrobacter* strains (considered *C. freundii* or *Citrobacter* species) could be arranged in nine genomospecies apart from *C. koseri* and *C. amalonaticus*. They named five new species: *C. farmeri* for *C. amalonaticus* biovar 1, and *C. youngae*, *C. braakii*, *C. werkmanii*, and *C. sedlakii* for strains that had been considered to be *C. freundii* or atypical *C. freundii*. Only 9 of 66 strains were shown genotypically to belong in *C. freundii*. The remaining 57 strains were allocated to seven genomospecies that could all be differentiated phenotypically. Four of them were named (*C. youngae*, *C. braakii*, *C. werkmanii*, and *C. sedlakii*), whereas three (number 9, 10, and 11) were not named, as they contained only three strains each.

Genomospecies 9, containing strains isolated from rodents, was subsequently named *C. rodentium* by Schauer et al. (1995), who studied three additional strains isolated from mouse intestine that were previously called *C. freundii* biotype 4280 (Barthold et al., 1976).

Janda et al. (1994) examined 235 *Citrobacter* strains. Within what was called a *C. freundii* complex, 37% were found to be *C. freundii*, 24% to be *C. youngae*, 13% *C. braakii*, and 6% *C. werkmanii*.

The recent study by Miki et al. (1996) showed that the test strains from the West and Edwards (1954) scheme for the Bethesda-Ballerup group mainly belonged in *C. youngae* (40 strains), *C. braakii* (25 strains), *C. werkmanii* (13 strains), and genomospecies 10 (six strains). Only three strains could be allocated to *C. freundii* in the new sense. Nine strains of the O-29 group ("Ballerup", in which the Vi antigen may occur) were found to belong in *C. braakii*.

The definition of *C. freundii* has thus changed; the new species and *C. freundii* can be differentiated phenotypically and genotypically, but there are no good "key" tests to characterize them; H_2S-positive strains are found in several species, and so are indole-positive strains. The relative distribution within the *C. freundii* complex evidently depends on how the strains included had been selected: strains sent to reference laboratories, or "nonselected" strains from clinical microbiology laboratories (some of the strains used by Janda et al., 1994). There is evidently a need for a thorough characterization of a large unselected collection of *Citrobacter* strains, both phenotypically and genotypically, in order to evaluate the relative importance of the species of the genus as now defined by Brenner and his co-workers.

Differentiation of the species of the genus *Citrobacter*

The differential characteristics of the species of *Citrobacter* are indicated in Table BXII.γ.215. Table BXII.γ.216 lists other characteristics of the species. See also Tables BXII.γ.193, BXII.γ.194, BXII.γ.195, and BXII.γ.196 in the chapter on *Enterobacteriaceae*.

List of species of the genus Citrobacter

1. **Citrobacter freundii** (Braak 1928) Werkman and Gillen 1932, 173[AL] (*Bacterium freundii* Braak 1928, 140.)
freun' di.i. M.L. gen. n. *freundii* of Freund, named after A. Freund, the bacteriologist who first observed that trimethylene glycol was a product of fermentation.

The morphology is as given for the genus. Usually motile. Usually not encapsulated, although encapsulated strains may occur.

The colony morphology is similar to that of *Escherichia coli*.

Physiological and biochemical characteristics are presented in Tables BXII.γ.215 and BXII.γ.216. Ewing (1986a) listed only 2.1% of strains as indole positive, but among the nine strains included in the study of Brenner et al. (1993), 38% were positive. Janda et al. (1994) found two indole-positive strains among 60 strains allocated to *C. freundii* sensu Brenner et al. (1993). The urease test is positive for most strains if Christensen's method is used, but usually negative if tested for the preformed enzyme.

Found in humans and animals including mammals, birds, reptiles, amphibians, and fish. Also found in soil, water, sewage, and food. Often found in clinical specimens such as urine, throat, sputum, blood, and wound swabs as an opportunistic or secondary pathogen.

The mol% G + C of the DNA is: 50–51 (T_m).

Type strain: ATCC 8090, DSM 30039, IFO 12681, NCTC 9750.

GenBank accession number (16S rRNA): AJ233408.

2. **Citrobacter amalonaticus** (Young, Kenton, Hobbs and Moody 1971) Brenner and Farmer 1982, 266[VP] (Effective publication: Brenner and Farmer 1981, 1140) (*Levinea amalonatica* Young, Kenton, Hobbs and Moody 1971, 58.)
a.ma.lo.na' ti.cus. Gr. prefix *a* not; M.L. adj. *malonaticus* pertaining to malonate; M.L. adj. *amalonaticus* not pertaining to malonate (i.e., not able to utilize malonate).

The morphology is as given for the genus. Motile. Not encapsulated.

Colonies on nutrient agar are translucent to opaque, resembling those of *E. coli*.

Physiological and biochemical characteristics are indicated in Tables BXII.γ.215 and BXII.γ.216. Some strains are late gelatin liquefiers.

Found in the feces of humans and animals and in soil,

[a]All strains (with few single exceptions) utilized the following carbon sources: *N*-acetyl-D-glucosamine, L-alanine, L-arabinose, L-aspartate, citrate, D-fructose, fumarate, D-galactose, D-galacturonate, D-gluconate, D-glucosamine, D-glucose, D-glucuronate, DL-glycerate, D-malate, L-malate, maltose, maltotriose, D-mannitol, D-mannose, mucate, L-rhamnose, D-ribose, D-saccharate, L-serine, D-sorbitol, succinate D-trehalose, and D-xylose. All strains (with two single exceptions) failed to utilize the following carbon sources within 96 h: L-arabitol, betaine, caprate, caprylate, i-erythritol, glutarate, histamine, L-histidine, HQ-beta-glucuronide, itaconate, D-melezitose, quinate, trigonelline, tryptamine, and tryptophan.

water, and sewage. Also found in a variety of human clinical specimens as an opportunistic pathogen.

The mol% G + C of the DNA is: 51–52 (T_m).

Type strain: ATCC 25405, NCTC 10805.

3. **Citrobacter braakii** Brenner, Grimont, Steigerwalt, Fanning, Ageron, and Riddle 1993, 657[VP]

braak' i.i. M.L. gen. n. *braakii* of Braak; named after Hendrik R. Braak, a Dutch microbiologist.

Morphology and cultural characteristics as given for the genus.

Physiological and biochemical characteristics are presented in Tables BXII.γ.215 and BXII.γ.216.

Found in human stools and isolated from animals.

The mol% G + C of the DNA is: unknown.
Type strain: ATCC 51113, CDC 80-58.
GenBank accession number (16S rRNA): AF025368.

4. **Citrobacter farmeri** Brenner, Grimont, Steigerwalt, Fanning, Ageron, and Riddle 1993, 654[VP]
far′mer.i. M.L. gen. n. *farmeri* of Farmer; named after J.J. Farmer III, an American bacteriologist.

Morphology and cultural characteristics as given for the genus.

Physiological and biochemical characteristics are presented in Tables BXII.γ.215 and BXII.γ.216.

Found in human stools, urine, wounds, and blood.

The mol% G + C of the DNA is: unknown.
Type strain: ATCC 51112, CDC 2991-81.
GenBank accession number (16S rRNA): AF025371.

5. **Citrobacter gillenii** Brenner, O'Hara, Grimont, Janda, Falsen, Aldová, Ageron, Schindler, Abbott and Steigerwalt 2000, 423[VP] (Effective publication: Brenner, O'Hara, Grimont, Janda, Falsen, Aldová, Ageron, Schindler, Abbott and Steigerwalt 1999, 2623.)
gil.len′.ii. N.L. gen. n. *gillenii* of Gillen; named after George Francis Gillen, an American microbiologist.

Morphology and cultural characteristics as given for the genus. Physiological and biochemical characteristics are present in Tables BXII.γ.215 and BXII.γ.216. Found in human stool, human urine, human blood, and environment.

The mol% G + C of the DNA is: unknown.
Type strain: ATCC 51117, CCUG 30796, CDC 4693–86, CIC 106783.

6. **Citrobacter koseri** Frederiksen 1970, 93[AL]
ko.ser.i. M.L. gen. n. *koseri* of Koser; named after Stewart A. Koser, an American bacteriologist.

The morphology is as given for the genus. Motile. Not encapsulated.

Colonies on nutrient agar are translucent to opaque, resembling those of *E. coli*. Cultures often have a distinct fecal odor.

Physiological and biochemical characteristics are presented in Tables BXII.γ.215 and BXII.γ.216.

Found in the feces of humans and animals and in soil, water, sewage, and food. Also isolated from human clinical specimens such as urine, throat, nose, and sputum and wound swabs. Causes neonatal meningitis, often complicated with cerebral abscesses, and often fatal. Some cases occur in small outbreaks.

The mol% G + C of the DNA is: 51–52 (T_m).
Type strain: ATCC 27028.

7. **Citrobacter murliniae** Brenner, O'Hara, Grimont, Janda, Falsen, Aldová, Ageron, Schindler, Abbott and Steigerwalt 2000, 423[VP] (Effective publication: Brenner, O'Hara, Grimont, Janda, Falsen, Aldová, Ageron, Schindler, Abbott and Steigerwalt 1999, 2623.)
mur.lin′.i.ae. N.L. gen. n. *murliniae* of Murlin; named after Alma C. McWhorter-Murlin, an American microbiologist.

Morphology and cultural characteristics as given for the genus. Physiological and biochemical characteristics are presented in Tables BXII.γ.215 and BXII.γ.216. Found in human stool, human wound, human blood, human urine, and food.

The mol% G + C of the DNA is: unknown.
Type strain: ATCC 51118, CCUG 30797, CDC 2970–59, CIC 104556.

8. **Citrobacter rodentium** Schauer, Zabel, Pedraza, O'Hara, Steigerwalt, and Brenner 1996, 362[VP] (Effective publication: Schauer, Zabel, Pedraza, O'Hara, Steigerwalt, and Brenner 1995, 2067.)
ro.den′ti.um. L. part. adj. used as a gen. n. *rodentium* of rodents (gnawing animals).

Morphology and cultural characteristics as given for the genus; however, four strains were nonmotile, and two showed motility only after 4 days.

Physiological and biochemical characteristics are presented in Tables BXII.γ.215 and BXII.γ.216. Citrate utilization was late or absent.

Found in rodents only; includes strains known to produce transmissible murine colonic hyperplasia, associated with the presence of an *eaeA* gene in the isolate.

The mol% G + C of the DNA is: unknown.
Type strain: ATCC 51116, CDC 1843-73.
GenBank accession number (16S rRNA): AF025363.

9. **Citrobacter sedlakii** Brenner, Grimont, Steigerwalt, Fanning, Ageron, and Riddle 1993, 657[VP]
sed.lak′i.i. M.L. gen. n. *sedlakii* of Sedlak; named after Jiri Sedlák, a Czechoslovakian bacteriologist.

Morphology and cultural characteristics as given for the genus.

Physiological and biochemical characteristics are presented in Tables BXII.γ.215 and BXII.γ.216.

Found in human stools, blood, and wounds.

The mol% G + C of the DNA is: unknown.
Type strain: ATCC 51115, CDC 4696-86.
GenBank accession number (16S rRNA): AF025364.

10. **Citrobacter werkmanii** Brenner, Grimont, Steigerwalt, Fanning, Ageron, and Riddle 1993, 657[VP]
werk′mani.i. M.L. gen. n. *werkmanii* of Werkman; named after Chester H. Werkman, an American bacteriologist.

Morphology and cultural characteristics as given for the genus.

Physiological and biochemical characteristics are presented in Tables BXII.γ.215 and BXII.γ.216.

Found in human stools and blood, and in soil.

The mol% G + C of the DNA is: unknown.
Type strain: ATCC 51114, CDC 876-58.
GenBank accession number (16S rRNA): AF025373.

11. **Citrobacter youngae** Brenner, Grimont, Steigerwalt, Fanning, Ageron, and Riddle 1993, 654[VP]
young′ae. M.L. gen. n. *youngae* of Young; named after Viola M. Young, an American bacteriologist.

Morphology and cultural characteristics as given for the genus.

Physiological and biochemical characteristics are presented in Tables BXII.γ.215 and BXII.γ.216.

Found in human stools, urine, and wounds, and isolated from animals and food.

The mol% G + C of the DNA is: unknown.
Type strain: ATCC 29935, CDC 460-61.

Genus XI. **Edwardsiella** *Ewing and McWhorter 1965, 37*^{AL}

Riichi Sakazaki

Ed.ward.si.el′ la. M.L. dim. ending *-ella*; M.L. fem. n. *Edwardsiella* named after the American bacteriologist P.R. Edwards (1901–1966).

Straight rods, ~1.0 × 2.0–3.0 µm, conforming to the general definition of the family *Enterobacteriaceae*. Gram negative. **Motile by peritrichous flagella**, but nonmotile strains may occur. Facultatively anaerobic. Growth occurs on ordinary media with small colonies (0.5–1.0 mm in diameter) after 24 h incubation. Optimum temperature, 37°C, except for *E. ictaluri*, which prefers a lower temperature. **Nicotinamide and amino acids are required for growth.** Reduce nitrate to nitrite. Ferment D-glucose with the production of acid and often gas. Also **ferment a few other carbohydrates but are inactive compared to many taxa in the family *Enterobacteriaceae*. Usually resistant to colistin but susceptible to most other antibiotics, including penicillin.** Frequently isolated from river fish and cold-blooded animals and their environment, particularly fresh water. Pathogenic for eels, catfish, and other animals, sometimes causing economic losses; also opportunistic pathogen and possibly rare cause of gastroenteritis for humans. A member of the *Gammaproteobacteria*.

The mol% G + C of the DNA is: 53–59.

Type species: **Edwardsiella tarda** Ewing and McWhorter *in* Ewing, McWhorter, Escobar and Lubin 1965, 37.

Further descriptive information

Most of studies on *Edwardsiella* concentrated on *E. tarda*; little information is available on other species. Encapsulated strains possessing significant glycocalixes have not been found in members of *Edwardsiella*, but some strains may produce slime substance (Wong et al., 1989). They are afimbriate. Wong et al. (1989) and Janda et al. (1991b) reported that approximately half of strains of *E. tarda*, but not *E. hoshinae* and *E. ictaluri*, produce afimbrial mannose-resistant hemagglutination (MRHA) against guinea pig erythrocytes. Aoki and Holland (1985), who analyzed outer membrane composition of *E. tarda*, found a large number of prominent protein bands in all strains, with major bands present at 27, 35, and 46 kDa, and a cluster of three or four outer membrane proteins located in each strain at 52–56 kDa. Studies of the lipopolysaccharide of three species of *Edwardsiella* indicated that each species may be divided into different chemoforms (Nomura and Aoki, 1985). Since strains of *E. tarda* require nicotinamide and amino acids including cysteine and methionine (d'Empaire, 1969) for their growth and other species of the genus probably have similar requirements, strains of *Edwardsiella* grow less luxuriantly than other members of the *Enterobacteriaceae* and form smaller colonies on ordinary agar plates within 24 h of incubation at 37°C. In contrast with other two *Edwardsiella* species, the optimum growth temperature of *E. ictaluri* is between 25 and 30°C and growth is very slow on plating media, often requiring 2–3 d incubation at 30°C to form typical colonies 1 mm in diameter. Biochemically, *E. ictaluri* is also the least active species of *Edwardsiella*.

Plasmids ranging from 2–120 MDa are harbored in many strains of *Edwardsiella* (Lobb and Rhoades, 1987; Janda et al., 1991a). The presence of R plasmids that mediate antibiotic resistance was reported in *E. tarda* by Aoki et al. (1977). Lobb and Rhoades (1987) recognized that catfish isolates of *E. ictaluri* always harbored two plasmids of 5.7 and 4.9 kb (pCL1 and pCL2, respectively). They suggested that plasmid function may be metabolically important to the host bacterium, or that these plasmids may code for factors important to the virulence, or both. Moreover, Lobb et al. (1993) found that green knife fish isolates of the organisms were serologically distinct from those of catfish and harbored four plasmids with relative mobilities of 6.0, 5.7, 4.1, and 3.1 kb, of which 5.7- and 4.1-kb plasmids strongly hybridized to probes specific for pCL1 and pCL2. Hamon et al. (1969) demonstrated bacteriocin production and sensitivity within *E. tarda*.

For *E. tarda*, two independent serotyping schemes were reported by Sakazaki (1967) and Edwards and Ewing (1972). Currently, an international serotyping scheme combining the two schemes mentioned above and comprising 61 O groups and 45 H antigens has been established by Tamura et al. (1988). Lobb et al. (1993) suggested the possibility of serotyping of *E. ictaluri* as an epidemiological tool. Other typing schemes such as bacteriocin typing, bacteriophage typing, and biotyping have not been studied for *Edwardsiella*.

Strains of *Edwardsiella* are primarily resistant to colistin and polymyxin B, but are usually susceptible to other antimicrobial agents including penicillin G, ampicillin, carbenicillin, streptomycin, kanamycin, gentamicin, tetracycline, chloramphenicol, cephalosporins, sulfadiazine, and, with few exceptions, nalidixic acid (Muyembe et al., 1973; Reinhardt et al., 1985). However, Waltman et al. (1986) reported more resistance to sulfa compounds, streptomycin, and methicillin by disk diffusion testing. These differences may be linked to the source of strains tested. All three species may show large zones around penicillin-impregnated disks. This is an unusual finding for members of the *Enterobacteriaceae*. Clark et al. (1991b) found that strains of *E. tarda*, most originating from human sources, have uniform susceptibility to 22 antibiotics. Although they produced β-lactamase, all strains showed susceptibility to β-lactamase inhibitors. Members of *Edwardsiella* are apparently more susceptible to 2,4-diamino-6,7-diisopropyl pteridine (vibriostatic agent O/129, Sigma) than other *Enterobacteriaceae* (Chatelain et al., 1979; Grimont et al., 1980).

There have been no definitive studies indicating *E. tarda* as a potential cause of human intestinal diseases, but a number of papers from tropical countries such as Madagascar (Fourquet et al., 1975), Zaire (Makulu et al., 1973), Tahiti (Fourquet et al., 1975), Dominica (de Inchaustegui et al., 1976), Panama (Kourany et al., 1977), Cuba (Rakovsky and Aldová, 1965), Australia (Iveson, 1973), India (Bhat et al., 1967; Sakazaki et al., 1971), Thailand (Bockemühl et al., 1971; Ovartlarnporn et al., 1986), Viet-Nam (Nguyen-Van-Ai et al., 1975), Philippines (Tocal and Mezez, 1968), Malaysia (Gilman et al., 1971), and Singapore (Tan et al., 1977) have reported an etiologic relationship of this species to diarrheal diseases. On the other hand, *E. tarda* is also found in the feces of healthy people, although the rate of the isolation is extremely low. Onogawa et al. (1976) found only one positive culture from 97,704 food handlers and 25 positive cultures from 255,896 schoolchildren. Makulu et al. (1973) found no *E. tarda* cultures among 841 healthy subjects in Zaire. Iveson (1973) suggested that the number of isolations of *E. tarda* depends upon culture methods for stool specimens, the geographic area of the

study, and the season in which the survey is performed. In those people from whose stool specimens of *E. tarda* have been isolated, the percentage of diarrheal patients has varied from 25% (Kourany et al., 1977) to more than 75% (Bockemühl et al., 1971; Makulu et al., 1973). A higher isolation rate has invariably been recognized among patients with diarrhea than among asymptomatic people (Bhat et al., 1967; Gilman et al., 1971; Makulu et al., 1973; Nguyen-Van-Ai et al., 1975). In tropical countries there is a tendency for *E. tarda* to be isolated from diarrheal stools together with well-established enteropathogens such as *Salmonella*, *Shigella*, *Vibrio cholerae*, *Vibrio parahaemolyticus*, and intestinal parasites (Bhat et al., 1967; Bockemühl et al., 1971; Sakazaki et al., 1971; Makulu et al., 1973; Kourany et al., 1977). The incidence is rare in industrialized countries, but intestinal infection with *E. tarda* was also reported by King and Adler (1964), Chatty and Gavan (1968), and Desenclos et al. (1990) in the United States, and by Vandepitte et al. (1983) in Belgium.

Although *E. tarda* may be able to cause diarrhea, the organism should not be considered as an "inherent" pathogen such as *Salmonella* and *Shigella*. Marques et al. (1984) demonstrated the invasiveness of *E. tarda* in HeLa cells. Janda et al. (1991a) confirmed this finding with HEp-2 cells. However, invasive strains of *E. tarda* give constantly negative results in the Sereny test, suggesting that they have no KepA-like locus as is found in *Shigella* (Ullah and Arai, 1983b; Marques et al., 1984). Janda and Abbott, (1993a) suggested that HEp-2 invasion by *E. tarda* was a microfilament-dependent process. Furthermore, they suggested the cell-associated hemolysin, which was originally demonstrated by Watson and White (1979), as a second major virulence marker. The hemolysin is not released in sufficient amounts under usual growth conditions. Activity of the hemolysin is enhanced by Ca^{2+} and Mg^{2+} and may play a role in infection through epithelial cell destruction leading to an inflammatory infiltrate in the intestinal mucosa, or it could destroy villus cells or disturb intestinal absorption function resulting in diarrhea. In addition to these, Ullah and Arai (1983a) and Janda et al. (1991b) suggested that mannose-resistant hemagglutinins, serum resistance, a dermatotoxin, and chondroitinase activity may be related to human pathogenicity of *E. tarda*. These associations are independent of serovars or source of strains. Whether intestinal infection with *E. tarda* in humans is linked to strains possessing these virulence factors remains to be determined. Bockemühl et al. (1983) reported that some *E. tarda* strains produced a heat-stable enterotoxin (ST) similar to that produced by enterotoxigenic *Escherichia coli*. However, the enterotoxigenic activity was recognized only in culture supernatants concentrated by ultrafiltration. Janda et al. (1991a) also tested *E. tarda* for ST-like activity, but all strains were negative.

Extraintestinal infections with *E. tarda* are well documented, although these occur only rarely in most industrialized countries. It causes meningitis, endocarditis, bacteremia, osteomyelitis, urinary tract infections, or wound infection (Gonzalez and Ruffolo, 1966; Field et al., 1967; Chatty and Gavan, 1968; Okubadejo and Alausa, 1968; Sonnenwirth and Kallus, 1968; Jordan and Hadley, 1969; Pankey and Seshul, 1969; Bockemühl et al., 1971; Sachs et al., 1974; Koshi and Lalitha, 1976; Le Frock et al., 1976; Clarridge et al., 1980; Rao et al., 1981; Sechter et al., 1983; Maserati et al., 1985; Martinez, 1987; Vohora and Torrijos, 1988; Wilson et al., 1989a; Vartian and Septimus, 1990; Hargreaves and Lucey, 1990; Coutlee et al., 1992; Walton et al., 1993; Zighelboim et al., 1992). In most cases of extraintestinal infection, *E. tarda* has been an opportunist in persons with underlying diseases or in conditions with predisposing factors. Infants and the aged tend to be most susceptible to infections with *E. tarda*. *E. tarda* appears to cause serious infection in patients with preexisting liver disease or in those with altered levels of available iron. In cases of wound infection, patients who tend to develop severe infection often have a recent history of fishing, swimming, or injury caused by marine-related items. In extraintestinal infections with *E. tarda*, cell-associated hemolysin is also suggested as a virulence factor, in which a possible function of this hemolysin could be the acquisition of host iron through lysis of erythrocyte to release hemoglobin stores.

E. tarda has been infrequently isolated from warm-blooded animals such as dogs, pigs, cattle, monkeys, rats, panthers, skunks, seals, sea lions, and birds (Ewing et al., 1965; Wallace et al., 1966; Arambulo et al., 1967; Chamoiseau, 1967; Sakazaki, 1967; Tocal and Mezez, 1968; d'Empaire, 1969; Otis and Behler, 1973; White et al., 1973; Owens et al., 1974; Nguyen-Van-Ai et al., 1975; Kourany et al., 1977; Coles et al., 1978). *E. tarda* was associated with diseases in some of those animals, but its pathogenic role in warm-blooded animals is unknown.

Two ecological groups of hosts, cold-blooded animals and fish, could be considered as reservoirs of *E. tarda*. Since Sakazaki and Murata (1962) first suggested *E. tarda* as a normal intestinal inhabitant of snakes, it has been recognized that a wide range of reptiles and amphibians including snakes, crocodiles, alligators, toads, lizards, frogs, and turtles, are possible natural reservoirs for *E. tarda* (Wallace et al., 1966; d'Empaire, 1969; Jackson et al., 1969; White et al., 1969, 1973; Iveson, 1971; Makulu et al., 1973; Meyer and Bullock, 1973; Otis and Behler, 1973; Sharma et al., 1974; Van Der Waaiji et al., 1974; de Inchaustegui et al., 1976; Roggendorf and Müller, 1976; Bartlett et al., 1977; Kourany et al., 1977; Wyatt et al., 1979; Tan et al., 1978). On the other hand, Van Damme and Vandepitte (1980) reported the isolation of *E. tarda* from various kinds of river fish in Zaire. It is considered that river fish and their environment seem to constitute the natural habitat of *E. tarda* and to be the most possible source of human infection, at least in tropical countries. Vandepitte et al. (1983) described protracted diarrhea in an infant associated with *E. tarda*, which was possibly introduced from a tropical aquarium fish in the home of the patient. Trust and Bartlett (1974) reported the presence of *E. tarda* in water samples from aquariums containing goldfish or tropical ornamental fish. Wyatt et al. (1979) recognized *E. tarda* in freshwater catfish and in their environment. Human wound infection with this organism resulting from swimming or diving accidents was reported by Chatty and Gavan (1968) and Clarridge et al. (1980).

E. tarda can cause outbreaks of "red disease" in pond-cultured eels (Hoshina, 1962; Wakabayashi and Egusa, 1973) or "emphysematous putrifactive disease" in channel catfish (Meyer and Bullock, 1973). Kusuda et al. (1977) reported *E. tarda* as causing an outbreak in cultured sea beam. Amandi et al. (1982) showed that *E. tarda* is often isolated from salmonid fish and other fish species in the Pacific Northwest of the United States, and that it is pathogenic for chinook salmon, steelhead and rainbow trout, as well as channel catfish.

E. hoshinae is associated with animals but only eight isolates were originally reported (Grimont et al., 1980). From their paper, the presently known habitats of *E. hoshinae* include reptiles, birds, and water. Although two human isolates of this species were included in their report, those came from feces of individuals without diarrhea; thus there is no evidence that *E. hoshinae* can cause human disease. Another species of *Edwardsiella*, *E. ic-*

taluri, is the causative agent responsible for acute septicemia of catfish. Since the first publication by Hawke et al. (1981), this disease has become a significant problem in the aquaculture of channel catfish in the southeastern United States (Waltman et al., 1986). Shotts et al. (1986) suggested that pathogenesis of *E. ictaluri* may proceed through gastrointestinal tract infection. Enteric septicemia caused by *E. ictaluri* occurs when the temperature ranges from 22–28°C and progresses rapidly, resulting in significant mortality. The isolation of *E. ictaluri* from nonictalurid fish, such as the tropical danio or green knifefish, was also documented (Waltman et al., 1985). Janda et al. (1991b) reported that *E. ictaluri* lacked the invasiveness and cell-associated hemolysin recognized in *E. tarda*, and the lower frequency of these two activities in *E. hoshinae*.

Enrichment and Isolation Procedures

E. tarda and *E. hoshinae* can grow on plating agar media used in enterobacteriology, such as MacConkey, xylose-lysine-deoxycholate (XLD), Hektoen enteric, deoxycholate-citrate, and Salmonella–Shigella agars. Like *Salmonella*, strains of *E. tarda* produce distinguishable black colonies on XLD and Hektoen enteric agars because of H_2S production. As they require some growth factors, their growth may be slower on those media than other enteric bacteria.

Makulu et al. (1973) and Wyatt et al. (1979) reported that tetrathionate or selenite broths as enrichment media may be successful for the isolation of *E. tarda*. Iveson (1971, 1973), who carried out a comparative study to evaluate enrichment media to isolate *E. tarda* from the cloacal contents of tiger snakes and human feces, showed that strontium chloride B broth[1] was the most satisfactory for isolating *E. tarda*, as well as *Salmonella*. After 24 h of incubation at 37°C or 43°C, plates of deoxycholate citrate agar are streaked from the enrichment culture.

On the other hand, Wyatt et al. (1979) evaluated several media for the isolation of *E. tarda* from catfish and the environmental water and found that the most effective isolation of *E. tarda* was obtained with selective enrichment in double-strength SS broth[2] followed by plating on single-strength SS agar. They pointed out that salmonellae were not isolated with this method. A 1-ml amount of lactose broth pre-enrichment is transferred to the double-strength SS broth. After incubation at 35°C for 24 h, cultures are streaked on an SS agar plate.

Muyembe et al. (1973) pointed out that resistance of *E. tarda* to 10 µg/ml colistin can be used in isolation. On the isolation agar plate containing 10 µg/ml colistin, most enteric bacteria are inhibited, with the exception of *Serratia*, *Proteus*, *Providencia*, *Morganella*, *Cedecea*, and some strains of *Yersinia* that are colistin-resistant. Little information is available on the isolation of *E. ictaluri*. Agar medium containing colistin is also effective for the isolation of *E. ictaluri*. The optimum growth temperature of *E. ictaluri* is between 25 and 30°C and growth is slow, often requiring 2–3 days incubation to form colonies 1 mm in diameter.

1. Strontium chloride B broth (g/l): Bacto-tryptone (Difco), 5.0; NaCl, 8.0; K_2HPO_4, 1.0; and $SrCl_2$, 34.0. Sterilization is done by heating at 100°C for 30 min (final pH, 5.0–5.5).

2. Double-strength SS broth (g/l): SS agar, dehydrated, 120, and glucose 5. The mixture is stirred without heat to dissolve the ingredients except agar. The agar is removed by filtration through a Whatman no. 1 filter. The broth is heated at 100°C for 5 min and dispensed to 10-ml quantities into a tube (18 × 180 mm). The tubes are steamed for 30 min.

Maintenance Procedures

Strains of *Edwardsiella* usually survive well at least for 5 years without subculture when the culture is stabbed into a tube with semisolid medium. The tube is tightly sealed with a rubber stopper or with paraffin-coated corks and kept at room temperature in the dark without transfer. A semisolid agar containing 1% Bacto-casitone (Difco), 0.3% yeast extract, 0.5% NaCl, and 0.3% agar (pH 7.2) is an excellent choice for this purpose. However, important cultures should also be preserved at −70°C. Freeze-drying can also be used for long-term preservation.

Procedures for Testing Special Characters

L-Pyrrolidonyl aminopeptidase test Dissolve 10 mg of L-pyrrolidonyl-β-naphthylamide (Sigma) in 10 ml of 95% ethanol. Dip sterile cotton swabs into the solution and rotate each swab several times with firm pressure on the inside wall of the tube to remove excess fluid. Dry the swabs overnight at 37°C and store at −20°C. For testing, make a heavy suspension (MacFarland no. 1) of the test culture into 0.2–0.3 ml of 0.1 M phosphate buffer (pH 7.4), then dip the reagent swab into the suspension and incubate at 37°C for 10 min. Finally, add a drop of cinnamaldehyde solution (*p*-dimethylaminocinnamaldehyde [Sigma] 0.5 g; glacial acetic acid 3.5 ml; ethylene glycol-1-methylester 6.0 ml; sodium lauryl sulfate 3.5 g; and distilled water 90 ml; store in a screw-capped brown container in a refrigerator). A positive result is shown by a pink or red color.

β-Galactosidase and β-glucuronidase tests Dissolve 20 mg each of 4-methylumbelliferyl-β-D-galactopyranoside and 4-methylumbelliferyl-β-D-glucuronide (Sigma) in a small volume of dimethyl sulfoxide, and bring the volume to 10 ml with 0.1 M phosphate buffer (pH 7.4). Dip sterile cotton swabs into the solution and rotate each swab several times with firm pressure on the inside wall of the tube to remove excess fluid. Dry the swabs overnight at 37°C and store at −20°C. For testing, make a heavy suspension (MacFarland no. 1) of the test culture in 0.2–0.3 ml of 0.1 M phosphate buffer (pH 7.4). Dip the reagent cotton swab in the suspension, and incubate at 37°C for 30 min. A positive reaction is indicated by development of blue fluorescence under long-wave (360 µm) ultraviolet lamp.

Differentiation of the genus *Edwardsiella* from other genera

Edwardsiella is biochemically somewhat similar to *E. coli*, *Salmonella*, *Citrobacter* spp., *Leminorella* spp., *Proteus*, and *Providencia*, but is easily differentiated based on activities of L-pyrrolidonyl aminopeptidase, β-galactosidase, β-glucuronidase, and phenylalanine (or tryptophan) deaminase, indole production, and maltose and D-xylose fermentation. Table BXII.γ.217 presents differential characteristics of *Edwardsiella* and other similar members of the *Enterobacteriaceae*. In addition, susceptibilities to penicillin and colistin and to the vibriostatic agent O/129 are useful for differentiation of *Edwardsiella*. Strains of *Edwardsiella* may have zones of inhibition around a penicillin-G disk and no zone around a colistin disk, whereas many groups of the *Enterobacteriaceae* usually have the opposite patterns. *Edwardsiella* may show zones around a 10-µg disk of O/129.

Taxonomic Comments

Edwardsiella was independently reported by several investigators early in the 1960s. Sakazaki and Murata (1962) and Sakazaki (1967) reported a new group of organisms in the family *Ente-*

robacteriaceae that were isolated from snakes in 1959 and suggested a vernacular name "Asakusa group" for this group. King and Adler (1964) described the isolation of a culture of the organism and gave it the name "Bartholomew group". Later, Ewing et al. (1965) suggested the scientific name *Edwardsiella tarda* for a group of organisms that had been known as biotype 1483-59 in their laboratory since 1959, and indicated that these organisms were similar to those of the Asakusa and Bartholomew groups. Although the genus *Edwardsiella* with the single species *E. tarda* was proposed by Ewing et al. (1965), there was some question about this designation based upon only phenotypic characterization. Brenner et al. (1974b) demonstrated that strains of *E. tarda* were highly related by DNA hybridization, regardless of their source. They also reported that *Edwardsiella tarda* was only 8–29% related to other genera in the family *Enterobacteriaceae* and was distinct from other members of the family.

Grimont et al. (1980) described a new biogroup designated biogroup 1 of *E. tarda* that was distinguished from biochemically typical strains by its acid production from sucrose, D-mannitol, and L-arabinose, but was closely related to the latter by DNA hybridization. Walton et al. (1993) reported the isolation of a single strain of sucrose-positive, but D-mannitol- and L-arabinose-negative *E. tarda* mimicking biogroup 1 from a patient with cholelithiasis.

The second species of the genus was recognized by Grimont et al. (1980) among the organisms formerly identified as atypical *E. tarda*, and the name *Edwardsiella hoshinae* was proposed for this species. Hawke et al. (1981) reported the third species, *Edwardsiella ictaluri*, associated with septicemia and death in catfish.

Hoshina (1962) recognized an organism as an etiologic agent of "red disease" in eels and named it *"Paracolobactrum anguillimortiferum"*. Based on the International Code of Bacterial Nomenclature 1953 and 1962, *"Paracolobactrum anguillimortiferum"* of Hoshina was a legitimate name for this species. Sakazaki and Tamura (1975) suggested a new combination *"Edwardsiella anguillimortifera"* instead of *Edwardsiella tarda*, because they considered the name *E. tarda* was a junior synonym of *"Paracolobactrum anguillimortiferum"*. Farmer et al. (1976) pointed out differences of some biochemical reactions in descriptions between Hoshina (1962) and Ewing et al. (1965), and emphasized the legitimacy and validity of *Edwardsiella tarda*. Unfortunately, no type strain of *"Paracolobactrum anguillimortiferum"* was designated by Hoshina, and strains studied by him were no longer available. In this status, *"P. anguillimortiferum"* should be considered as a doubtful name, and *E. tarda* is the name that should be used to avoid unnecessary confusion in the literature.

Acknowledgments

Riichi Sakazaki, who died in 2002, spent more than forty years at the Nippon Institute of Biological Sciences. His illustrious career focused on the classification and epidemiology of human and fish pathogens in Japan, particularly pathogenic bacteria in the families *Vibrionaceae* and *Enterobacteriaceae*. His contributions to Japanese bacteriology paralleled those of Drs. Edwards and Ewing in the U.S. He discovered and described many species in the genera *Enterobacter*, *Edwardsiella*, and *Vibrio*, and he developed serotyping schemes for *V. cholerae* and *V. parahaemolyticus*, as well as for several important species of *Enterobacteriaceae*. His research was always careful and comprehensive. He was one of the first Japanese scientists to publish in English language journals, thereby making his impressive accomplishments available to the world. He was recognized as one of the world's foremost experts on the genus *Vibrio* and on many genera in *Enterobacteriaceae*. He was a member of the WHO Subcommittees on the Taxonomy of *Vibrionaceae* and on the Taxonomy of *Enterobacteriaceae* for more than thirty years. He authored chapters on these organisms in three editions of *Bergey's Manual*. He was a good friend to the Bergey's Trust, as well as to all who knew him.

Differentiation of the species of the genus *Edwardsiella*

Table BXII.γ.218 presents the differential characteristics of the species and biogroups of *Edwardsiella*. Table BXII.γ.219 shows additional biochemical features of those organisms. In the H_2S production test, *E. tarda* biogroup 1 and *E. hoshinae* give a weakly positive reaction in the butt of Kligler iron agar but are usually negative in the butt portion of triple sugar iron agar in which acid produced by sucrose fermentation interferes to combine hydrogen sulfide with Fe^{2+}.

List of species of the genus Edwardsiella

1. **Edwardsiella tarda** Ewing and McWhorter *in* Ewing, McWhorter, Escobar and Lubin 1965, 37[AL]

tar' da. L. fem. adj. *tarda* slow (intended meaning was "inactive," referring to the fermentation on only a few carbohydrates compared to many other *Enterobacteriaceae*).

The characteristics are as given for the genus and listed in Tables BXII.γ.218 and BXII.γ.219.

Occurs in a wide variety of animals, rarely in the feces of healthy people. It is an opportunistic human pathogen, which may cause wound infection and probably some cases of diarrheal diseases.

The mol% G + C of the DNA is: 55–58 (T_m).

Type strain: ATCC 15947, DSM 30052.

GenBank accession number (16S rRNA): AF053975 and AF015259.

[d]Weakly positive but may be negative in the butt of TSI agar.

[e]Some strains may be negative.

Additional Remarks: These sequences are not from the type strain.

2. **Edwardsiella hoshinae** Grimont, Grimont, Richard and Sakazaki 1981b, 216[VP] (Effective publication: Grimont, Grimont, Richard and Sakazaki 1980, 349.)
ho.shi′ nae. M.L. gen. n. *hoshinae* of Hoshina; named after the late Toshikazu Hoshina, the Japanese bacteriologist who was one of the first to describe an organism that was probably an *Edwardsiella*.

The characteristics are as described for the genus and indicated in Tables BXII.γ.218 and BXII.γ.219. Hydrogen sulfide is weakly produced in Kligler iron agar but may be negative in TSI agar.

Most isolates are from animals. There is no evidence that this species causes diarrhea.

The mol% G + C of the DNA is: 56–57 (T_m).

Type strain: 2-78, ATCC 33379, CIP 78-56.

3. **Edwardsiella ictaluri** Hawke, McWhorter, Steigerwalt and Brenner 1981, 400[VP]
ic.ta.lu′ ri. Ictalurus the genus name for catfish; M.L. fem. adj. *ictaluri* pertaining to catfish.

The characteristics are as described for the genus and as indicated in Tables BXII.γ.218 and BXII.γ.219.

E. ictaluri is the most fastidious of the three *Edwardsiella* species. Growth is very slow on plating media. It seems to prefer a lower temperature, although characteristic biochemical reactions are apparent at 36°C (Tables BXII.γ.218 and BXII.γ.219). Biochemically, it is also the least active of the three *Edwardsiella* species.

The antibiotic susceptibility by disk diffusion is difficult to determine because the strains grow so poorly on Mueller-Hinton agar at 37°C. They must be incubated at 25°C instead.

Occurs as a pathogen of catfish.

The mol% G + C of the DNA is: 53 (Bd).

Type strain: SECFDL, GA 7752, ATCC 33202, CDC 1976-78.

Genus XII. **Enterobacter** *Hormaeche and Edwards 1960b, 72[AL] Nom. Cons. Opin. 28, Jud. Comm. 1963, 38*

PATRICK A.D. GRIMONT AND FRANCINE GRIMONT

En.te.ro.bac′ ter. Gr. neut. n. *enteron* intestine; M.L. masc. n. *bacter* equivalent of bacterium, a small rod; M.L. masc. n. *Enterobacter* intestinal small rod.

Straight rods, 0.6–1.0 × 1.2–3.0 μm, conforming to the general definition of the family *Enterobacteriaceae*. **Motile by peritrichous flagella** (generally 4–6). Gram negative. **Facultatively anaerobic.** Growth occurs readily on ordinary media. Glucose is fermented with production of acid and gas (generally CO_2:H_2 = 2:1). Gas is not produced from glucose at 44.5°C. **Most strains give a positive Voges–Proskauer reaction and a negative methyl red test.** An alkaline reaction occurs in Simmons citrate and malonate broth. Nitrate is reduced to nitrite. H_2S is not produced from thiosulfate. Tetrathionate is not reduced. **Corn oil and tributyrin are not hydrolyzed. Gelatin, DNA, and Tween 80 are either not, or very slowly, hydrolyzed.** L-Arabinose, D-cellobiose, D-fructose,

D-galactose, D-galacturonate, gentiobiose, D-gluconate, D-glucosamine, D-glucose, D-glucuronate, 2-ketogluconate, L-malate, D-mannitol, D-mannose, D-trehalose, and D-xylose utilized by all or almost all strains, as sole source of carbon and energy. L-rhamnose utilized by all strains except *Enterobacter asburiae*. L-Arabitol, ethanolamine, itaconate, 3-phenylpropionate, L-sorbose, D-tartrate, tryptamine, and xylitol are not utilized. *meso*-Erythritol, gentisate, glutarate, and tricarballylate not utilized except by some strains of *Enterobacter gergoviae*. D-melezitose not utilized except by some strains of *Enterobacter sakazakii*. Optimum temperature for growth is 30°C. Most clinical strains grow at 37°C; some environmental strains give erratic biochemical reactions at 37°C. Widely distributed in nature; common in man and animals.

The mol% G + C of the DNA is: 52–60 (Bd).

Type species: **Enterobacter cloacae** (Jordan 1890) Hormaeche and Edwards 1960b72. Nom. Cons. Opin. 28, Jud. Comm. 1963, 38 (*Bacillus cloacae* Jordan 1890, 836.)

Further descriptive information

Phylogenetic treatment The phylogenetic approach using sequences of the *rrs* gene (encoding 16S rRNA) does not provide sufficient resolution when closely related enterobacterial species are studied, and branching is often unreliable. However, some sequence comparisons have corroborated DNA–DNA hybridization studies. *Enterobacter aerogenes* is more closely related to *Klebsiella* species than to *E. cloacae*, the type species of the genus *Enterobacter*. Therefore, in this volume, *E. aerogenes* has been treated with the genus *Klebsiella* under the name *K. mobilis*. *Enterobacter agglomerans* and several species of the *E. agglomerans* complex cluster together and away from *E. cloacae*. *E. agglomerans* has been transferred to a new genus, *Pantoea*, and in this volume, the *E. agglomerans* complex is treated with the genus *Pantoea*. *Enterobacter intermedius* (originally named *E. intermedium*; corrected by von Graevenitz (1990)) has a *rrs* sequence identical with that of *Kluyvera cochleae*. Furthermore, DNA–DNA hybridization has shown the type strains of *E. intermedius* and *K. cochleae* to be 99% related with a thermal instability of hybridized molecules of 1.5°C (D.J. Brenner, personal communication). Therefore, *E. intermedius* is not treated in this chapter. (See the section on Other organisms in the chapter on the genus *Kluyvera*.)

The *Enterobacter* species treated in this chapter do not cluster together in an *rrs* sequence comparison. However, after *rpoB* sequence comparison, all species and subgroups in the *E. cloacae* complex composed of *E. cloacae*, *Enterobacter asburiae*, *Enterobacter hormaechei*, and the type strain of *Enterobacter dissolvens*) form a cluster (P.A.D. Grimont, unpublished data). *Enterobacter cancerogenus*/*Enterobacter taylorae* and *E. agglomerans* DNA group VII (not a member of *Pantoea*) form a cluster near *Leclercia adecarboxylata*. *Enterobacter amnigenus*, *Enterobacter nimipressuralis*, and *Enterobacter kobei* constitute another cluster. *Enterobacter cowanii* clusters with *E. agglomerans* DNA group IX (not a member of *Pantoea*) (unpublished data). More work is needed to establish criteria for delineating genera and ascertaining the phylogenetic position of all *Enterobacter* species.

Nutrition and growth conditions Best results are obtained when *Enterobacter* cultures are incubated at 30°C. At 37°C, yellow pigmentation of *E. sakazakii* may be weak. *E. sakazakii* is able to grow at 44°C.

Media used in the isolation of *Enterobacter* species are similar to those used for other *Enterobacteriaceae*. On nutrient agar, *E. cloacae*, *E. gergoviae*, *E. amnigenus*, and *E. nimipressuralis* form colonies that are round, 2–3 mm in diameter, and slightly iridescent or flat with irregular edges (Richard, 1984). *E. sakazakii* strains forms bright yellow colonies at 25°C or pale yellow colonies at 37°C, 1–3 mm in diameter. These colonies are smooth, mucoid, or dry (Farmer et al., 1980a).

Differential media that are not inhibitory for the *Enterobacteriaceae* are often used. These are bromothymol blue-lactose agar, phenol red-lactose agar, Drigalski lactose agar, eosin methylene blue agar, or MacConkey agar. It should be remembered that some strains in a species known to produce acid from lactose might fail to do so and thus give lactose-negative colonies on differential media.

In Biotype-100 strips (BioMerieux, Craponne, France), or in a minimal medium containing ammonium sulfate as the nitrogen source, the following compounds serve as sole carbon sources for most *Enterobacter* strains: *N*-acetyl-D-glucosamine, D-alanine, L-alanine, L-arabinose, L-aspartate, D-cellobiose, D-fructose, fumarate, D-galactose, D-galacturonate, gentiobiose, D-gluconate, D-glucosamine, D-glucose, D-glucuronate, L-glutamate, glycerol, 2-ketogluconate, DL-lactate, L-malate, D-mannitol, D-mannose, L-proline, D-ribose, L-serine, succinate, D-trehalose, and D-xylose. L-rhamnose is utilized by all strains except for most *E. asburiae* strains.

Most strains cannot utilize the following substrates as sole carbon and energy sources : L-arabitol, ethanolamine, itaconate, 3-phenylpropionate, and L-sorbose. The following substrates are not utilized except by some strains of *E. gergoviae*: *meso*-erythritol, gentisate, glutarate, histamine, 3-hydroxybenzoate, and tricarballylate. D-melezitose is not utilized, except by some strains of *E. sakazakii*.

Metabolism When pyrroloquinoline quinone (PQQ) is added, gluconate is produced from D-glucose in the presence of iodoacetate under aerobic conditions by all *Enterobacter* species by means of a glucose dehydrogenase. Only *E. gergoviae*, *E. sakazakii*, *E. cowanii*, and *E. hormaechei* genomic group (*E. cloacae* group III) can produce gluconate without added PQQ (Bouvet et al., 1989). Data are not available for *E. kobei* and *E. pyrinus*. A reducing compound, 2-ketogluconate, is also produced from gluconate by *E. gergoviae* by means of a gluconate dehydrogenase (Bouvet et al., 1989). 2,5-Diketogluconate is not produced from 2-ketogluconate (Bouvet et al., 1989).

Most *Enterobacter* species and biogroups give a positive Voges–Proskauer reaction (except *E. kobei*) and Simmons' citrate tests, motility (except some strains of *E. asburiae*); acid production from D-glucose, D-mannitol, salicin, L-arabinose, L-rhamnose (except most strains of *E. asburiae*), D-xylose, trehalose, D-cellobiose, and maltose; hydrolysis of *o*-nitrophenyl-β-D-galactoside (ONPG), and nitrate reduction. All *Enterobacter* species produce gas from D-glucose.

Most *Enterobacter* species or biogroups are negative for the following tests: H_2S production from thiosulfate, phenylalanine deaminase, tetrathionate reduction, tributyrin and corn oil hydrolysis, and β-glucuronidase.

Bacteriophage and bacteriocin typing Phage typing has been used for *E. cloacae*. Gaston (1987b) isolated 76 phages active against *E. cloacae* from sewage. Of these, 26 phages were selected after numerical taxonomic analysis of their reaction patterns on 92 *E. cloacae* strains. This system has been tried on 384 isolates, 94% of which were susceptible to at least one phage. 325 phage susceptibility patterns were observed. Reproducibility of patterns was 100% when duplicate testing was on the same day, but the

reproducibility was only 40% when duplicate testing was done after 18 months (Gaston, 1987a).

Three different schemes have been developed for typing *E. cloacae* strains by susceptibility to bacteriocins. Freitag and Friedrich (1981) were able to type 51 of 65 strains (78%) which were assigned to 23 bacteriocin types designated A through X (type Y contained non-typable isolates). Traub et al. (1982) found 9% of 256 *E. cloacae* isolates to be bacteriocinogenic. Bacteriocins were produced by 16 strains after induction by mitomycin. A total of 308 isolates from various clinical sources were studied and 79% fell into 52 bacteriocin types leaving 21.4% of the isolates untypable. Bauernfeind and Petermüller (1984) found 132 of 149 isolates to produce bacteriocins. With a set of eight bacteriocin-producing strains, typability of 134 clinical isolates was 96.3%. A total of 44 different bacteriocin types could be distinguished. Only 11 (8. 2%) of the isolates fell into the largest bacteriocin type.

Antigenic structure *E. cloacae* serotyping schemes have been devised. Sakazaki and Namioka (1960) distinguished 53 O- and 56 H-antigens in agglutination tests ; 170 isolates were distributed among 79 serotypes. Bacterial suspensions had to be boiled in order to be agglutinated by the O-antisera. Unfortunately, epidemiological investigations using this serotyping scheme have not been reported.

Gaston et al. (1983) devised a serotyping scheme based on heat-stable somatic (O) antigens. 28 antisera including 11 absorbed sera were used, thus defining 28 O-serogroups. Of 300 clinical isolates from 66 hospitals, 78% were typable, 11% were not agglutinated by any of the sera, and 11% were autoagglutinable in saline.

Pathogenicity *Enterobacter* species are found in the natural environment including water, sewage, vegetables, and soil. The increased prevalence of *Enterobacter* spp. as nosocomial pathogens may be due to a greater resistance to disinfectants and antimicrobial agents than that of other members of the *Enterobacteriaceae*. Contaminated medicinal agents can be sources of outbreaks. Maki and Martin (1975) showed that *E. cloacae*, *E. agglomerans* and *Serratia marcescens* multiplied better in 5% dextrose solution at 25°C than did other members of the *Enterobacteriaceae*.

The pathogenicity of *Enterobacter* spp. has been reviewed by Sanders and Sanders (1997). Most *Enterobacter* bacteremias are acquired in the hospital. *E. cloacae* predominates, followed by *E. agglomerans*, *E. sakazakii*, and others. 14–53% of bacteremias that involve *Enterobacter* spp. are polymicrobial. *Enterobacter* bacteremias occur in patients with severe underlying diseases. Cases involving previously healthy individuals can be caused by administration of a contaminated medical product. The mortality rate is similar to that due to other enteric bacilli. A study of patients undergoing cardiac surgery suggested that *E. cloacae* might be more virulent than *E. aerogenes* (*Klebsiella mobilis*). Among patients colonized by *E. cloacae*, 26% developed an infection, whereas only 7% of those colonized by *K. mobilis* developed an infection.

In the lower respiratory tract, *Enterobacter* spp. have been involved in asymptomatic colonization of respiratory secretions, purulent bronchitis, lung abscess, pneumonia, and empyema. Pneumonia occurs in lung transplant recipients, patients with severe underlying diseases, and in elderly persons who are institutionalized.

Enterobacter spp. are a common cause of nosocomial infections of surgical wounds and burns. Other infections involving the skin and soft tissues are cellulitis, fasciitis, abscesses, emphysema, and myositis. Endocarditis due to *Enterobacter* spp. occurs in intravenous drug abusers and individuals with prosthetic valves.

Enterobacter spp. have been involved in biliary sepsis. Bacteremias after hepatic transplantation or endoscopic retrograde cholangiopancreatography, hepatic gas gangrene, fulminant emphysematous cholecystitis, acute suppurative cholangitis, and peritonitis following small intestine obstruction have been reported.

Urinary tract infections due to *Enterobacter* spp. range from asymptomatic bacteriuria to pyelonephritis and urosepsis. *Enterobacter* meningitis, ventriculitis, brain abscess, and infections near foreign bodies have been reported. *Enterobacter* spp. are infrequently the cause of postoperative endophthalmitis, but consequences are devastating (loss of vision or eye). Occasionally, severe septic arthritis, osteomyelitis, infections of multiple bones and joints in infants and children, vertebral osteomyelitis, bilateral hip infections and prosthetic hip infections due to *Enterobacter* spp. have been reported (reviewed by Sanders and Sanders, 1997).

Other species in the *E. cloacae* complex (*E. dissolvens*, *E. asburiae*, *E. hormaechei*) may have been reported as *E. cloacae* due to taxonomic uncertainties. *E. hormaechei* has been isolated from wounds, sputum, and blood (O'Hara et al., 1989). An outbreak of *E. hormaechei* infection and colonization among vulnerable, low-birth-weight premature infants has been described (Wenger et al., 1997). In our opinion, the *E. hormaechei* phenotype as described by O'Hara et al. (1989) is a biogroup of a larger genomic species. Thus, the strains that caused an outbreak in Marseille hospitals were identified as belonging to the *E. hormaechei* genomic species, although they resembled *E. cloacae* in classical biochemical tests (Davin-Regli et al., 1997). Our observation is that most *E. cloacae* that cause nosocomial infections belong to the *E. cloacae* group III/ *E. hormaechei* genomic species (unpublished data).

E. asburiae strains were isolated from clinical specimens, mostly urine, respiratory tract, feces, wounds, and blood (Brenner et al., 1986). The clinical significance of this organism is not known.

Enterobacter dissolvens has not yet been reported in clinical specimens and has only been recovered from environmental sources. *E. dissolvens* was first isolated by Rosen (1922) from diseased corn and is found in rotting cornstalks.

The role of *E. sakazakii* in pathology and as a contaminant has been reviewed by Nazarowec-White and Farber (1997). Little is known about the presence of *E. sakazakii* in the environment. *E. sakazakii* has frequently been found in powdered substitutes for breast milk in many countries together with other enteric bacteria. It has also been recovered from liquid formula and milk subjected to ultra high temperature (UHT) processing. Numerous reports of *E. sakazakii* meningitis and generalized sepsis have been reported in neonates. Powdered infant formula was implicated in several cases. Even when death did not occur, severe complications or sequelae were observed (brain abscesses, necrotizing enterocolitis, hydrocephalus). There have been only three reports of *E. sakazakii* infections in adults (an ulcer in the foot of a diabetic patient, urosepsis in an elderly patient, and bacteremia) (Nazarowec-White and Farber, 1997).

E. cancerogenus (*E. taylorae*) has only rarely been associated with human infections. Septicemia and urinary tract infections in patients with underlying diseases have been observed. Wound infections after severe trauma or crush injuries have been described. Some of them were chronic or unresolving infections. An environmental source was suspected (Abbott and Janda, 1997).

E. nimipressuralis has not yet been reported in clinical specimens and has only been recovered from environmental sources.

E. amnigenus is mainly found in water, but some strains were isolated from clinical specimens such as respiratory tract, wound, or feces (Farmer et al., 1985a).

E. gergoviae occurs in a variety of environmental sources such as water, cosmetics and clinical sources in France, Africa, and the United States (Richard et al., 1976; Brenner et al., 1980b). Multiply drug resistant strains have been found in urine samples during an infection outbreak (Richard et al., 1976).

Pathogenesis Adhesive properties may be important in the establishment or maintenance of bacterial infections. Adhesins are often also hemagglutinins (HA) and may or may not be located on fimbriae. Most strains of *Enterobacter amnigenus*, *E. cloacae*, and *E. sakazakii* produce a mannose-sensitive hemagglutinin (MS-HA) associated with type-1 fimbriae, i.e., thick, channeled fimbriae having an external diameter of 7–8 nm. These fimbriae can be coated by type-1 fimbrial antiserum against *E. cloacae* 035 but not by type-1 fimbrial antiserum against *Klebsiella pneumoniae* K55/1 (Adegbola and Old, 1983b). No other hemagglutinin and fimbrial type has been observed in these species.

Seven of eight *E. gergoviae* strains produce a mannose-resistant *Klebsiella*-like hemagglutinin (MR/K-HA) that agglutinates tanned ox erythrocytes and is associated with type-3 fimbriae, i.e., thin, non-channelled fimbriae having an external diameter 4–5 nm. These fimbriae can be coated with type-3 fimbrial antiserum against *K. oxytoca* K70/1 (Adegbola and Old, 1983b). No other hemagglutinin and fimbrial type has been observed in this species.

All *E. cloacae* strains tested could adhere to and invade HEp-2 cells (Keller et al., 1998). Only two of 14 *E. cloacae* isolates adhered to the human cell line Intestine-407 (Livrelli et al., 1996).

The outer membrane protein OmpX plays a role in the invasion of rabbit ileal tissue by *E. cloacae*. Invasiveness varies directly with the level of OmpX in the outer membrane (De Kort et al., 1994).

Iron is essential for bacterial growth. In the human body, iron is complexed to carrier molecules such as transferrin (in the serum) or lactoferrin (in milk and other secretions), or sequestered within cells (in heme proteins). When growing under iron-limiting conditions, potentially pathogenic *Enterobacteriaceae* produce high affinity systems to solubilize and import the required iron. These iron-chelating compound produced are mostly of two sorts, phenolate (e.g., enterochelin) and hydroxamate (aerobactin) siderophores (Payne, 1988). All strains of *E. cloacae*, *E. gergoviae*, and *E. sakazakii* tested by Reissbrodt and Rabsch (1988) produced enterochelin. Some strains of all these species produced aerobactin. Aerobactin was first isolated from a strain of *K. mobilis* (then *"Aerobacter aerogenes"*) (Gibson and Magrath, 1969). Aerobactin and cloacin DF13 bind to the same receptor sites located in the outer membrane (Van Tiel-Menkveld et al., 1982). Aerobactin is encoded by a relatively simple genetic system that has been extensively characterized. Only four genes are required for synthesis of aerobactin (Carbonetti and Williams, 1984). *E. cloacae* harbor a relatively large conjugative plasmid encoding susceptibility to cloacine DF13 as well as production and uptake of aerobactin (Krone et al., 1985).

Most clinical strains of *E. cloacae* examined have been resistant to serum bactericidal activity and could produce aerobactin and mannose-sensitive hemagglutinin (Keller et al., 1998).

Antibiotic sensitivity The antibiotic sensitivity of *Enterobacter* spp. has been reviewed by Sanders and Sanders (1997). *E. cloacae* is naturally resistant to ampicillin, cephalothin and other older cephalosporins, and cefoxitin. Most strains are sensitive to ureidopenicillins and carboxypenicillins. Strains are not very sensitive to cefamandole and cefuroxime but are more sensitive to expanded-spectrum cephalosporins and aztreonam. The highest sensitivity is to carbapenems (e.g., imipenem). Most strains are sensitive to aminoglycosides and ciprofloxacin. The sensitivity to trimethoprim-sulfamethoxazole is variable.

All species of *Enterobacter* examined to date produce a chromosomally encoded group 1 β-lactamase. This enzyme is produced only at low levels (noninducible) by *E. gergoviae* and some strains of *E. sakazakii*, which explains the greater sensitivity of these strains to ampicillin, older cephalosporins, and cefoxitin. The enzyme is inducible in *E. cloacae*, *E. cancerogenus*, *E. asburiae*, and most strains of *E. sakazakii*, and these strains are resistant to ampicillin, older cephalosporins, and cefoxitin (Sanders and Sanders, 1997).

The *ampD* mutation in *E. cloacae* stably derepresses the chromosomal β-lactamase, which is then produced at high levels, causing the strains to be resistant to extended-spectrum cephalosporins, broad-spectrum penicillin, and aztreonam. These mutants remain sensitive to carbapenems and cefepime. However, additional mutations involving permeability through the outer envelope can lead to resistance to these agents. A chromosomally encoded carbapenemase has been reported (Sanders and Sanders, 1997).

Strains can acquire plasmid-borne resistance determinants encoding group 2b (TEM-1, TEM-2, or SHV-1) or group 2d (OXA-1) β-lactamases. Strains carrying such plasmids are susceptible to extended-spectrum cephalosporins and β-lactamase inhibitor-β-lactam drug combinations. Resistance to extended-spectrum cephalosporins can also be acquired with plasmids encoding group 2be β-lactamase (extended-spectrum β-lactamases).

Resistance to aminoglycosides is due to the production of one or more aminoglycoside-inactivating enzymes. The most frequently occurring enzymes are acetylating enzymes AAC(3)-II, AAC(6′), AAC(3)-III, AAC(3)-I, and AAC(3)-V. A nucleotidylating enzyme, ANT(2″), may also occur (Sanders and Sanders, 1997).

Ecology Nitrogen-fixing strains of *E. cloacae* have been isolated from the roots of dryland and wetland rices (Ladha et al., 1983). The nitrogen-fixing *E. cloacae* strains isolated by Bally et al. (1983) belong to *E. cloacae* genomic group 5 (P.A.D. Grimont, unpublished observations). A strain identified as *E. cloacae* suppresses sporangium germination in *Pythium ultimum* (the cause of seed and root diseases of a wide variety of plants). This is achieved by a competitive utilization of fatty acids present in the exudate of germinating seeds (Van Dijk and Nelson, 2000). Some strains identified as *E. cloacae* are endophytic symbionts of corn (Hinton and Bacon, 1995).

A strain identified as *E. asburiae* is a cotton endophyte that is able to colonize internal tissues of different plant species (Quadt-Hallmann and Kloepper, 1996).

E. nimipressuralis has been described as being the causal agent of wetwood in elm trees (Carter, 1945). *Enterobacter cancerogenus* (as *Erwinia cancerogena*) has been described as the causal agent of a canker disease of poplar (*Populus* species). *Enterobacter pyrinus* causes a pear brown leaf spot disease in Korea (Chung and Cho, 1993).

Enrichment and Isolation Procedures

All media designed for the isolation of *Enterobacteriaceae* can be used for the isolation of *Enterobacter* species: MacConkey agar, Drigalski lactose agar, Hektoen agar, deoxycholate lactose citrate agar, etc. *Enterobacter* can also grow on media for general use, such as blood agar, nutrient agar, tryptic soy agar, bromocresol purple lactose agar, etc.

There are no selective media for *Enterobacter* species. The requirements for devising a selective medium are (i) a precise and stable delineation of the genus (or species, if the medium is to be species specific), (ii) known common properties within the genus (or species) which are uncommon outside the genus (or species), and (iii) a clinical, public health or special need for such selective medium. Due to pending changes in the delineation of the genus *Enterobacter* and the species *E. cloacae*, conditions (i) and (ii) are not met. Except for some epidemiological studies, the selective isolation of *Enterobacter* spp. is rarely necessary, since the presence of *Enterobacter* spp. in pluribacterial habitats (feces, throat, skin) is clinically meaningless. The public health significance of *Enterobacter* spp. in water or foods is uncertain. Isolation of *Enterobacter* spp. from clinical specimens is done either by direct plating on blood agar, tryptic soy agar or nutrient agar (e.g., pus, urine) or by plating after prior growth in tryptic soy broth or nutrient broth (blood, pus, cerebrospinal fluid).

Maintenance Procedures

Strains are initially grown on tryptic soy agar at their optimum temperature and then stabbed into a medium[1] designed for maintenance of *Enterobacteriaceae* and related organisms. The cultures are stored at room temperature in a dark, dry place. Cultures may be also preserved by freeze-drying. Freeze-drying is the best procedure for preservation of pigmented strains.

Procedures for Testing Special Characters

Procedures for carbon source utilization (using Biotype-100 strips), glucose oxidation, gluconate- and 2-ketogluconate dehydrogenase, Voges–Proskauer (Richard's modification), and β-xylosidase tests are given in the chapter on *Serratia* in this volume.

Differentiation of the genus *Enterobacter* from other genera

Because the genus is not monophyletic and may be split further, differentiation of the genus should be at the species level.

Taxonomic Comments

The history of some species of the genus *Enterobacter* can be confusedly traced to the end of the nineteenth century. *"Bacillus lactis aerogenes"* was isolated by Escherich (1885) from milk and renamed *"Bacillus aerogenes"* by Kruse (1896) and *"Aerobacter aerogenes"* by Beijerinck (1900b). Differentiation of this organism from Friedländer's bacillus (now *Klebsiella pneumoniae*) was not clear before 1955, and most authors considered *"B. lactis aerogenes"* or *"Aerobacter aerogenes"* as nonmotile, or as containing motile and nonmotile strains (Grimbert and Legros, 1900; Edwards and Fife, 1955). This led Edwards and Fife (1955) to state that *"A. aerogenes"* strains were in fact *Klebsiella* strains.

"Bacterium cloacae" was described by Jordan (1890) and transferred to a new genus *"Cloaca"* as *"Cloaca cloacae"* by Castellani and Chalmers (1920). *Bergey's Manual* (Bergey et al., 1923) transferred this species to the genus *"Aerobacter"* as *"A. cloacae"*. Because *"Aerobacter aerogenes"* was indistinguishable (at that time) from *Klebsiella pneumoniae*, it was proposed that the species *"A. aerogenes"* disappear (Edwards and Fife, 1955) although disappearance of the type species (*"A. aerogenes"*) implied disappearance of the genus (*"Aerobacter"*).

A significant step forward occurred when Møller (1955) devised simple methods for testing amino-acid decarboxylases. The *"Cloaca"* group, being arginine-positive, could now easily be distinguished from the *Klebsiella* group (arginine-negative) by biochemical tests. This lead to the finding of motile strains of the *"Cloaca"* group which were arginine-negative and produced gas from inositol and glycerol (Hormaeche and Munilla, 1957). These were called "Cloaca B" (arginine-positive strains forming the "Cloaca A group"). After reexamination of many cultures with decarboxylase tests, Hormaeche and Edwards (1958) redefined the genus *"Aerobacter"* to include two species, *"A. aerogenes"* ("Cloaca B") and *"A. cloacae"* ("Cloaca A"). The type species was reaffirmed to be *"A. aerogenes"*.

In an attempt to avoid confusion resulting from the reclassification in the genus *Klebsiella* of many nonmotile strains previously labeled *"A. aerogenes"*, Hormaeche and Edwards (1960a, b) proposed a new genus, *Enterobacter*, as a substitute for *"Aerobacter"*. This genus was then composed of *E. cloacae* (type species) and *E. aerogenes*. The Judicial Commission of the International Committee on Nomenclature of Bacteria placed the name *Enterobacter* on the list of conserved names (Judicial Commission, 1963).

The genus *Erwinia* has long been a depository for plant-associated members of the *Enterobacteriaceae*. Several species of this genus were found phenotypically similar to *Enterobacter* species (*Erwinia herbicola*, *Erwinia ananas**, *Erwinia uredovora*, *Erwinia milletiae*, *Erwinia dissolvens*, *Erwinia nimipressuralis*) (Lelliott, 1974; Lelliott and Dickey, 1984) or highly related to *Enterobacter* species by DNA hybridization (*Erwinia dissolvens*, *Erwinia nimipressuralis*) (Steigerwalt et al., 1976).

The other *Enterobacter* species have been described after delineation by DNA–DNA hybridization. DNA–DNA hybridization has allowed bacteriologists to modify the circumscription of some species and to find synonymies.

Enterobacter taylorae was described based on clinical strains closely related to *E. cloacae* (Farmer et al., 1985b). The species was later found synonymous to *Enterobacter cancerogenus* by both DNA relatedness and phenotypic characters (Grimont and Ageron, 1989).

Early DNA relatedness studies on *E. cloacae* (Steigerwalt et al., 1976) showed the genomic heterogeneity of this nomenspecies. In work done in our laboratory (Grimont and Grimont, 1992; and unpublished) on 49 strains previously identified as *E. cloacae*, 45 strains fell into five DNA relatedness groups (1 to 5). Group 1 contained only three strains, including the type strains of *E. cloacae* and *E. dissolvens*. DNA from these type strains showed some divergence (ΔT_m values of 4.5°C). In spite of a search for similar strains in our large laboratory collection, no other strain of group 1 could be found. Group 2 contained seven strains, including

1. Maintenance medium (g/liter): Bacto-peptone (Difco), 10.0, NaCl, 5.0: Bacto-agar (Difco), 10.0; pH 7.4. The medium should be dispensed into small (9.5–10 × 90 mm) screw-capped tubes.

**Editorial Note:* Mergaert et al. (1993) transferred *Erwinia ananas* to the genus *Pantoea* as *P. ananas*; the name was corrected to *Pantoea ananatis* by Trüper and De' Clari (1997).

reference strain CDC 1347-71 (Steigerwalt et al., 1976). Group 3 contained 15 strains, including the type strain of *Enterobacter hormaechei*. This group was slightly heterogeneous with ΔT_m values ranging from 0.0–4.0°C. Group 4 contained 17 strains and could be split into three subgroups based on ΔT_m values (0.0–2.5°C within subgroup and 4.0–6.5°C between subgroups). Subgroup 4a contained the type strain of *Enterobacter asburiae*. Group 5 (earlier referred to as group 6 (Bouvet et al., 1989)) contained three nitrogen-fixing strains.

Three problems are raised by this study. The first problem involves *E. hormaechei*. A group of similar strains (Enteric group 75), which differ phenotypically from *E. cloacae*, was genomically distinct from the type strain of *E. cloacae* and thus described as a new species, *E. hormaechei* (O'Hara et al., 1989). In our group 3, we found only one strain phenotypically similar to *E. hormaechei*. All other strains of group 3 fit the classical definition of *E. cloacae* (Richard, 1984). Group 3 strains (including *E. hormaechei*) produce an active glucose dehydrogenase, and this property differentiates group 3 from the other groups in the *E. cloacae* complex (Bouvet et al., 1989; P.A.D. Grimont, unpublished observations). Group 3 should be named *E. hormaechei*, and the species definition should be emended.

The second problem involves *E. asburiae*. Enteric group 17 differed from *E. cloacae* by some phenotypic features and DNA hybridization showed Enteric Group 17 (*E. asburiae*) to be distinct from the type strain of *E. cloacae*. Our subgroup 4a is genomically and phenotypically identical with *E. asburiae*. However, subgroups 4b and 4c are less differentiable from *E. cloacae* by phenotypic characteristics. Group 4 (including subgroups 4a, 4b, and 4c) should be called *E. asburiae*, and the species definition should be amended.

The third problem is in fact the cause of the other two. The choice of the neotype strain for *E. cloacae* was unfortunate. This strain was isolated from cerebrospinal fluid, which is not the usual habitat of what is currently known as *E. cloacae*. There are two possible solutions: either the nomenclatural rules are followed, in which case *E. cloacae* (our group 1) will disappear from routine clinical laboratory work (because most strains presently labeled *E. cloacae* are in fact *E. hormaechei* or *E. asburiae*), or the type strain can be changed and a new one designated from our group 2 (which can be encountered in clinical microbiology, although less frequently than *E. hormaechei* and *E. asburiae* genomic species).

Some species that were included in the genus *Enterobacter* are now excluded; these are discussed below.

The group of strongly proteolytic strains named *"Aerobacter liquefaciens"* by Grimes and Hennerty (1931) was included in the genus *Enterobacter* by Edwards and Ewing (1972). The species was transferred to the genus *Serratia* as *S. liquefaciens* by Bascomb et al. (1971).

A group of strains named *Hafnia* by Møller (1954) was included in the genus *Enterobacter* as *E. hafniae* (Ewing and Fife, 1968). This species appeared in the 8th edition of the *Bergey's Manual* (Buchanan and Gibbons, 1974) as *Hafnia alvei*. Steigerwalt et al. (1976) favored the separation of *Hafnia alvei* from the genus *Enterobacter* based on DNA relatedness studies.

E. aerogenes is closer to *Klebsiella pneumoniae* (about 55% DNA relatedness) than to *E. cloacae* (about 45% relatedness) (Brenner et al., 1972c; Steigerwalt et al., 1976). In a numerical taxonomy study (Bascomb et al., 1971), *E. aerogenes* was so similar to the genus *Klebsiella* that transfer of this species to the genus *Klebsiella* was proposed. Since the name *"K. aerogenes"* had been used for bacteria that are indistinguishable from *K. pneumoniae* by DNA relatedness, the name *K. mobilis* was proposed for *E. aerogenes* (Bascomb et al., 1971). The species is treated in the chapter on the genus *Klebsiella* as *K. mobilis*.

E. agglomerans is a very complex group of environmental bacteria that may cause opportunistic infections. The name covers many (20–40) genomic groups (Brenner et al., 1988b) or phenons (Gavini et al., 1983b; Verdonck et al., 1987). In addition to this diversity, strains of the *E. agglomerans* complex are not closely related to *E. cloacae* (the type species of the genus *Enterobacter*) by DNA relatedness. Some groups in this complex have been placed in new genera (*Rahnella aquatilis*, *Ewingella americana*, *Leclercia adecarboxylata*). A new genus, *Pantoea*, has been proposed for several groups of the *E. agglomerans* complex. These are treated in the chapter on the genus *Pantoea*.

Enterobacter intermedius (originally named *E. intermedium*; corrected by von Graevenitz (1990)) was a Voges–Proskauer positive species found in water and unpolluted soil (Izard et al., 1980). However, it has an *rrs* sequence identical to that of *Kluyvera cochleae*. Furthermore, DNA–DNA hybridization has shown the type strains of *E. intermedius* and *K. cochleae* to be 99% related with a thermal instability of hybridized molecules of 1.5°C (D.J. Brenner, personnal communication).

Differentiation of the species of the genus *Enterobacter*

Tables BXII.γ.220 and BXII.γ.221 give the characteristics differentiating the species and unnamed genomic groups in the genus *Enterobacter*.

List of species of the genus Enterobacter

1. **Enterobacter cloacae** (Jordan 1890) Hormaeche and Edwards 1960b, 72[AL]. Nom. Cons. Opin. 28, Jud. Comm. 1963, 38 (*Bacillus cloacae* Jordan 1890, 836.)

clo.a' cae. L. n. *cloaca* a sewer; L. gen. n. *cloacae* of sewer.

The cell and colonial morphology are as given for the genus. Physiological and nutritional characteristics are presented in Tables BXII.γ.220, BXII.γ.221 and BXII.γ.222. Several DNA hybridization groups compose this species. Some of these DNA groups can be identified to named species (*E. dissolvens*, *E. asburiae*, or *E. hormaechei*) with different circumscriptions than originally published. Occurs in water, sewage, soil, meat, and hospital environments and on the skin and in the intestinal tracts of man and animals as a commensal. May cause nosocomial infections

The mol% G + C of the DNA is: 52–54 (T_m).

Type strain: ATCC 13047, CIP 60.85, DSM 30054, JCM 1232, LMG 2783, NCTC 10005.

GenBank accession number (16S rRNA): AJ417484.

This strain is very close by DNA–DNA hybridization to the type strain of *E. dissolvens* and may not properly represent the strains routinely identified as *E. cloacae*.

D-Raffinose	−	+	+	+	+	+	+
D-Sorbitol	−	+	+	+	+	+	+

[a] +, all strains positive in 1–2 days; −, strains negative in 4 days; d, positive or negative in 1–4 days.

[b] Five strains representing *E. hormaechei* (including the type strain) and received from the Centers for Disease Control corresponded to biogroup 3a.

2. **Enterobacter amnigenus** Izard, Gavini, Trinel and Leclerc 1981b, 37[VP]

am.ni′ge.nus. L. adj. *amnigenus* coming from water.

The cell and colonial morphology are as given for the genus. Physiological and nutritional characteristics are presented in Table BXII.γ.220. Isolated from water and rarely from clinical samples.

The mol% G + C of the DNA is: 60 (Bd).

Type strain: ATCC 33072, CCUG 14182, CIP 103169, DSM 4486, JCM 1237, LMG 2784, NCTC 12124..

GenBank accession number (16S rRNA): AB004749.

3. **Enterobacter asburiae** Brenner, McWhorter, Kai, Steigerwalt and Farmer III 1988b, 220[VP] (Effective publication: Brenner, McWhorter, Kai, Steigerwalt and Farmer III 1986, 1117.)

as.bur′i.ae. N.L. gen. n. *asburiae* named in honor of Marie Alyce Fife-Asbury, an American bacteriologist.

The cell and colonial morphology are as given for the genus. Physiological and nutritional characteristics are included in Tables BXII.γ.220 and BXII.γ.221.

The type strain belongs in DNA group 4a in the *E. cloacae* complex.

The mol% G + C of the DNA is: 55 (T_m).

Type strain: ATCC 35953, CIP 103358, JCM 6051, NCTC 12123.

GenBank accession number (16S rRNA): AB004744.

4. **Enterobacter cancerogenus** (Urosevic 1966) Dickey and Zumoff 1988, 373[VP] *Erwinia cancerogena* Urosevic 1966, 500.)

can.cer.o′ge.nus. L. *cancer* crab, the disease cancer; L. v. *gigno* to produce; L. masc. adj. *cancerogenus* cancer-inducing.

The cell and colonial morphology are as given for the genus. Physiological and nutritional characteristics are presented in Table BXII.γ.220.

Isolated from cankers in poplars (*Populus* species) in

Czechoslovakia and in clinical specimens. *Enterobacter taylorae* (Farmer et al. 1985b; type strain ATCC 35317 = CDC 2126-81) is a junior synonym of *E. cancerogenus* (Grimont and Ageron, 1989).

The mol% G + C of the DNA is: not determined.

Type strain: ATCC 33241, CCUG 25231, CFBP 4167, CIP 103787, ICMP 5706, LMG 2693, NCBBP 2176.

GenBank accession number (16S rRNA): Z96078.

5. **Enterobacter cowanii** Inoue, Sugiyama, Kosako, Sakazaki and Yamai 2001, 1619[VP] (Effective publication: Inoue, Sugiyama, Kosako, Sakazaki and Yamai 2000, 419.)
co.wa′ ni.i. M.L. gen. n. *cowani* of Cowan, named after S.T. Cowan, British bacteriologist.

The cell morphology is as given for the genus. Colonies on nutrient agar are often yellow pigmented. Physiological and nutritional characteristics are presented in Table BXII.γ.220. Isolated from diverse clinical specimens but clinical significance is unknown. May be found in foods.

The mol% G + C of the DNA is: 53 (HPLC).

Type strain: 88-76, CIP 107300, JCM 10956.

6. **Enterobacter dissolvens** (Rosen 1922) Brenner, McWhorter, Kai, Steigerwalt and Farmer III 1988b, 220[VP] (Effective publication: Brenner, McWhorter, Kai, Steigerwalt and Farmer III 1986, 1119 (*"Phytomonas dissolvens"* Rosen 1922, 497; *Erwinia dissolvens* (Rosen 1922) Burkholder 1948a, 472.)
dis.sol′ vens. L. part. adj. *dissolvens* dissolving.

The cell and colonial morphology are as given for the genus. Physiological and nutritional characteristics are included in Tables BXII.γ.220 and BXII.γ.221. Presently, it is not possible to phenotypically differentiate *E. dissolvens* from *E. cloacae*.

The type strain belongs in DNA group 1 in the *E. cloacae* complex. Originally isolated from diseased corn.

The mol% G + C of the DNA is: 54 (Bd).

Type strain: ATCC 23373, CIP 105586, ICMP 1570, JCM 6049, LMG 2683, NCBBP 1850.

GenBank accession number (16S rRNA): AJ417485, Z96079.

The type strain belongs in the *Enterobacter cloacae* complex.

7. **Enterobacter gergoviae** Brenner, Richard, Steigerwalt, Asbury and Mandel 1980b, 1[VP]
ger.go′ vi.ae. M.L. gen. n. *gergoviae* of Gergovie Highland, France.

The cell and colonial morphology are as given for the genus. Physiological and nutritional characteristics are presented in Table BXII.γ.220. Occurs in various environmental sources such as cosmetics or water. Has also been recovered from clinical specimens.

The mol% G + C of the DNA is: 60 (Bd).

Type strain: ATCC 33028, CIP 76.1, DSM 9245, JCM 1234, LMG 5739, NCTC 11434.

GenBank accession number (16S rRNA): AB004748.

8. **Enterobacter hormaechei** O'Hara, Steigerwalt, Hill, Farmer, Fanning and Brenner 1990, 105[VP] (Effective publication: O'Hara, Steigerwalt, Hill, Farmer, Fanning and Brenner 1989, 2048.)
hor.ma.e′ che.i. M.L. gen. n. *hormaechei* of Hormaeche, named after Estenio Hormaeche, Uruguayan microbiologist.

The cell and colonial morphology are as given for the genus. Physiological and nutritional characteristics are presented in Tables BXII.γ.220 and BXII.γ.221. Oxidation of glucose into gluconate in the absence of PQQ is a characteristic of the *E. hormaechei* genomic group. Isolated from clinical specimens.

The mol% G + C of the DNA is: not determined.

Type strain: ATCC 49162, CCUG 27126, CIP 103441.

GenBank accession number (16S rRNA): AJ417450.

9. **Enterobacter kobei** Kosako, Tamura, Sakazaki and Miki 1997, 915[VP] (Effective publication: Kosako, Tamura, Sakazaki and Miki 1996, 264.)
kobe.i. M.L. gen. n. *kobei* pertaining to the city of Kobe, Japan.

The cell and colonial morphology are as given for the genus. Physiological and nutritional characteristics are presented in Table BXII.γ.220. Isolated from diverse clinical specimens but clinical significance is unknown. May be found in foods.

The mol% G + C of the DNA is: 53 (T_m).

Type strain: ATCC BAA-260, CIP 105566, DSM 13645, JCM 8580.

10. **Enterobacter nimipressuralis** (Carter 1945) Brenner, McWhorter, Kai, Steigerwalt and Farmer 1988b, 220[VP] (Effective publication: Brenner, McWhorter, Kai, Steigerwalt and Farmer III 1986, 1119 (*"Erwinia nimipressuralis"*) Carter 1945, 423; Dye 1969a, 83.)
ni.mi.pres.su.ra′ lis. L. adv. *nimis* overmuch; L. n. *pressura* pressure; M.L. adj. *nimipressuralis* with excessive pressure.

The cell and colonial morphology are as given for the genus. Physiological and nutritional characteristics are presented in Table BXII.γ.220. Reported as the causative agent of "wetwood" disease in elm trees (Carter, 1945).

The mol% G + C of the DNA is: 55 (Bd).

Type strain: ATCC 9912, CIP 104980, ICMP 1577, JCM 6050, NCPPB 2045.

GenBank accession number (16S rRNA): Z96077.

11. **Enterobacter pyrinus** Chung, Brenner, Steigerwalt, Kim, Kim and Cho 1993b, 161[VP]
pyr′ i.nus. L. n. *pyrus* pear; L. suff. *-inus* belonging to; L. adj. *pyrinus* from pears.

The cell and colonial morphology are as given for the genus. Physiological and nutritional characteristics are presented in Table BXII.γ.220. Isolated from brown leaf spot lesions on pear trees in Korea.

The mol% G + C of the DNA is: 57–61 (T_m).

Type strain: ATCC 49851, CFBP 4168, CIP 104019, DSM 12410, ICMP 12530.

12. **Enterobacter sakazakii** Farmer, Asbury, Hickman and Brenner 1980a, 575[VP]
sa.ka.za′ ki.i. M.L. gen. n. *sakazakii* of Sakazaki; named after the Japanese bacteriologist, Riichi Sakazaki.

The cell and colonial morphology are as given for the genus. Physiological and nutritional characteristics are presented in Table BXII.γ.220. Occurs in the environment and in foods. May contaminate milk powder and subsequent nutritional preparations and then cause generalized infection (septicemia, meningitis) in newborns.

The mol% G + C of the DNA is: 57 (T_m).

Type strain: ATCC 29544, CCUG 14558, CIP 103183, DSM 4485, JCM 1233, LMG 5740, NCTC 11467.

GenBank accession number (16S rRNA): AB004746.

Genus XIII. **Erwinia** *Winslow, Broadhurst, Buchanan, Krumwiede, Rogers and Smith 1920, 209*[AL] *emend. Hauben, Moore, Vauterin, Steenackers, Mergaert, Verdonck and Swings 1999a, 1*

LYSIANE HAUBEN AND JEAN SWINGS

Er.wi' ni.a. M.L. fem. n. *Erwinia* named after Erwin F. Smith.

Straight rods, 0.5–1.0 × 1.0–3.0 µm; occur singly or in pairs. Gram negative. Motile by peritrichous flagella. Facultatively anaerobic, but anaerobic growth by some species is weak. Optimum temperature, 27–30°C; maximum temperature for growth is 40°C. Oxidase negative. Catalase positive. **Pectinase negative.** Acid is produced from fructose, D-galactose, D-glucose, and sucrose but not from adonitol, arabitol, dextrin, dulcitol, inulin, maltose, starch, and tagatose. Utilize fumarate, D-galactose, gluconate, D-glucose, glycerol, β-methylglucoside, malate, and succinate, but not L-arabitol, benzoate, butanol, methanol, oxalate, propionate, or sorbose as carbon- and energy-yielding sources. Utilize L-alanine, L-glutaminic acid, glycylglycine, and L-serine, but not kynureninic acid and trigonelline, as nitrogen sources. Sensitive to chloramphenicol, furazolidone, nalidixinic acid, oxytetracyline, and tetracycline. Do not possess arginine dihydrolase, caseinase, pectinase, phenylalanine deaminase, or urease. Associated with plants as pathogens, saprophytes, or constituents of the epiphytic flora.

The species of the genus *Erwinia* comprise a distinct phylogenetic group, as determined by 16S rRNA gene sequence comparisons, and are characterized by 14 generic signature nucleotides (Table BXII.γ.223).

Erwinia species cause plant diseases that include mainly blights and wilts. The pathogen usually starts to cause damage in the vascular tissue and then spreads throughout the plant. Ingress by the pathogen generally occurs through natural openings and wounds.

The mol% G + C of the DNA is: 49.8–54.1.

Type species: **Erwinia amylovora** (Burrill 1882) Winslow, Broadhurst, Buchanan, Krumwiede, Rogers and Smith 1920, 209 emend. Hauben, Moore, Vauterin, Steenackers, Mergaert, Verdonck and Swings 1999a, 1 (*Micrococcus amylovorus* Burrill 1882, 134.)

FURTHER DESCRIPTIVE INFORMATION

Gas production is comparatively weak or absent. Decarboxylases for arginine, lysine, or ornithine cannot be detected by Møller's method (Møller, 1955). Formation of putrescine occurs when the amino acids are decarboxylated under aerobic conditions (Zherebilo and Gvozdyak, 1976). Glutamic acid is not decarboxylated. Lipases are rarely produced. Additional characteristics of the species of the genus are given in Tables BXII.γ.223, BXII.γ.224, and BXII.γ.225.

Fermentation end products from glucose are CO_2 and different combinations of succinate, lactate, formate, and acetate; some strains form 2,3-butanediol and some ethanol (White and Starr, 1971). Starch is not hydrolyzed beyond dextrins.

Sequence analyses on 16S rDNA of the species of the genus *Erwinia* by Kwon et al. (1997) and Hauben et al. (1998a) are in good agreement and place the genus *Erwinia* within the *Enterobacteriaceae*, closely related to the genera *Pantoea*, *Pectobacterium*, *Brenneria*, and *Enterobacter* (Fig. BXII.γ.201; Table BXII.γ.223).

Burrill (1882) was the first to attribute the cause of a plant disease to a bacterium, which he named *"Micrococcus amylovorus"*. In successive taxonomic studies, the bacterium was renamed *"Bacillus amylovorus"* (Trevisan, 1889a), *"Bacterium amylovorus"* (Chester, 1897), *"Bacterium amylovorum"* (Serbinov, 1915), and finally *Erwinia amylovora* (Winslow et al., 1920). *Erwinia* species cause plant diseases that include blights, die back, leaf spots, wilts, and crown rot. *Erwinia tracheiphila* overwinters in the bodies of cucumber beetles (*Diabrotica vittata* Fabr. and *D. duodecimpunctata* Oliv.) (Leach, 1964).

Phytopathogenicity of *Erwinia rhapontici* and *Erwinia persicina** may be due to the release of proferrorosamines (Feistner et al., 1997).

ENRICHMENT AND ISOLATION PROCEDURES

In general, *Erwinia* can be easily isolated. The affected plant material is washed in tap water, followed by sterile water, and dried by paper toweling. Surface sterilization (3 min in 1:10 dilution of 5.25% active sodium hypochlorite) is sometimes detrimental for isolation. Affected tissue is removed from a young lesion or the edge of older necrotic areas by a sterile scalpel; the tissue is crushed in sterile water, saline, or buffer solution and is streaked onto a solid medium, such as nutrient agar or yeast dextrose chalk agar (YDC) (0.5% yeast extract, 1% dextrose, 3% calcium carbonate) (Dye, 1968). The isolation of *E. tracheiphila* is more easily accomplished by aseptically cutting the affected stem, placing the two cut stem surfaces together, and then gently pulling apart, removing a portion of the threads of bacteria and placing them in nutrient broth or onto a solid medium (Burkholder, 1960b). The delicate growth of *E. tracheiphila* will appear in 3–4 d; frequent transfer is necessary, but virulence may be reduced or lost after repeated transfers.

The isolation of some *Erwinia* species can be facilitated by use of selective-differential media, but such media are usually not necessary. *E. amylovora* will grow on MS medium (Miller and Schroth, 1972) and produce characteristic colonies. Later, Schroth and Hildebrand (1980) substituted D-mannitol by D-sorbitol in the MS medium for the isolation of *E. amylovora*. The medium of Crosse and Goodman (1973)[1] or CCT medium[2] can also be used for *E. amylovora*. A soluble pink pigment is produced by *E. persicina* and *E. rhapontici* (Hao et al., 1990) on medium containing 1% casitone, 0.3% yeast extract, 0.5% NaCl, and 0.7% agar.

MAINTENANCE PROCEDURES

Stock cultures of *Erwinia* species should be grown on standard media of choice at 25–30°C until good growth occurs. The cul-

Editorial Note: Erwinia persicina was originally known as *Erwinia persicinus*; the name was corrected by Euzéby (1998).

1. Crosse and Goodman's medium consists of sucrose, 160 g; nutrient agar, 12 g; 0.1% crystal violet in absolute ethanol, 0.8 ml; 0.1% cycloheximide, 20 ml; 380 ml distilled water.

2. CCT medium consists of sucrose, 100 g; D-sorbitol, 10 g; 1% tergitol anionic 7, 30 ml; 0.1% crystal violet in absolute ethanol, 2 ml; nutrient agar (Difco), 23 g; 970 ml distilled water; after autoclaving add 2 ml 1% (w/v) thallium nitrate and 50 mg cycloheximide (Ishimaru and Klos, 1984).

tures can be maintained for a maximum of 3 weeks in a refrigerator (4–5°C).

For long-term preservation, erwiniae can be successfully stored as lyophilized cultures usually suspended in a filter sterilized mixture of 200 ml horse serum (Oxoid SR035C) to which 1675 mg nutrient broth (Oxoid) and 20 g glucose in 67 ml distilled water is added. Strains have also been stored in liquid nitrogen and in glycerol at −80°C (broth + 15% glycerol). Regular viability controls are recommended.

Differentiation of the genus *Erwinia* from other genera

Characteristics that differentiate *Erwinia* from the genera *Pectobacterium*, *Pantoea*, and *Brenneria* are given in Table BXII.γ.223. As it is very difficult to differentiate them phenotypically; genomic methods are recommended for differentiation.

Taxonomic Comments

The genus *Erwinia*, named after the phytobacteriologist Erwin F. Smith, was created in 1920 to unite all Gram-negative, fermentative, nonsporulating, peritrichously flagellated plant-pathogenic bacteria (Winslow et al., 1920). The taxonomy of the genus *Erwinia* and designation of species in the genus has been complicated by the heterogeneity of the strains included in the taxon. It has been suggested in the past that members of the genus be placed into new groupings with other members of the *Enterobacteriaceae* (Starr and Mandel, 1969; White and Starr, 1971). This concept also was supported by studies of DNA–DNA relatedness (Gardner and Kado, 1972), DNA relatedness (Brenner et al., 1974a), and DNA–DNA segmental relatedness (Murata and Starr, 1974).

Waldee (1945) suggested that *Erwinia* should be limited to pathogens (*E. amylovora*, *Erwinia salicis*, and *E. tracheiphila*) that cause necrotic or wilt diseases, utilize a restricted range of carbon compounds, and usually require organic nitrogen compounds for growth, and that the biochemically more active soft rotting pathogens (*Erwinia carotovora* and *Erwinia chrysanthemi*) should be placed in a separate genus *Pectobacterium*. Although some workers have supported this suggestion (Brenner et al., 1973b, 1974a), it was not generally accepted because some species are taxonomically intermediate between these two groups, i.e., they resemble *E. carotovora* in most of their characteristics but do not cause rots.

Taxonomic changes since the previous edition of *Bergey's Manual of Systematic Bacteriology* The species *Erwinia herbicola*, *Erwinia milletiae* (Gavini et al., 1989b), *Erwinia ananas*, *Erwinia uredovora*, and *Erwinia stewartii* (Mergaert et al., 1993) have been transferred to the genus *Pantoea*. The species *incertae sedis Erwinia dissolvens*, *Erwinia nimipressuralis* (Brenner et al., 1986), and *E. cancerogena* (Dickey and Zumoff, 1988) have been transferred to the genus *Enterobacter*. Five new *Erwinia* species and two new subspecies were created: *Erwinia alni* (Surico et al., 1996), *Erwinia billingiae* (Mergaert et al., 1999), *Erwinia cacticida* (Alcorn et al., 1991), *Erwinia persicina* (Hao et al., 1990), *Erwinia psidii* (Rodrigues-Neto et al., 1987), *E. carotovora* subsp. *odorifera* (Gallois et al., 1992), and *E. carotovora* subsp. *wasabiae* (Goto and Matsumoto, 1987).

Confusion exists about the organisms named *Erwinia carnegieana*. None of the original isolates are available and no strains have been isolated corresponding to the original description (Alcorn and Orum, 1988). The type strain of *E. carnegieana* NCPPB 439 is nonpectinolytic and non-plant pathogenic and was identified as a *Klebsiella pneumoniae* (Graham, 1964; Edwards and Ewing, 1972; Alcorn and Orum, 1988).

Recently obtained sequence data allowed estimations of phylogenetic relationships, shed a new light on these earlier viewpoints, and raised new perspectives for the taxonomy of the genus

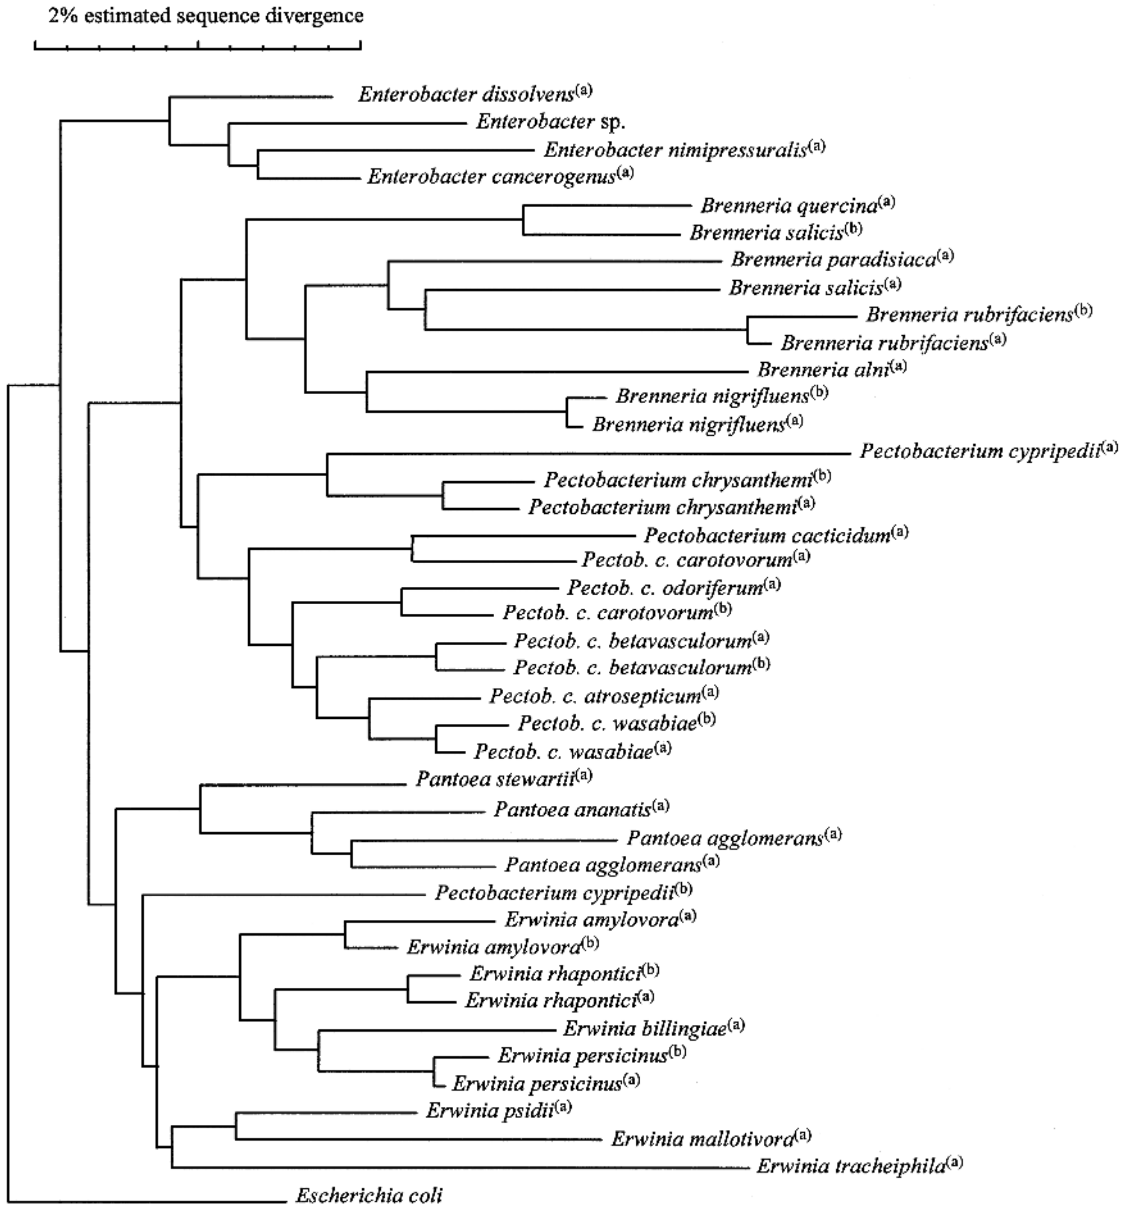

FIGURE BXII.γ.201. Neighbor-joining dendrogram depicting the estimated phylogenetic relationships among the genera *Erwinia*, *Pectobacterium*, *Brenneria*, *Pantoea*, and *Enterobacter*, based on pairwise comparisons of nearly complete 16S rDNA sequences calculated with the software package GeneCompar (Applied Maths, Kortrijk, Belgium), after removal of all unknown bases and gaps. The distance between two species is obtained by summing the lengths of the connecting horizontal branches using the scale on the top. *Pectob. c.* = *Pectobacterium carotovorum* subspecies; *(a)*: 16S rDNA sequence obtained from Hauben et al. (1998a); *(b)*: 16S rDNA sequence obtained from Kwon et al. (1997).

Erwinia. After comparison of the 16S rDNA sequences of representatives of the genus *Erwinia* with other members of the *Enterobacteriaceae*, the phylogenetic positions of the *Erwinia* species were determined, and led to the emended description of the genera *Erwinia* and *Pectobacterium* and to the description of the new genus *Brenneria* (Hauben et al., 1998a).

Differentiation of the species of the genus *Erwinia*

The characteristics of the species of *Erwinia* are given in Tables BXII.γ.223, BXII.γ.224, and BXII.γ.225. Only four strains of *E. tracheiphila* were studied, and data for this species should be treated with caution.

List of species of the genus Erwinia

1. **Erwinia amylovora** (Burrill 1882) Winslow, Broadhurst, Buchanan, Krumwiede, Rogers and Smith 1920, 209^{AL} emend. Hauben, Moore, Vauterin, Steenackers, Mergaert, Verdonck and Swings 1999a, 1 (*Micrococcus amylovorus* Burrill 1882, 134.)
a.my.lo′vo.ra. Gr. n. *amylum* starch; L. v. *voro* to devour; M.L. fem. adj. *amylovora* starch-destroying.

The characteristics are as given for the genus and as listed in Tables BXII.γ.224 and BXII.γ.225.

The virulence of *E. amylovora* is often correlated with its capacity to produce extracellular polysaccharides (or EPS, e.g., amylovoran), lipopolysaccharide, a high-molecular-mass levan, a low-molecular-mass glucan (Roberts and Coleman, 1991), and levansucrase (Gross et al., 1992). Levansucrase-negative mutants show retarded development of necrotic symptoms on inoculated pear seedlings (Geier and Geider, 1993). RcsA and RcsB are two regulator proteins that interact with the promoter of the operon for amylovoran biosynthesis (Bereswill and Geider, 1997; Kelm et al., 1997). The genes *amsA* to *amsI* are required for exopolysaccharide synthesis (Bugert and Geider, 1995, 1997).

After 2–3 days at 27°C, colonies on 5% sucrose nutrient agar are typically white, domed, shining, mucoid (levan type) with radial striations, and a dense flocculent center or central ring. Nonlevan forms are isolated rarely.

Several regions of the bacterial DNA of *E. amylovora* are species specific and can be used for identification by (1) a PCR assay with primers AMSbL (5′-GCTACCAGCAGGGTGAG-3′) and AMSbR (5′-TCATCACGATGGTGTAG-3′) derived from the ams region, with an annealing temperature of 49°C (Bereswill et al., 1995); (2) a typical banding pattern derived from arbitrarily primed PCR with oligonucleotide APT1 (5′-CAGGACGCTACTTGTGT-3′), annealing temperature 32°C, from the sequence of transposon Tn5 (Bereswill et al., 1995); (3) a PCR assay with primers, primer A (5′-CGGTTTTTAACGCTGGG-3′) and primer B (5′-GGGCAAATACTCGGATT-3′), annealing at 52°C, derived from a 29-kb plasmid (pEA29) that modulates the development of fire blight (Falkenstein et al., 1989; Bereswill et al., 1992); (4) nested PCR with primers A (5′-CGGTTTTTAACGCTGGG-3′), B (5′-GGGCAAATACTCGGATT-3′), AJ75 (5′-CGTATTCACGGCTTCGCAGAT-3′), and AJ76 (5′-ACCCGCCAGGATAGTCGCATA-3′) with an annealing temperature of 52°C, and PCR-dot-blot hybridizations derived from pEA29 (McManus and Jones, 1995); and (5) a PCR assay with primers EaF (5′-GCGCAGTAAAGGGTGACAGCCCCGTACACAAAAAGGCACT-3′) and EaR (5′-CCCTAGCCGAAACAGTGCTCTACCCCCGG-3′) derived from the 23S rDNA sequence, with an annealing temperature of 72°C (Maes et al., 1996).

Repetitive element PCR (rep-PCR) (McManus and Jones, 1994) and RAPD fingerprinting (Momol et al., 1997) can distinguish *E. amylovora* strains isolated from Pomaceae from strains isolated from *Rubus* (subfamily Rosaceae). Pulsed field gel electrophoresis (PFGE) can distinguish *E. amylovora* strains of different geographical origin (Zhang and Geider, 1997).

E. amylovora produces harpins, bacterial protein elicitors that induce hypersensitive response-like necrosis when infiltrated into nonhost plants such as tobacco (Wei et al., 1992). Harpin activates a myelin basic protein kinase in tobacco leaves (Popham et al., 1995; Adam et al., 1997) and elicits active oxygen production in suspension cells (Baker et al., 1993). The secretion of harpin occurs via a type III pathway, similar to the export system of pathogenic proteins of *Yersinia* spp. (Bogdanove et al., 1996). These proteins are encoded by the *hrp* gene cluster, consisting of seven transcriptional units (Wei and Beer, 1995; Kim et al., 1997b). The *dsp* genes also affect pathogenicity but not the eliciting of a hypersensitive response (Roberts and Coleman, 1991). The expression of the *hrp* and *dsp* genes is temperature-sensitive.

Plasmid pULB113 was found in *E. amylovora*, mediating chromosomal mobilization and R-prime formation (Chatterjee et al., 1985). The self-transmissible 56-kb plasmid Ea322 is not involved in pathogenicity (Steinberger et al., 1990). pEa8.7, an 8.7-kb plasmid was found in streptomycin- and sulfonamide-resistant strains (Palmer et al., 1997). The genes *strA* and *strB* were found in streptomycin-resistant strains (Chiou and Jones, 1991, 1995; McManus and Jones, 1994).

Cells infected with bacteriophage ERA103 produce an enzyme that degrades the extracellular polysaccharide of noninfected cells (Vandenburgh et al., 1985). *E. amylovora* cells are sensitive to bacteriophage Mu, which can be used as a genetic tool (Vanneste et al., 1990).

Several monoclonal antibodies have been produced against *E. amylovora* strains (Schaad, 1979) that can be used for the detection of the bacterium in suspensions as well as in contaminated twigs, plant fluids, and fruit tissues. The following methods can be applied: (1) Slide agglutination tests: agglutination with *E. amylovora* antiserum is a common and accurate method of determination (Lelliott, 1968; Zielke et al., 1993; Arsenijevic et al., 1994); the species is serologically homogeneous and has few agglutinogens in common with related species or with the saprophytes found in diseased material. (2) Immunofluorescence techniques (IFT) (Lin et al., 1987; Zielke et al., 1993). (3) Enzyme-linked immunosorbent assays (double-antibody sandwich [DAS]-ELISA) (Laroche and Verhoyen, 1984; Lin et al., 1987; Zielke et al., 1993). The sensitivity of the three methods is approximately the same, i.e., 10^5 cells/ml.

Pantoea agglomerans and *Pseudomonas fluorescens* are antagonistic toward *E. amylovora* (Wilson et al., 1992; Wilson and Lindow, 1993; Wodzinski et al., 1994; Kearns and Hale, 1995, 1996; Mercier and Lindow, 1996).

E. amylovora causes a necrotic disease (fire blight) of most species of the Pomaceae and of some species in other subfamilies of the Rosaceae. Early in the season blossom and tips of twigs die back. Leaves shrivel and blacken and remain attached to the blackening stem that frequently crooks characteristically at the tip. The disease may progress into larger branches or even the trunk and form a canker. A *forma specialis* has been described from raspberry (*Rubus idaeus*) by Starr and Folsom (1951).

The mol% G + C of the DNA is: 53.6–54.1 (Bd).

Type strain: ATCC 15580, ICMP 1540, LMG 2024, NCPPB 683.

GenBank accession number (16S rRNA): Z96088, U80195.

2. **Erwinia aphidicola** Harada, Oyaizu, Kosako and Ishikara 1998, 1083^{VP} Harada, Oyaizu, Kosako and Ishikara 1997, 354

a.phi' di.co.la. L. *aphid* the aphid; L. suff. *-cola* dweller; M.L. n. *aphidicola* aphid dweller.

Cells are Gram-negative, oxidase-negative, catalase-positive, fermentative rods (0.5–0.6 × 1.6–2.0 μm), and motile by means of peritrichous flagella. All strains grow well on nutrient agar and common laboratory media. Colonies on peptone-yeast extract agar are circular and smooth. These organisms grow well at 25, 30, and 35°C, but not at 42°C. Cells are motile. Voges–Proskauer test is positive, and cells can reduce nitrate. Cells can utilize citrate and malonate. Pigment is not produced. Indole is not produced. No gelatin liquefaction or tryptophan deaminase activity. H_2S production from sodium thiosulfate. No arginine hydrolase activity, no lysine decarboxylase activity, no ornithine decarboxylase activity, no deoxyribonuclease activity, and no urease activity. Acid is produced from the following carbohydrates: glycerol, erythritol, L-arabinose, D-ribose, D-xylose, adonitol, D-galactose, D-glucose, D-fructose, D-mannose, L-rhamnose, inositol, D-mannitol, *N*-acetyl-D-glucosamine, amygdalin, arbutin, esculin, salicin, cellobiose, maltose, melibiose, sucrose, trehalose, raffinose, D-xylitol, β-gentiobiose, D-lyxose, D-fucose, D-gluconate, 2-keto-D-gluconate, and 5-keto-D-gluconate.

The mol% G + C of the DNA is: unknown.

Type strain: IAM 14479.

3. **Erwinia billingiae** Mergaert, Hauben, Cnockaert and Swings 1999, 382^VP^

bil.ling' i.ae. L. gen. n. *billingiae* of Billing, named after Eve Billing, who first isolated these organisms.

The characteristics are as given for the genus and are further listed in Tables BXII.γ.224 and BXII.γ.225.

Antisera prepared against live or heat-killed cells, nonpurified or purified immunogens have been used for the differentiation or identification of *E. tracheiphila* (Elrod, 1946).

Strains were isolated from stem cankers, diseased blossoms, and immature fruits mainly of rosaceous trees, often in association with plant pathogens, and are considered as secondary invaders rather than primary pathogens.

The mol% G + C of the DNA is: 54.1–55.1 (T_m, Bd)

Type strain: LMG 2613, NCPPB 661.

GenBank accession number (16S rRNA): Y13249.

4. **Erwinia mallotivora** Goto 1976, 472[AL] emend. Hauben, Moore, Vauterin, Steenackers, Mergaert, Verdonck and Swings 1999a, 1.

mal.lo.ti' vo.ra. M.L. n. *Mallotus* a genus of trees; L. v. *voro* to devour; M.L. adj. *mallotivora Mallotus*-destroying.

The characteristics are as described for the genus and are further listed in Tables BXII.γ.224 and BXII.γ.225.

Colonies on nutrient agar without sucrose are 1.5 mm in diameter, white, raised, transparent, and circular with smooth surfaces and entire margins after 2 d. Colonies on nutrient agar with 5% sucrose are flat, white, circular with entire margins and smooth surfaces, butyrous, and transparent after 1 d; after 4 d colonies are domed, circular, white, mucoid, and translucent, and sometimes possess radial striations.

Causes a leaf spot of Akamegashiwa, Mongolian oak (*Mallotus japonicus*). Initially, dark green spots appear on the leaves next to the veins. As the disease evolves, these spots grow and turn dark brown with a yellow border. Eventually, the leaf dies and twigs wilt.

The mol% G + C of the DNA is: 49.8–51.0 (Bd).

Type strain: ATCC 29573, ICMP 5705, LMG 2708, NCPPB 2851.

GenBank accession number (16S rRNA): Z96084.

5. **Erwinia persicina** Hao, Brenner, Steigerwalt, Kosaka and Komagata 1990, 382[VP] (*"Erwinia nulandii"*)

per.si' cin.a. M.L. adj. *persicina* peach color, because of the pinkish or peach-colored pigment of this organism.

The characteristics are as described for the genus and are further listed in Tables BXII.γ.224 and BXII.γ.225.

Strains vary in their ability to utilize adonitol, L-arginine, β-gentiobiose, and glucosamine. Resistance to ampicillin, carbenicillin, cefazolin, cephalothin, colistin, kanamycin, mydecamycin, nalidixic acid, sufisoxazole, and tobramycin varies.

Strains were isolated from, but are not pathogenic for, tomato, banana, and cucumber. Strains are pathogenic to bean pods and seeds. One *E. persicina* strain was recently isolated from a human (O' Hara et al., 1998).

The mol% G + C of the DNA is: 52–54 (T_m).

Type strain: ATCC 35998, CDC 9108-82, LMG 11254.

GenBank accession number (16S rRNA): Z96086, U80205.

Additional Remarks: The type strain was isolated from a tomato by Komagata and Okada in 1962.

6. **Erwinia psidii** Rodrigues-Neto, Robbs and Yamoshiro 1988, 328[VP] (Effective publication: Rodrigues-Neto, Robbs and Yamoshiro 1987, 348.)

psi' di.i. L. n. *Psidium* generic name.

The characteristics are as described for the genus and are further listed in Tables BXII.γ.224 and BXII.γ.225.

Pathogenic to guava (*Psidium guajava* L.) causing a dieback of twigs and branches, characterized by a collapse of the vascular tissue. In artificial inoculations, the bacterium was also pathogenic to strawberry guava (*Psidium cattleianum* Lam.), jambolana (*Eugenia jambolana* Lam.), and "melaleuca" (*Melaleuca viridiflora* Brogn. and Gris.), and to all members of the Myrtaceae family.

The mol% G + C of the DNA is: is 51.7–52.2 (T_m).

Type strain: ATCC 49406, ICMP 8426.

7. **Erwinia pyrifoliae** Kim, Gardan, Rhim and Geider 1999, 905[VP]

py.ri.fo' liae. L. gen. fem. n. *pyrifoliae* of *pyrifolia*, the species name of the host plant, the Nashi pear, *Pyrus pyrifolia.*

Cells are Gram-negative, nonsporeforming, peritrichous, straight rods. The strains are facultatively anaerobic; oxidase is not produced. Nitrates are not reduced. This species conforms to the definition of the family *Enterobacteriaceae.* Strains grow on YPDA medium (1% yeast extract, 2% polypeptone, 2% glucose, and 20 μg/ml adenine hemisulfate), producing colonies that are 2 mm after 48 h at 28°C. Colonies are circular, white, well-domed, and opaque. Glucose (dextrose) is fermented without gas production. Voges–Proskauer test is (weakly) positive. Polypectate gel is not acidified or liquefied. Arginine dihydrolase, lysine decarboxylase and ornithine decarboxylase are not present. Indole is not produced from tryptophan. Reducing compounds are produced from sucrose. Acid is not produced

from inulin, lactose, methyl-α-glucoside, melibiose, D-arabitol, D-arabinose, or raffinose. Acid is produced from mannitol, sorbitol, and saccharose. There is no alkalinization of malonate, citrate, or D-tartrate. β-Galactosidase is not produced. The following substrates are utilized as sole sources of carbon and energy: D-fructose, D-galactose, D-trehalose, saccharose, methyl-D-glucopyranoside, D-ribose, L-arabinose, glycerol, *myo*-inositol, D-mannitol, D-sorbitol, L-malate, *N*-acetyl-D-glucosamine, D-gluconate, succinate, fumarate, L-glutamate, and L-proline. The following substances are not utilized: D-mannose, D-sorbose, α-D-melibiose, D-raffinose, maltotriose, maltose, α-lactose, lactulose, methyl-β-galactopyranoside, D-cellobiose, β-gentiobiose, esculin, D-xylose, palatinose, α-L-rhamnose, α-L-fructose, D-arabitol, L-arabitol, xylitol, dulcitol, D-tagatose, maltitol, D-turanose, adonitol, hydroxyquinoline β-glucoside, 3-methyl-D-glucopyranoside, D-saccharate, mucate, L-tartrate, D-tartrate, *meso*-tartrate, D-malate, *trans*-aconitate, tricarballylate, D-glucuronate, D-galacturonate, keto-D-gluconate, L-tryptophan, phenylacetate, protocatechuate, *p*-hydroxybenzoate, quinate, *m*-hydroxybenzoate, benzoate, phenylpropionate, *m*-coumarate, trigonelline, betaine, putrescine, aminobutyrate, histamine, DL-lactate, caprate, caprylate, L-histidine, glutarate, DL-glycerate, aminovalerate, ethanolamine, tryptamine, itaconate, hydroxybutyrate, D-alanine, malonate, propionate, L-tyrosine, and ketoglutarate.

The pathogen was isolated from necrotic symptoms of leaves and branches of *Pyrus pyrifolia* cv. "Shingo". It is closely related to the fire blight pathogen *Erwinia amylovora* by the DNA sequence of the 16S rDNA, but distantly by its intergenic transcribed spacer region (ITS). It does not contain plasmid pEA29 (Rhim et al., 1999).

The mol% G + C of the DNA is: 52 (T_m).

Type strain: Ep16/96, CFBP 4172, CIP 106111, DSM 12163.

GenBank accession number (16S rRNA): AJ009930.

8. **Erwinia rhapontici** (Millard 1924) Burkholder 1948a, 475[AL] emend. Hauben, Moore, Vauterin, Steenackers, Mergaert, Verdonck and Swings 1999a, 1 (*Phytomonas rhapontica* (sic) Millard 1924, 11; *Pectobacterium rhapontici* (Millard 1924) Patel and Kulkarni 1951b, 80; *Erwinia carotovora* biovar rhapontici (Millard 1924) Dye 1969a, 93.)
rha.pon′ti.ci. M.L. n. *rhaponticum* specific epithet of *Rheum rhaponticum*, rhubarb; M.L. gen. n. *rhapontici* of rhubarb.

The characteristics are as described for the genus and are further listed in Tables BXII.γ.224 and BXII.γ.225. Produces proferrorosamine A.

Causes a crown rot of rhubarb (*Rheum rhaponticum*) that extends into the center of the root, pink grain of wheat that will show a cavity below the hilum (Roberts, 1974) and internal browning of hyacinth bulbs, and occurs epiphytically and saprophytically in lesions caused by other bacteria (Sellwood and Lelliott, 1978; Kokoskova, 1992). Rots potato, onion, and cucumber slices slowly, weakly, and erratically (Sellwood and Lelliott, 1978).

The mol% G + C of the DNA is: 51.0–53.1 (Bd).

Type strain: ATCC 29283, ICMP 1582, LMG 2688, NCPPB 1578.

GenBank accession number (16S rRNA): Z96087, U80206.

9. **Erwinia tracheiphila** (Smith 1895) Bergey, Harrison, Breed, Hammer and Huntoon 1923, 173[AL] emend. Hauben, Moore, Vauterin, Steenackers, Mergaert, Verdonck and Swings 1999a, 1 (*Bacillus tracheiphilus* Smith 1895, 364.)
tra.che.i′phi.la. L. n. *trachia* the windpipe; Gr. adj. *philus* loving; M.L. adj. *tracheiphila* trachea-loving, i.e., growing in the tracheiphila of the vascular bundles.

The characteristics are as given for the genus and are further listed in Tables BXII.γ.224 and BXII.γ.225.

Antisera prepared against live or heat-killed cells, nonpurified or purified immunogens have been used for the differentiation or identification of *E. tracheiphila* (Elrod, 1946).

Grows very poorly on nutrient agar but moderately well on yeast extract glucose chalk agar (YCC) (10 g glucose, 5 g yeast extract, 30 g $CaCO_3$, 1.5% agar, 1 l distilled water) or glucose nutrient agar.

Causes a vascular wilt of *Cucurbita* species, *Cirullus lanatus*, and *Cucumis melo*. At first dull wilted areas appear on leaves. Later whole leaves and stems wilt, shrivel, and die. Infection is systemic and bacterial ooze is usually obvious at the cut ends of vascular tissues.

The mol% G + C of the DNA is: 50–52 (T_m, Bd).

Type strain: ATCC 33245, LMG 2906, NCPPB 2452.

GenBank accession number (16S rRNA): Y13250.

Genus XIV. **Ewingella** *Grimont, Farmer, Grimont, Asbury, Brenner and Deval 1984a, 91[VP]* *(Effective publication: Grimont, Farmer, Grimont, Asbury, Brenner and Deval 1983a, 41)*

Caroline M. O'Hara and J.J. Farmer III

Ewing.el′la. M.L. dim. ending *-ella*; M.L. fem. n. *Ewingella* named to honor William H. Ewing an American bacteriologist who made many contributions to the nomenclature and classification of the families *Enterobacteriaceae* and *Vibrionaceae*.

Small rod-shaped cells, 0.6–0.7 × 1–1.8 μm, conforming to the general definition of the family *Enterobacteriaceae*. Contains the enterobacterial common antigen. Motile by 3–10 peritrichous flagella. Facultatively anaerobic. Gram negative, oxidase negative, catalase positive. **Some strains grow faster and are more active biochemically at 25°C than 36°C. Positive reactions for methyl red, Voges–Proskauer, citrate utilization (Simmons), ONPG test, nitrate reduction to nitrite, and acid production from D-glucose, D-mannitol, salicin, trehalose, D-arabitol, D-mannose, and D-galactose.** Utilize 35 of 156 carbon sources. Negative reactions for indole production, H_2S production (TSI), urea hydrolysis, phenylalanine deaminase, lysine decarboxylase, arginine dihydrolase, ornithine decarboxylase, gelatin hydrolysis (22°C), growth in KCN, malonate utilization, acetate utilization, lipase (corn oil), DNase production, pigment production, and fermentation of sucrose, dulcitol, adonitol, *myo*-inositol, D-sorbitol, L-arabinose, raffinose, maltose, D-xylose, cellobiose, α-methyl-D-glucoside, erythritol, melibiose, and mucate. No visible gas is produced during

fermentation. Susceptible to colistin, nalidixic acid, sulfadiazine (most strains), gentamicin, streptomycin, kanamycin, tetracycline, chloramphenicol, and carbenicillin (disk diffusion method on Mueller-Hinton agar); **resistant to penicillin and cephalothin**; variable susceptibility to ampicillin.

Isolated from human clinical specimens that are normally sterile such as blood and urine. Also isolated from other clinical specimens such as throat, sputum, and wounds. **Isolated from outbreaks of bacteremia, and from outbreaks of pseudobacteremia traced to contaminated collection tubes.** Probably an **opportunistic pathogen** with a low capacity to cause extraintestinal infections in humans. Occurs in water, food, and mollusks. Implicated as the cause of internal stipe necrosis of cultivated mushrooms. **A rarely isolated genus of *Enterobacteriaceae*.**

The mol% G + C of the DNA is: 53.6–55.2.

Type species: **Ewingella americana** Grimont, Farmer, Grimont, Asbury, Brenner and Deval 1984a, 91 (Effective publication: Grimont, Farmer, Grimont, Asbury, Brenner and Deval 1983a, 41.)

Further descriptive information

Ewingella has been isolated from a variety of clinical specimens. In CDC's culture collection, blood and wound isolates account for 22 of 60 isolates. The blood isolates were usually from pneumonia or surgery patients. Five were from an outbreak of bacteremia in the intensive care unit of a community hospital (Pien and Bruce, 1986). All patients had undergone either cardiovascular or peripheral vascular surgery prior to infection. The probable source was a contaminated ice bath used to cool syringes for cardiac output determinations. *E. americana* was cultured from the bath. Twenty "blood isolates" and 15 environmental isolates were related to an outbreak of pseudobacteremia in a pediatric hospital that was traced to cross contamination from nonsterile citrated blood collection tubes (McNeil et al., 1987a). Additional case reports of bacteremia have been described by Pien et al. (1983) and DeVreese et al. (1992). In these reports, blood isolates were from immunocompetent patients who had undergone coronary bypass surgery and cholecystectomy, respectively.

Wounds of thumb, toe, hand, finger, and leg accounted for nine of 60 isolates. One isolate was thought to be a colonizer (Bear et al., 1986) of a leg wound, but there was insufficient information to evaluate the clinical significance of the other strains. Heizmann and Michel (1991) described a patient with conjunctivitis, and *E. americana* was isolated from both eyes. Strains of *E. americana* have also been isolated from respiratory specimens, including sputum, throat, and tracheal aspirate, and from urine and ear.

Clinical significance The clinical significance of *E. americana* and its ability to actually cause infections is still being evaluated. Systematic study and more good case reports are needed. The blood cultures and case reports suggest that *Ewingella* is an opportunistic pathogen. Only one isolate has come from feces, and there is no evidence that *E. americana* can actually cause diarrhea or intestinal infections.

Other isolates Environmental isolates have been from aqueous solutions in the hospital environment, water, mollusks (Müller et al., 1995a), and mushrooms (Inglis and Peberdy, 1996; Inglis et al., 1996).

Internal stipe necrosis of mushrooms In 1996 Inglis and Peberdy found that *E. americana* was often present on the commercially cultivated mushroom *Agaricus bisporus*. In a second paper Inglis et al. (1996) presented evidence that *E. americana* caused this browning reaction known as internal stipe necrosis. This is a potentially serious disease to the mushroom industry in the United Kingdom, which has sales worth over 400 million dollars.

Isolation, identification, culture preservation, phenotypic characterization Strains of *E. americana* are not difficult to grow, and are typical *Enterobacteriaceae* in most respects. See the chapter on the family *Enterobacteriaceae* for general information on growth, plating media, working and frozen stock cultures, media and methods for biochemical testing, identification, computer programs, and antibiotic susceptibility. Some strains of *E. americana* grow better, and are more active biochemically at 25°C than at 35°C.

Biochemical reactions and differentiation from other *Enterobacteriaceae* Table BXII.γ.193 in the introductory chapter on *Enterobacteriaceae* gives the results for *E. americana* in 47 biochemical tests normally used for identification (Farmer et al., 1985a; Farmer, 1999). There are no genus- or species-specific tests or sequences for identification. The best approach is to do a complete set of phenotypic tests (growth on plating media, biochemical tests, antibiogram, etc.) and compare the results with all the other named organisms in the family *Enterobacteriaceae*. This approach is described in more detail in the introductory chapter on *Enterobacteriaceae*. The biochemical results of a test strain can be compared to all the organisms listed in Table BXII.γ.193 in the chapter on the family *Enterobacteriaceae*. Several computer programs greatly facilitate analyzing the results. Table BXII.γ.226 may be helpful in differentiation.

Taxonomic Comments

Discovery and DNA–DNA hybridization After the work had been completed on the characterization and description of the genus *Cedecea* (Grimont et al., 1981a), there remained a group of 10 strains that were phenotypically similar to, but distinct from, *Cedecea*. The group was named "Enteric Group 40" (Farmer, unpublished data; mentioned in Grimont et al., 1983a), and it was differentiated from *Cedecea* strains by a negative lipase (corn oil) reaction and several other tests. DNA–DNA hybridization indicated that Enteric Group 40 was less than 21% related to the other *Enterobacteriaceae*. Based on these data, Grimont et al. (1983a) proposed that Enteric Group 40 be reclassified as a new genus *Ewingella*, with a single species *Ewingella americana*.

Another genus named *Ewingella* In literature searches a source of possible confusion is the genus of radiolarians also named *Ewingella* (Pessagno, 1969).

Phylogeny based on 16S rDNA sequencing An unpublished sequence of 1398 bases has been deposited by P.W. Inglis for *E. americana* strain NCPPB 3905 (PI 98) described by Inglis and Peberdy (1996) and Inglis et al. (1996), which is a mushroom strain, not the type strain. A 16S rRNA tree that includes *E. americana* can be found in the section on *Budvicia* in this *Manual*. These 16S rDNA sequencing data agree with data from DNA–DNA hybridization, and both lead to the conclusion that *Ewingella* is distinct from other genera of *Enterobacteriaceae*. In the tree, *Rahnella* is the closest relative, in agreement with the tree published by Spröer et al. (1999), which shows these two genera on a distinct branch. However, the two trees differ in the placement of other organisms.

TABLE BXII.γ.226. Differentiation of *Ewingella americana* from several other *Enterobacteriaceae*[a]

Test	*Ewingella americana*	*Cedecea davisae*	"*Enterobacter agglomerans* complex"[b]	*Rahnella aquatilis*	*Serratia marcescens*
Lipase (corn oil)	0[b]	91	0	0	98
DNase at 25°C	0	0	0	0	98
Malonate utilization	0	91	65	73	3
Gas from D-glucose	0	70	20	98	55
Gelatin liquefaction at 22°C	0	0	0	0	90
Fermentation of:					
L-Arabinose	0	0	95	100	0
D-Arabitol	87	100	50	6	0
D-Sorbitol	0	0	30	96	99
Yellow pigment production at 25°C	0	0	75	0	0

[a]Each number gives the percentage positive after 2 d incubation at 36°C (unless a different temperature is indicated) and is based on the data summarized by Farmer (2003). Most positive reactions occur within 24 h.

[b]See Farmer (2003) for a more detailed description of this "vernacular name". It is a term defined for practical identification in the clinical microbiology laboratory. It includes over a dozen DNA–DNA hybridization groups that were originally included in the species *Enterobacter agglomerans*, which is now known to be a heterogeneous species.

List of species of the genus Ewingella

1. **Ewingella americana** Grimont, Farmer, Grimont, Asbury, Brenner and Deval 1984a, 91[VP] (Effective publication: Grimont, Farmer, Grimont, Asbury, Brenner and Deval 1983a, 41.)
a.mer.i.can′ a. M.L. adj. *americana* to denote that the original 10 strains were isolated in the United States of America.

The characteristics are as described for the genus and as listed in Table BXII.γ.193 in the chapter on the family *Enterobacteriaceae*. Occurs in human clinical specimens and the environment. May cause internal stipe necrosis of the mushroom species *Agaricus bisporus*, which is a potentially serious disease to the mushroom industry in the United Kingdom.

In the original study, Grimont et al. (1983a) noted that all 10 strains of *E. americana* were highly related by DNA–DNA hybridization. The relative binding percentages at both 60°C and 75°C were greater than 73%. For this reason a single species was defined and named. However, strain 0679-79 had a ΔT_m value of 5.5 at 60°C, which was much higher than all the other strains, which had values of 1.2–2.5.

Grimont et al. (1983a) defined two biogroups of *E. americana* based on three phenotypic differences. Biogroup 1 was defined to include nine strains, and does not ferment L-rhamnose and D-xylose, and is β-xylosidase negative. Biogroup 2 included strain 0679-79 described above, and was positive for these three tests. Phenotypically, this strain differed in other ways (Table II of Grimont et al., 1983a).

The original 10 strains (Grimont et al., 1983a) were very active biochemically at 36°C. However, other strains studied since 1983 have been biochemically more active at 25°C than at 36°C. These strains should be studied at both temperatures.

Additional studies are needed to determine if the unusual strains described above and the newly described strains from different habitats are genetically different from the type strain of *E. americana*.

The mol% G + C of the DNA is: 53.6–55.2 (T_m).

Type strain: ATCC 33852, CCUG 14506, CDC 1468-78, CIP 8194, DSM 4580, NCTC 12157.

Additional Remarks: The American Type Culture Collection includes four other strains from human clinical specimens: ATCC 33850, blood; ATCC 338514, sputum; ATCC 33853, gallbladder; ATCC 33854, thumb wound.

Genus XV. **Hafnia** *Møller 1954, 272*[AL]

Riichi Sakazaki

Haf′ ni.a. L. fem. n. *Hafnia* the old name for Copenhagen.

Straight rods, ~1.0 × 2.0–5.0 µm, conforming to the general definition of the family *Enterobacteriaceae*. Not encapsulated. Gram negative. **Motile by peritrichous flagella at 30°C**, but nonmotile strains may occur. Facultatively anaerobic. Oxidase negative. Catalase positive. **The majority of strains utilize citrate as a sole carbon source at 30°C** after 3–4 d of incubation. Nitrate is reduced to nitrite. H_2S is not produced in the butt of Kligler iron agar. Gelatinase, lipase, and deoxyribonuclease are not produced. Alginate is not utilized. Pectate is not decomposed. Phenylalanine deaminase is not produced. **Lysine and ornithine decarboxylase tests are positive**, but the arginine dihydrolase test is negative. D-Glucose is fermented with the production of acid and gas. **Acid is not produced from D-sorbitol, raffinose, melibiose, D-adonitol, D-arabitol, and *myo*-inositol.** The methyl red

test is usually positive at 35°C and negative at 22°C. Acetylmethylcarbinol is usually produced from D-glucose at 22–28°C but may not be produced at 35°C. Occur in the feces of humans and a wide range of animals including birds; also occur in sewage, soil, water, and dairy products. A member of the *Gammaproteobacteria*.

The mol% G + C of the DNA is: 48–49.

Type species: **Hafnia alvei** Møller 1954, 272.

Further descriptive information

Members of *Hafnia* are able to grow at 35°C, but many of their physiological and biochemical activities at this temperature are irregular. The majority of strains are motile at 25–30°C, but may be nonmotile at 35°C. Although most strains fail to produce acetylmethylcarbinol from D-glucose at 35°C, they give a positive Voges–Proskauer reaction when incubated at 22–28°C. They produce gas from D-glucose and about 60% of them grow on Simmons citrate agar after incubation for 3–4 d at 25°C, but in many strains these reactions may be negative at 35°C. Lactose is not fermented, but plasmid-mediated lactose-positive strains may occur (Le Minor and Coynault, 1976).

Members of *Hafnia* are defined as H_2S-negative organisms. Møller (1954) and Kauffmann (1954) defined the *Hafnia* group of *Bacteria* as H_2S-producing organisms, since the majority of strains of *Hafnia alvei* slightly darken ferric chloride-gelatin medium (Kauffmann, 1954) and SIM medium (Difco). However, they fail to blacken the butt of Kligler iron agar and of triple sugar iron agar. Ewing (1960) suggested, for the H_2S test of the family *Enterobacteriaceae*, that sensitivity of the test should be placed at a certain level, and that either Kligler iron agar or triple sugar iron agar serves this purpose because each easily permits group differentiation within the family.

The serology of *Hafnia* was first studied by Stuart and Rustigian (1943), who divided their cultures of biotype 32011, the majority of which are now classified in *Hafnia* (Sakazaki and Namioka, 1957), into eight serovars. Eveland and Faber (1953) studied serologically 58 strains of biotype 32011 and reported 21 somatic and 22 flagellar antigens. Deacon (1952) also carried out a serological study on 17 cultures of *"Aerobacter cloacae"* including biotype 32011 and recognized 12 somatic and 6 flagellar antigens among the cultures. Serology of cultures that were biochemically defined as members of the genus *Hafnia* was studied by Sakazaki (1961) and Matsumoto (1963, 1964). They established an antigenic scheme of the *Hafnia* group consisting of 68 O groups and 34 H antigens. However, the scheme is no longer available, because many test strains for O and H antigens have been lost. Independent of the scheme of previous workers, Baturo and Raginskaya (1978) have published another antigenic scheme including 39 O and 35 H antigens of *H. alvei*. Intergeneric relationships of O antigens were recognized between *Hafnia* cultures and other members of the family *Enterobacteriaceae* (Stamp and Stone, 1944; Eveland and Faber, 1953; Harada et al., 1957; Sakazaki, 1961; Matsumoto, 1963, 1964; Sedlák and Slajsova, 1966). Deacon (1952) reported the diphasic variation in the H antigens of the *Hafnia* strains he studied, but Sakazaki (1961) and Matsumoto (1963) failed to confirm such variation. Some *Hafnia* strains may have K antigen and alpha antigen of Stamp and Stone (1944) (Deacon, 1952; Emslie-Smith, 1961). Sakazaki (1961) suggested that the K antigen that inhibits the O agglutination was a slime antigen.

The majority of strains of *H. alvei* are susceptible to carbenicillin, streptomycin, gentamicin, kanamycin, tetracycline, polymyxin B, and nalidixic acid, but resistant to cephalosporins and ampicillin. Washington et al. (1971) noted a definite difference between *H. alvei* and *Serratia liquefaciens* with respect to susceptibility testing of ampicillin and polymyxin B. They reported that most of the isolates of *Serratia liquefaciens* were susceptible to ampicillin at 20 μg/ml, while none of the *Hafnia* strains were. On the other hand, all of the *Hafnia* strains tested were susceptible to polymyxin B at 10 μg/ml, whereas only 6% strains of *Serratia liquefaciens* were.

A *Hafnia*-specific bacteriophage 1672 that provides a reliable tool for the identification of *Hafnia* strains was described by Guinée and Valkenburg (1968). They reported that the phage 1672 lysed all 100 strains of *H. alvei* tested, whereas it did not lyse strains of *Enterobacter*, *Klebsiella*, *Citrobacter*, *Serratia*, and *Salmonella*.

H. alvei occurs in humans and animals, including birds, and in natural environments such as soil, sewage, and water. McClure et al. (1957) described occurrence of the organisms in wild and caged birds, none of which appeared sick. Occasionally, the organisms cause illness. Kume (1962) described a case of equine abortion in which *H. alvei* was isolated from a fetus and lochia in pure culture. Gelev et al. (1990) reported epizootic hemorrhagic septicemia in rainbow trout associated with *H. alvei*.

Although it is difficult to assign a clear-cut clinical significance, *H. alvei* has been reported to cause septicemia (Englund, 1969; Mobley, 1971), respiratory tract infections (Washington et al., 1971; Klapholz et al., 1994; Fazal et al., 1997), meningitis (Mojtabaee and Siadati, 1978), abscesses (Washington et al., 1971; Agustin and Cunha, 1995), urinary tract infections (Whitby and Muir, 1961), and wound infections (Washington et al., 1971; Berger et al., 1977). In most cases, however, it has been found in mixed culture and seems to be an opportunistic pathogen that produces infections in patients with some underlying illness or predisposing factors such as diabetes, chronic renal failure, chronic obstructive pulmonary disease, malignancy, and HIV infection. Washington et al. (1971), who reviewed the epidemiology of *H. alvei* isolated in their laboratory, concluded that the majority of the isolates originated in the respiratory tract and were considered to be commensals, while a few were secondary invaders. They also reported that previous administration of ampicillin or cephalosporins was a common feature of patients who acquired the organisms nosocomially.

There has been a controversy on whether *H. alvei* is enteropathogenic. Kauffmann (1954) suggested that the organisms of the *Hafnia* group are probably nonpathogenic for humans. Matsumoto (1963) reported the isolation of this organism from 13% of stool specimens from apparently healthy individuals. Ewing (1986a) reported that "members of this species are not known to be incitants of gastroenteritis." On the other hand, earlier investigators (Stuart and Rustigian, 1943; Stuart et al., 1943; Deacon, 1952; Eveland and Faber, 1953) incriminated biotype 32011 of paracolon bacteria or non-lactose-fermenting *"Aerobacter cloacae"*, which are now classified in *Hafnia alvei*, as a causative agent of intestinal disorder. Harada et al. (1957) reported the isolation of *H. alvei* from sporadic cases of diarrheal diseases. Emslie-Smith (1961) suggested a possible role for *H. alvei* in gastroenteritis. In addition, Ratnam et al. (1979) reported the incrimination of *H. alvei* in a nosocomial outbreak of gastroenteritis. However, no conclusive evidence on enteropathogenicity of the *Hafnia* has been obtained. Albert et al. (1991, 1992) reported that strains of *H. alvei* isolated from diarrheal stools produced the attaching-effacing (AE) lesion in rabbits and HEp-2 cells resembling enteropathogenic *Escherichia coli* (EPEC), and that the virulence-associated gene *eaeA* was shared between EPEC and *H. alvei*. In addition, Ridell et al. (1995) found that *eaeA*-positive strains of

H. alvei have some characteristic properties in which they give negative reactions in the 2-ketogluconate and histidine assimilation tests and a positive reaction in the 3-hydroxybenzoate assimilation test in contrast with *eaeA*-negative strains. On the other hand, Ismaili et al. (1996) examined 11 strains of *H. alvei* isolated from children with diarrhea in Canada, and a Bangladesh *H. alvei* strain for AE lesion formation, presence of *eaeA* gene, profile of outer membrane protein extracts, chromosomal macrorestriction fragments, and plasmids. They found that, in contrast with the Bangladesh strain, which possessed the *eaeA* gene and forms the AE lesion, none of the Canadian strains had the *eaeA* gene, nor did they form the AE lesion. The outer membrane protein profile of all of the Canadian strains were identical to each other but differed from that of the Bangladesh strain. In addition, pulsed-field gel electrophoresis and plasmid profile analyses of the Canadian strains differed substantially from those of the Bangladesh strain. Their results indicate that there is heterogeneity among *H. alvei* strain factors associated with enteropathogenicity. Ridell et al. (1994) found an epidemiological association of *H. alvei* with diarrhea. *H. alvei* was isolated from 16% of adult Finnish tourists who visited Morocco and contracted diarrhea, but from 0% of tourists without diarrhea. *H. alvei* was isolated only from 2% of another group of adult Finnish patients with diarrhea. However, the authors found that those Finnish strains from diarrheal patients were negative for AE lesion formation and did not have the *eaeA* gene of EPEC. These recent papers suggest that some strains of *H. alvei* have the potential to cause diarrhea and that, although AE lesion formation is a virulence factor, mechanisms other than AE lesion formation may also be involved in the association of *H. alvei* with diarrhea.

Enrichment and Isolation Procedures

H. alvei can grow on less selective isolation media for enterobacteria such as eosin-methylene blue, MacConkey, xylose–lysine–deoxycholate, and Hektoen enteric agars. On highly selective isolation media, such as Salmonella–Shigella and deoxycholate-citrate agars, many of the *Hafnia* cultures would be inhibited. The *Hafnia* organisms may not grow on bismuth sulfite agar. Colonies of *H. alvei* on less inhibitory plating agar media are relatively large, translucent, circular, low convex, and colorless, with a smooth surface and entire edge and resemble those of *Salmonella* (*Hafnia* strains are sometimes misidentified as H_2S-negative *Salmonella*). Some strains may produce pink colonies on media containing sucrose. Rarely does a strain produce mucoid colonies. For the differential isolation of *H. alvei*, MacConkey agar containing 1% sorbitol may be useful, on which colorless colonies of *H. alvei* can be distinguished from other intestinal inhabitants, because the former is lactose- and sorbitol-negative but the latter are usually positive for these sugars.

There are no selective enrichment broth media for the isolation of *H. alvei*. Many strains of *H. alvei* may grow in selenite and tetrathionate broth media, but some strains fail to grow in those broths. Ability of *H. alvei* to grow at lower temperature may be applied for cold enrichment, which is a useful procedure for the isolation of *Yersinia* strains.

Maintenance Procedures

Stock cultures may be maintained at room temperature in a semisolid medium consisting of 1.0% Bacto-casitone (Difco), 0.3% yeast extract, 0.5% NaCl, and 0.3% agar (pH 7.0). *Hafnia* strains remain viable for up to several years without subculture if the culture is sealed with a rubber stopper or a cork soaked in hot paraffin wax. Strains may also be preserved by lyophilization.

Procedures for Testing Special Characters

The specific bacteriophage 1672 was isolated from surface water with *H. alvei* 1672 as the propagating strain using the following method (Guinée and Valkenburg, 1968). A well-dried nutrient agar plate is surface-inoculated with a fresh broth culture of the strain to be tested. After decantation of the plate at room temperature for 15 min, a drop of the undiluted phage 1672 is spotted on the plate with a Pasteur pipette and the plate is again allowed to dry. Readings are made after 16–20 h of incubation at 35°C. Clear plaques with a diameter of 1–5 mm may be produced. The phage preparation is obtained after the usual purification and will contain around 10^9 plaque-forming units/ml. The phage is not inactivated by heating at 60°C for 30 min.

The L-pyrrolidonyl aminopeptidase test is performed by dissolving 10 mg of L-pyrrolidonyl-β-naphthylamide (Sigma) in 10 ml of 95% ethanol. Dip sterile cotton swabs into the solution and rotate each swab several times with firm pressure on the inside wall of the tube to remove excess fluid. Dry the swabs overnight at 37°C and store at −20°C. Make a heavy suspension (MacFarland no. 1) of the test culture into 0.2–0.3 ml of 0.1 M phosphate buffer (pH 7.4), then dip the reagent swab into the suspension and incubate at 37°C for 10 min. Finally, add a drop of cinnamaldehyde solution.[1] A positive result is shown by a pink or red color.

The β-glucuronidase test is performed by dissolving 20 mg of 4-methylumbelliferyl-β-D-glucuronide (Sigma) in a small volume of dimethyl sulfoxide and bringing the volume to 10 ml with 0.1 M phosphate buffer (pH 7.4). Dip sterile cotton swabs into the solution and rotate each swab several times with firm pressure on the inside wall of the tube to remove excess fluid. Dry the swabs overnight at 37°C and store at −20°C. For testing, make a heavy suspension (MacFarland no. 1) of the test culture in 0.2–0.3 ml of 0.1 M phosphate buffer (pH 7.4). Dip the reagent cotton swab in the suspension and incubate at 37°C for 30 min. A positive reaction is indicated by development of blue fluorescence under long wave (360 μm) ultraviolet lamp.

Differentiation of the genus *Hafnia* from other genera

Hafnia are often misidentified as members of *Enterobacter* or *Serratia*. Members of the genus *Hafnia* give a positive reaction in lysine and ornithine decarboxylase tests but are negative in arginine dihydrolase test. In differentiating *Hafnia* from *Enterobacter* and *Serratia*, in which some species show the same reactions in those tests, the failure of *Hafnia* to ferment raffinose, D-sorbitol, adonitol, and *i*-inositol may be valuable. Moreover, members of *Hafnia* have no activity of pyrrolodonyl aminopeptidase, although *Enterobacter* and *Serratia* possess this enzyme. Stuart et al. (1943) and Eveland and Faber (1953) described a close similarity between paracolon biotype 32011, which is now classified in the *Hafnia*, and *Salmonella* in biochemical reactions. Like *Salmonella*, *Hafnia* cultures are positive in tests of lysine and ornithine decarboxylases and negative in tests of indole, urease, and fermentation of lactose and sucrose, as well as in the Voges–Proskauer

1. Cinnamaldehyde solution contains *p*-dimethlaminocinnamaldehyde (Sigma), 0.5 g; glacial acetic acid, 3.5 ml; ethylene glycol-1-methylester, 6.0 ml; sodium lauryl sulfate, 3.5 g; and distilled water, 90 ml. Store in a screw-capped brown container in a refrigerator.

reaction at 35°C, although *Hafnia* cultures fail to produce H_2S. In addition, Eveland and Faber (1953) and Harada et al. (1957) reported that the *Hafnia* cultures are often agglutinated by *Salmonella* O antisera. *Hafnia* cultures may also be misidentified with some non-lactose-fermenting *Escherichia coli* strains, because the former gives a negative reaction in tests of Voges–Proskauer and citrate utilization at 35°C. However, *E. coli* produces indole and β-glucuronidase, while *Hafnia* is negative in these two tests. On the other hand, *Hafnia* is occasionally misidentified with Shiga toxin-producing *E. coli* O157:H7, because both organisms fail to ferment sorbitol and to produce β-glucuronidase. In addition, some strains of *H. alvei* are agglutinated by *E. coli* O157 antiserum (Aleksič et al., 1992). *Yokenella regensburgei*, which was first considered to be *Hafnia*, is another organism to be differentiated from the *Hafnia*. *Y. regensburgei* is different from *Hafnia* in its ability to utilize citrate, and to produce acid from cellobiose, melibiose, and D-arabitol. *Y. regensburgei* cannot be lysed by the *Hafnia* specific bacteriophage. Table BXII.γ.227 indicates the differential characteristics between *Hafnia* and biochemically similar taxa.

Taxonomic Comments

The bacteria of the genus *Hafnia* have been described under several names: *"Bacillus asiaticus"* and *"Bacillus asiaticus"* biovar "mobilis" (Castellani, 1912, cited by Ewing and Fife, 1968), *"Bacterium cadaveria"* (Gale and Epps, 1943), biotype 32011 of the genus *"Aerobacter"* (Stuart et al., 1943), *"Enterobacter alvei"* (Sakazaki, 1961), *Enterobacter aerogenes* subsp. *"hafniae"* (Ewing, 1963), and *"Enterobacter hafniae"* (Ewing and Fife, 1968). However, *Hafnia alvei* (Møller, 1954) is the only correct name for these organisms. Møller (1954) found a new group of organisms, in which a supposedly authentic strain of *"Bacillus paratyphi-alvei"* of Bahr (1919) was included. He proposed the name *Hafnia alvei* for this group of bacteria because he considered that Bahr's strain ought to be regarded as the type strain of this group. Sakazaki (1961) suggested the new combination *"Enterobacter alvei"* for *H. alvei*, because of its biochemical similarity to *Enterobacter*. Ewing and Fife (1968) pointed out that Bahr's strain, which had been designated as the type strain of *H. alvei* by Møller (1954), was not an authentic strain of this species, since biochemical reactions of the strain were not the same as those described by Bahr (1919). They considered therefore that the specific epithet *"alvei"* was illegitimate, and proposed the name *"Enterobacter hafniae"* for *H. alvei*. However, there is no doubt that Bahr's strain studied by Møller (1954) was a new bacterium at that time. In addition, numerical taxonomy studies by Johnson et al. (1975) and Gavini et al. (1976a) indicated that *Hafnia* strains retained a position separate from *Enterobacter*. In DNA–DNA hybridization studies, Steigerwalt et al. (1976) reported 11–26% relatedness of *H. alvei* with *Enterobacter* and *Klebsiella*. These data appear to justify the status of the *Hafnia* as a separate genus rather than including it in the genus *Enterobacter*.

Although only a single species, *Hafnia alvei*, has been designated, Steigerwalt et al. (1976) indicated in DNA reassociation studies that there were two genomospecies that were about 50% interrelated within the genus *Hafnia*. Overall phenotypic profiles may serve to separate the second subspecies from the named species *H. alvei*; however, it has not been named. Farmer et al. (1985a) referred to this second genomospecies as *Hafnia alvei* biogroup 1.

Priest et al. (1973) proposed that *Obesumbacterium proteus* Shimwell 1964, a common brewery contaminant, should be placed in the genus *Hafnia* as *"H. protea"*. They described two groups in this species by numerical analysis of phenotypic characteristics. Brenner (1981) determined DNA relatedness in both groups and found that one group appears to be a biovar of *H. alvei*, whereas the other is a new species that does not belong to the genus *Hafnia*.

Another group resembling *H. alvei*, *Yokenella regensburgei*, was first considered as a species of the genus *Hafnia*. Kosako et al. (1984), who studied the phenotypic and genotypic characteristics of both groups, confirmed that the former was distinct from members of the *Hafnia* and suggested the name *Yokenella regensburgei* for this group.

Acknowledgments

Riichi Sakazaki, who died in 2002, spent more than forty years at the Nippon Institute of Biological Sciences. His illustrious career focused on the classification and epidemiology of human and fish pathogens in Japan, particularly pathogenic bacteria in the families *Vibrionaceae* and *Enterobacteriaceae*. His contributions to Japanese bacteriology paralleled those of Drs. Edwards and Ewing in the U.S. He discovered and described many species in the genera *Enterobacter*, *Edwardsiella*, and *Vibrio*, and he developed serotyping schemes for *V. cholerae* and *V. parahaemolyticus*, as well as for several important species of *Enterobacteriaceae*. His research was always careful and comprehensive. He was one of the first Japanese scientists to publish in English language journals, thereby making his impressive accomplishments available to the world. He was recognized as one of the world's foremost experts on the genus *Vibrio* and on many genera in *Enterobacteriaceae*. He was a member of the WHO Subcommittees on the Taxonomy of *Vibrionaceae* and on the Taxonomy of *Enterobacteriaceae* for more than thirty years. He authored chapters on these organisms in three editions of *Bergey's Manual*. He was a good friend to the Bergey's Trust, as well as to all who knew him.

DIFFERENTIATION OF THE SPECIES OF THE GENUS *HAFNIA*

Table BXII.γ.228 presents the biochemical characteristics of *Hafnia* species, which are also useful for differentiation between *H. alvei* and unnamed genospecies (genomospecies 2).

List of species of the genus Hafnia

1. **Hafnia alvei** Møller 1954, 272[AL]

al′ve.i. L. n *alveus* a beehive; L. gen. n. *alvei* of a beehive.

The morphology is as given for the genus. Motility is most pronounced at 30°C. Nonmotile strains may be encountered occasionally.

Grows readily on ordinary media. Colonies on nutrient agar are generally 2–4 mm in diameter, smooth, moist, translucent, and gray, with a shiny surface and entire edge. Rare strains may produce mucoid colonies. Physiological and biochemical characteristics are presented in Table BXII.γ.228.

Found in the feces of humans and other animals, including birds. Also found in sewage, soil, water, and dairy products. It may be isolated in association with some pathological processes in patients with underlying illness. Some strains may cause diarrheal diseases.

The mol% G + C of the DNA is: 48.0–48.7 (T_m).

Type strain: ATCC 13337, DSM 30163, NCTC 8106.

GenBank accession number (16S rRNA): M59155.

Genus XVI. **Klebsiella** *Trevisan 1885, 105[AL] emend. Drancourt, Bollet, Carta and Roussselier 2001, 930*

PATRICK A.D. GRIMONT AND FRANCINE GRIMONT

Kleb.si.el′la. M.L. dim. ending *-ella;* M.L. fem. n. *Klebsiella* named after Edwin Klebs (1834–1913), a German bacteriologist.

Straight rods, 0.3–1.0 × 0.6–6.0 μm, arranged singly, in pairs or short chains; often surrounded by a **capsule**. Conform to the general definition of the family *Enterobacteriaceae*. Gram negative. **Nonmotile** (except *K. mobilis*). Facultatively anaerobic, having both a respiratory and a fermentative type of metabolism. Grow on meat extract media (except *K. granulomatis*, which has not been cultured), producing more or less dome-shaped, glistening colonies of varying degrees of stickiness depending on the strain and the composition of the medium. **Oxidase negative.** Glucose is fermented with the production of acid and gas (more CO_2 is produced than H_2), but anaerogenic strains occur. Most strains produce 2,3-butanediol as a major end product of glucose fermentation. The **Voges–Proskauer test is usually positive**. Lactic, acetic, and formic acids are formed in smaller amounts and ethanol in larger amounts than in a mixed acid fermentation. All strains utilize L-arabinose, D-arabitol, D-cellobiose, citrate, D-fructose, D-galactose, D-glucose, 2-ketogluconate, maltose, D-mannitol, D-melibiose, D-raffinose, D-trehalose, and D-xylose as sole carbon sources. With the exception of some *K. pneumoniae* subsp. *ozaenae* strains, all *Klebsiella* strains **utilize *myo*-inositol, L-rhamnose, and sucrose as sole carbon sources**. With the exception of some *K. pneumoniae* subsp. *ozaenae* and *K. pneumoniae* subsp. *rhinoscleromatis* strains, all strains utilize lactose and D-sorbitol as sole carbon sources. No strain utilizes betaine, caprate, caprylate, glutarate, itaconate, 3-phenylpropionate, and propionate. H_2S is not produced, β-glucuronides are not hydrolyzed, and L-tryptophan and L-histidine are not deaminated. Ornithine is not decarboxylated by klebsiellae strains except *K. mobilis*, *K. ornithinolytica*, and rare strains of *K. pneumoniae*. Most strains hydrolyze urea and β-galactosides. Some strains fix nitrogen. Occur in intestinal

contents, clinical specimens from humans and animals (e.g., horses, swine, monkeys), soil, water, or on plants.

The mol% G + C of the DNA is: 53–58.

Type species: **Klebsiella pneumoniae** (Schroeter 1886) Trevisan 1887, 94 (*Hyalococcus pneumoniae* Schroeter 1886, 1952.)

Further descriptive information

Phylogenetic treatment The agent of donovanosis, *Calymmatobacterium granulomatis*, was found to be so closely related to *Klebsiella pneumoniae* by *rrs* (16S rRNA gene) sequence comparison that the species was transferred to the genus *Klebsiella* as *Klebsiella granulomatis* (Carter et al., 1999; Kharsany et al., 1999). However, it is not known whether *K. granulomatis* is a species distinct from *K. pneumoniae*.

The phylogenetic position of klebsiellae has been addressed by *rrs*, *rpoB* (Drancourt et al., 2001), *gyrA*, and *parC* (Brisse and Verhoef, 2001) sequence comparison.

The genus *Klebsiella* was found to be polyphyletic by Drancourt et al. (2001). Cluster I contained *Klebsiella pneumoniae* subsp. *pneumoniae*, *K. pneumoniae* subsp. *ozaenae*, *K. pneumoniae* subsp. *rhinoscleromatis*, and *K. granulomatis*. Cluster II contained *K. planticola*, *K. ornithinolytica*, and *K. terrigena*. Cluster III contained *K. oxytoca*. As a consequence, cluster II was proposed to constitute a new genus, *Raoultella* (Drancourt et al., 2001). The position of *Klebsiella mobilis* (*Enterobacter aerogenes*) was very close to cluster II, although the proposal by Drancourt et al. (2001) did not include that species.

A somewhat different structure was found by Brisse and Verhoef (2001), who uncovered two groups. The first group contained *K. pneumoniae* with its three subspecies, and the second group contained *K. oxytoca*, *K. planticola*, *K. ornithinolytica*, *K. terrigena*, and *K. mobilis*. Furthermore, three clusters (KpI to KpIII) were evidenced in *K. pneumoniae*, which did not correlate with the named subspecies. These clusters may have different habitats and different physiological properties (D-adonitol fermentation, for example). *K. oxytoca* was composed of two clusters, the significance of which is unknown.

Cell morphology and cell wall composition The outermost layer of *Klebsiella* bacteria consists of a large polysaccharide capsule, a characteristic that distinguishes members of this genus from most other bacteria in the family (*Escherichia coli* strains with a heat-stable K antigen may form similar capsules). The cell wall is structured similarly to other *Enterobacteriaceae*. Above the cytoplasmic membrane is the peptidoglycan layer and the outer membrane containing lipopolysaccharide (LPS). In addition, *Klebsiella* strains may possess fimbriae (pili) (Duguid, 1959).

The production of the large capsules gives rise to large mucoid colonies of a viscid consistency. The capsular material also diffuses freely into the surrounding liquid medium as extracellular capsular material.

Nutrition and growth conditions Best results with biochemical tests are obtained when *Klebsiella* cultures are incubated at 30–35°C. *Klebsiella* strains (except *K. granulomatis*) grow readily on all kinds of media commonly used to isolate *Enterobacteriaceae*, such as nutrient agar, tryptic casein soy agar, bromocresol purple lactose agar, Drigalski agar, MacConkey agar, eosin-methylene blue (EBM) agar, and bromothymol blue (BTB) agar. *K. pneumoniae* and *K. oxytoca* colonies are lactose positive, more or less dome-shaped, 3–4 mm in diameter after overnight incubation at 37°C or 30°C, with a mucoid aspect and sometimes stickiness depending on the strain and the composition of the medium. *K. planticola*, *K. terrigena*, *K. ornithinolytica*, and *K. mobilis* (*Enterobacter aerogenes*) colonies are also lactose positive, 1.5–2.5 mm in diameter, dome-shaped, with a weakly mucoid aspect. *K. pneumoniae* subsp. *ozaenae*, *K. pneumoniae* subsp. *rhinoscleromatis*, and occasionally *K. pneumoniae* K1 strains grow more slowly on the same media, yielding voluminous, rounded, very mucoid, translucent, and confluent colonies in 48 h at 30°C or 37°C (Ørskov, 1981; Richard, 1982). Similar colonies, indistinguishable from those of *Klebsiella*, may be formed by other genera of the *Enterobacteriaceae*, particularly *E. coli* mucoid varieties with capsular K antigens.

The use of a carbohydrate-rich medium, such as bromothymol blue lactose agar or Hajna or Worfel–Ferguson medium, produces a better formed capsule than a carbohydrate-poor medium.

Almost all *Klebsiella* strains grow in minimal medium with ammonium ions or nitrate as sole nitrogen source and a carbon source, without growth factor requirement. Some *K. pneumoniae* K1 isolates require arginine or adenine or both as growth factors. *K. pneumoniae* subsp. *rhinoscleromatis* requires arginine and uracil but growth factor requirements of *K. pneumoniae* subsp. *ozaenae* are not fully determined (leucine, cysteine, and methionine are stimulatory). Ornithine can replace arginine for these requirements (Grimont et al., 1991).

K. granulomatis has not been grown axenically in artificial media. Cultures have been achieved *in vivo* in the yolk sac of developing chick embryo and in the developing chick embryo brain. Growth can be obtained in cell cultures, fresh mononuclear cells (Kharsany et al., 1997) or in Hep-2 human epithelial cell line (Carter et al., 1997).

Metabolism The characteristics useful for the identification of *Klebsiella* species are given in Table BXII.γ.229.

The Voges–Proskauer (VP) test is usually positive in *Klebsiella*, meaning that acetoin and 2,3-butanediol are produced during glucose fermentation. Some strains of *K. pneumoniae* subsp. *rhinoscleromatis*, do not form acetoin and 2,3-butanediol. In some strains, 2,3-butanediol is utilized and acetoin will disappear before the VP reaction is tested. Richard's modification of the VP test (Le Minor and Richard, 1993) most often gives positive results with *Klebsiella* strains (except *K. pneumoniae* subsp. *ozaenae* and subsp. *rhinoscleromatis*).

Carbon source utilization tests are conveniently obtained with Biotype-100 strips (BioMérieux, La Balme-les-Grottes, France) used with a minimal medium (Biotype Medium 1) containing 16 growth factors. *K. pneumoniae* subsp. *rhinoscleromatis* and some strains of *K. pneumoniae* subsp. *ozaenae* may need Biotype medium 2, which contains all known growth factors for enteric bacteria. The strips are examined for visual growth after 2 and 4 d (Grimont et al., 1991). Almost all *Klebsiella* strains utilize the following compounds as sole carbon and energy sources (provided growth factor requirements of some strains are met): *N*-acetyl-D-glucosamine, L-alanine, L-arabinose, D-arabitol, L-aspartate, D-cellobiose, citrate, D-fructose, L-fucose, fumarate, D-galactose, gentiobiose, D-gluconate, D-glucosamine, D-glucose, DL-glycerate, glycerol, *myo*-inositol, 2-ketogluconate, DL-lactate, lactose, D-malate, L-malate, maltose, maltotriose, D-mannitol, D-mannose, D-melibiose, 1-*O*-methyl-β-glucoside, L-proline, D-raffinose, D-ribose, L-serine, D-trehalose, and D-xylose. Esculin is hydrolyzed. H_2S, β-glucuronidase, phenylalanine deaminase, and tryptophan deaminase are not produced; DNA and tributyrin are not hydrolyzed. Almost no strain of *Klebsiella* can utilize the following com-

pounds as sole carbon and energy sources after 4-d incubation: betaine, caprate, caprylate, glutarate, itaconate, 3-phenylpropionate, and propionate. It is obvious from Table BXII.γ.229 that *K. pneumoniae* subsp. *ozaenae* and *K. pneumoniae* subsp. *rhinoscleromatis* are biotypes of *K. pneumoniae* with less nutritional versatility. There is no substrate utilized by subsp. *ozaenae* and subsp. *rhinoscleromatis* that is not utilized by subspecies subsp. *pneumoniae*. For this reason, it is necessary to check the identification

of these less active subspecies by capsular typing. Carbon source utilization tests are essential for the precise identification of *Klebsiella* species (Grimont et al., 1991). In Biotype-100 strips, *K. oxytoca* often produces a soluble yellow compound in all cupules showing some growth, and this may be analogous to the pigment produced by this species on ferric gluconate (Ørskov, 1984b). Growth on gentisate and 3-hydroxybenzoate never occurs with *K. pneumoniae* and *K. planticola*. Growth on histamine never occurs with *K. pneumoniae* and *K. oxytoca*. Growth on D-sorbose is always negative with *K. mobilis* (*E. aerogenes*) and growth on tricarballylate is always negative with *K. planticola*. Only *K. terrigena* and some strains of *K. oxytoca* can grow on D-melezitose, and only *K. planticola* and *K. terrigena* can grow on 3-*O*-methyl-D-glucose. These carbon sources are often sufficient for the identification of all *Klebsiella* species (Grimont et al., 1991).

Oxidation of glucose to gluconate (mediated by glucose dehydrogenase) in the absence of added pyrroloquinoline quinone is a distinctive property of *K. pneumoniae* subsp. *pneumoniae* and *K. mobilis* (Bouvet et al., 1989). The other species require the addition of cofactor pyrroloquinoline quinone to express glucose dehydrogenase activity. Gluconate is oxidized into 2-ketogluconate (by a gluconate dehydrogenase) by *K. pneumoniae* subsp. *pneumoniae*, *K. planticola*, *K. terrigena*, and *K. mobilis*, but not by *K. oxytoca*, *K. pneumoniae* subsp. *ozaenae*, and *K. pneumoniae* subsp. *rhinoscleromatis*. *Klebsiella* species do not oxidize 2-ketogluconate to 2,5-ketogluconate (Bouvet et al., 1989).

K. pneumoniae subsp. *pneumoniae* can grow fermentatively on glycerol thanks to a glycerol dehydrogenase type I (induced by glycerol and dihydroxyacetone) and 1,3-propanediol dehydrogenase, which are typical enzymes of the anaerobic glycerol dissimilation pathway (Bouvet et al., 1995a). Other species of *Klebsiella* cannot grow fermentatively on glycerol and possess a glycerol dehydrogenase, but no 1,3-propanediol dehydrogenase (Bouvet et al., 1995a).

Some *K. oxytoca* and *K. planticola* strains are capable of fixing nitrogen and are classified as associative nitrogen fixers (Ladha et al., 1983). Nitrogen fixation is catalyzed by the enzyme nitrogenase in the absence of combined nitrogen, and under anaerobic conditions. Nitrogen fixation in the facultative anaerobe *K. pneumoniae* occurs only under anaerobic or microaerobic conditions. Low O_2 concentrations enhance nitrogenase synthesis; higher O_2 concentrations inhibit both synthesis and activity (Hill et al., 1984).

Genetic recombination has been reported in *Klebsiella* (Matsumoto and Tazaki, 1970), and *K. pneumoniae* has been used by several workers for detailed genetic analysis of the genes involved in N_2 fixation (*nif* genes). These genes are clustered near the *his* region on the chromosome but can be mobilized and transferred to other organisms. The genetics and regulation of nitrogen fixation in *Klebsiella* have been reviewed by Gussin et al. (1986).

Klebsiella strains may harbor a *lac* plasmid giving a stronger lactose positive phenotype (Reeve and Braithwaite, 1973).

Klebsiella strains may be lysogenic, but phages used by some workers for phage typing have been isolated from stools or sewage (Slopek et al., 1967; Slopek, 1978). Many *Klebsiella* strains produce bacteriocin (klebecin) and typing sets of such producers can be selected (Slopek and Maresz-Babczyszyn, 1967; Edmondson and Cooke, 1979).

Antigenic structure The outer membrane contains the lipopolysaccharide (LPS) that forms the O-antigen. The oligosaccharide repeating units of the O-antigen consists of only a few carbohydrate components. Some of the O-antigens are homopolysaccharides such as galactans or mannans. There are only 12 different O-antigens. O-antigen determination is difficult because it is hampered by the stable K-antigens (Ørskov and Ørskov, 1984b).

Klebsiellae are enveloped by a polysaccharide capsule of considerable thickness. This constitutes the capsular or K-antigen. The capsular polysaccharide also diffuses freely into the liquid medium as extracellular capsular material. The *Klebsiella* capsular polysaccharides are acidic and composed of repeating units. Only a few carbohydrate constituents are found. Most K-antigens contain charged monosaccharide constituents such as glucuronic and hexoses, occasionally 6-deoxyhexoses. Noncarbohydrate constituents such as formyl, acetyl, or pyruvate groups are found. Following the pioneer work of Julianelle (1926), who determined the first three capsular types, a total of 82 K-antigens (K:1 to K:82) were described, although K:73, K:75, K:76, and K:78 were invalidated. There are thus only 78 available types. Cross-reactions among established K-antigens are numerous. K-antigen determination is traditionally by the capsular swelling reaction. When bacteria and the corresponding serum are mixed on a glass slide and observed under the microscope, the capsule becomes highly refractile and easily visible. Other methods include slide or tube agglutination, indirect immunofluorescence, and countercurrent immunoelectrophoresis (Ørskov and Ørskov, 1984b).

Some K-antigens are correlated with pathogenicity. *K. pneumoniae* subsp. *rhinoscleromatis* strains have capsular antigen K:3, whereas *K. pneumoniae* subsp. *ozaenae* strains are mostly K:4 and occasionally K:3 or K:5. *K. pneumoniae* subsp. *pneumoniae* strains recovered from respiratory tract infections have generally antigens K:1 to K:6, whereas strains form other nosocomial infections (e.g., urinary tract) have often antigens K:2, K:21, K:55, K:10, or K:24. Other K-types (17, 25, 22, 43, 1, 3, 33) can also be encountered (Le Minor and Richard, 1993). Strains found in the sperm of stallions and that cause metritis and abortion in mares contaminated with such sperm are often K:1, K:2, K:7, or K:30. Nosocomial *K. oxytoca* strains have been found with K:26, K:68, K:43, and less frequently K:26, K:21, K:18, or K:47. *K. mobilis* (*E. aerogenes*) strains most of the time can show capsular swelling with *Klebsiella* antisera. K-types associated with this species are often K:68 or K:26 and occasionally K:42, K:59, K:11, or K:4 (Le Minor and Richard, 1993).

Pathogenicity The genus *Klebsiella* is ubiquitous. Strains of this genus are found in surface water, sewage, soil, and on plants. They also colonize the mucosal surfaces of humans, horses, and swine (Podschun and Ullmann, 1998). In humans, *K. pneumoniae* is present as a commensal in the nasopharynx (detection rate, 1–6%) and in the intestinal tract (detection rate, 5–38%). In hospitals, colonization rates increase with the length of stay (detection rates, 77% in the stool, 19% in the pharynx, and 42% on the hands of patients) and hospital personnel can carry *K. pneumoniae* (Podschun and Ullmann, 1998). The high rate of colonization in patients is associated with the use of antibiotics.

The genus *Klebsiella* can be associated with different sorts of infections. *Klebsiella pneumoniae* is a cause of community-acquired bacterial pneumonia (Friedländer's pneumonia), occurring particularly in chronic alcoholics, and showing characteristic radio-

graphic abnormalities. The fatality rate is high if untreated (Podschun and Ullmann, 1998).

K. pneumoniae subsp. *rhinoscleromatis* is the causative agent of rhinoscleroma, a chronic infection that can involve the nasal cavity (most often) or the upper airways (pharynx, larynx, trachea). Typically, a granulomatous destructive and disfiguring process results in airway obstruction. Ultimately, extensive fibrosis and scarring occur. Histological features include mixed diffuse infiltrate of the upper and lower dermis with numerous plasmocytes, lymphocytes, neutrophils, and characteristic large macrophages with foamy cytoplasm (Mikulicz cells) and that contain *Klebsiella*.

K. pneumoniae subsp. *ozaenae* has been implicated in ozena, a chronic atrophic rhinitis giving off a very bad smell. However, the pathogenic role of the bacterium in this syndrome is less clear.

Klebsiella granulomatis (formerly *Calymmatobacterium granulomatis*) is the presumed causative agent of granuloma inguinale (donovanosis), a genital ulceration that is sexually transmissible. Histological features include dense dermal infiltrate of plasmocytes, neutrophils, and large macrophages with vacuolated cytoplasms that contain intracellular bacilli (Donovan bodies). The similarity of donovanosis and rhinoscleroma histological lesions has been pointed out (Carter et al., 1999).

Klebsiella spp. (with the exception of *K. pneumoniae* subsp. *rhinoscleromatis*, *K. pneumoniae* subsp. *ozaenae*, and *K. granulomatis*) are mostly considered nosocomial pathogens. *Klebsiella pneumoniae* and *K. mobilis* (*Enterobacter aerogenes*) are most frequently involved, although *K. oxytoca* and *K. planticola*, and rarely *K. terrigena*, can be found.

The urinary tract is the most common site of infection, and *K. pneumoniae* accounts for 6–17% of all nosocomial urinary tract infections (Podschun and Ullmann, 1998). *K. pneumoniae* is also a frequent cause of bacteremia. In premature infants, *K. pneumoniae* is often involved in neonatal sepsis.

The principal reservoir of *K. pneumoniae* in the hospital is the gastrointestinal tract of patients. The principal vectors are the hands of personnel. Occasional sources are contaminated medical equipment and blood products (Podschun and Ullmann, 1998).

Renewed interest in *Klebsiella* infections stemmed from the spread of multiresistant strains. *K. pneumoniae* is naturally susceptible to aminoglycosides. However, plasmids mediating aminoside-modifying enzymes have spread in the 1970s. In a French survey, 78% of *Klebsiella* isolates were susceptible to gentamicin, tobramycin, netilmycin, and amikacin. Different phenotypes of aminoside resistance were observed, involving resistance to gentamicin, tobramycin, netilmycin, and/or amikacin (Lemozy et al., 1985). The most frequent aminoside inactivating enzymes found produced by *Klebsiella* isolates were aminoglycoside-3′-*N*-acetyltransferases and aminoglycoside -2′′-*O*-nucleotidyltransferase (Lemozy et al., 1985).

Strains of *K. pneumoniae* and *K. oxytoca* that have not acquired any resistance determinant are naturally resistant to aminopenicillins (ampicillin) and carboxypenicillins (carbenicillin) and susceptible to other β-lactam antibiotics. This is due to the production of a chromosomal penicillinase, which is inhibited by clavulanic acid. A small zone of inhibition around 100–mg carbenicillin disks is typical of this phenotype (Jarlier, 1985). Acquired resistance arose from the production of a plasmid-determined penicillinase. The strains showed a higher resistance to carbenicillin (no zone around carbenicillin disks), and resistance to ureidopenicillins, cefalothin, cefamandole, and cefuroxime. Inactivation of amoxycillin was not blocked by clavulanic acid. However, these strains remained susceptible to third-generation cephalosporins (e.g., cefotaxime) (Jarlier, 1985). Since 1982, strains producing extended spectrum β-lactamases (ESBL) encoded by a plasmid have spread. *K. pneumoniae* strains resistant to ceftazidime were commonly producing a SHV-5 type β-lactamase in Europe and a TEM-10 or TEM-12 type in the United States. These strains account for 5% (USA) to 16% (France) of the *K. pneumoniae* tested (Podschun and Ullmann, 1998). These ESBL-producing strains have been susceptible to carbapenems (imipenem, meropenem). However, ESBL-producing *K. pneumoniae* resistant to imipenem have been isolated. They produce a β-lactamase of the AmpC type (Podschun and Ullmann, 1998). *Klebsiella mobilis* (*Enterobacter aerogenes*) was rarely encountered as a nosocomial pathogen until strains carried a plasmid encoding an ESBL. In France and Belgium, β-lactamases of type SHV-4, TEM-24, and TEM-3 were characterized in *K. mobilis*. It was shown that TEM-24 producing isolates found in several epidemics in different countries constituted mostly a single clone (Galdbart et al., 2000; De Gheldre et al., 2001; Mammeri et al., 2001).

Pathogenesis *Klebsiella* species are surrounded by a hydrophilic polysaccharide capsule, which is the first virulence factor described in klebsiellae (Toenniessen, 1914; Cryz et al., 1984). Simoons-Smit et al. (1984) showed that strains with K1, K2, K4, and K5 capsular antigens were more virulent for mice (skin model) than strains with K6 and K above 6. The loss of K antigen by K^+ strains resulted in the reduced virulence of their K^- variants. This reduced virulence may be explained by a higher degree of phagocytosis as measured by chemiluminescence response of human polymorphonuclear leukocytes (PMNLs) and by enhanced killing by either human PMNLs or human serum or both (Simoons-Smit et al., 1986). Other studies (mouse peritonitis model) found strains with antigens K1 and K2 more virulent than strains with other K antigens (Podschun and Ullmann, 1998). The K antigen plays a crucial role in protecting the bacterium from opsonophagocytosis in the absence of specific antibodies (Williams et al., 1983, 1986b; Simoons-Smit et al., 1986). The antiphagocytic function consists of inhibiting the activation or uptake of complement components, especially C3b. In addition, the K antigen inhibits the differentiation and functional capacity of macrophages *in vitro*. The degree of virulence conferred by a particular K antigen might be connected to the mannose content of the capsular polysaccharide (Podschun and Ullmann, 1998). K2 serotype is among the most common K-type isolated from patients with urinary tract infection, pneumonia, or bacteremia. K2 is the predominant serotype of human isolates worldwide, whereas K2 strains are very rarely encountered in the environment (Podschun and Ullmann, 1998).

Strains of *K. pneumoniae*, *K. oxytoca*, *K. planticola*, and *K. terrigena* may produce thick, channeled (type-1) fimbriae associated with mannose-sensitive hemagglutination (MS-HA). *K. mobilis* (*E. aerogenes*) produces antigenically similar fimbriae. Type 1 fimbriae mediate the attachment of *K. pneumoniae* to uroepithelial cells (Williams and Tomas, 1990) and to ciliated tracheal cells *in vitro* (Fader et al., 1988).

Strains of *K. pneumoniae*, *K. oxytoca*, *K. planticola*, and *K. terrigena* may also produce thin, nonchanneled (type-3) fimbriae associated with mannose-resistant hemagglutinins of the *Klebsiella* type (MR/K-HA). These fimbriae are efficient in promoting adherence to the roots of various grasses and cereals (Haahtela and

Korhonen, 1985). They are capable of binding to endothelial cells, respiratory tract epithelial cells, and uroepithelial cells. In the kidney, they mediate bacterial adhesion to tubular basement membranes, Bowman's capsules, and renal vessels (Podschun and Ullmann, 1998). Three new putative colonization factors have also been described (Podschun and Ullmann, 1998).

The most important role of the O antigen is to protect *K. pneumoniae* from complement-mediated killing (Williams and Tomas, 1990). For this protection, O antigen chain length seems to be important (McCallum et al., 1989).

Iron is essential for bacterial growth. Brewer et al. (1982) observed that virulence was enhanced by hyperferremi. Since in the human body iron is complexed to carrier molecules such as transferrin (in the serum) or lactoferrin (in milk and other secretions), or sequestered within cells (in heme proteins), potentially pathogenic *Enterobacteriaceae* produce high-affinity systems (siderophores) to solubilize and import the required iron. The iron-chelating compounds produced are mostly of two sorts, phenolates (e.g., enterochelin) and hydroxamates (aerobactin) (Payne, 1988). Almost all strains of *Klebsiella* produce enterochelin whereas only a few produce aerobactin (Williams et al., 1987). Nassif and Sansonetti (1986) correlated the virulence of *K. pneumoniae* serotypes K1 or K2 with the presence of a 180-kb plasmid encoding the hydroxamate siderophore aerobactin. Aerobactin is an essential factor of pathogenicity and the 180-kb plasmid carries additional genes encoding other virulence factors (Nassif and Sansonetti, 1986). Some strains of *K. pneumoniae* express a ferric aerobactin uptake system without making the chelator itself. This may confer a selective advantage in mixed infections in competition with other aerobactin-producing bacteria (Williams and Tomas, 1990).

The production of cytotoxins, enterotoxins, and hemolysins have been sporadically described (Podschun and Ullmann, 1998).

Ecology Klebsiellae have been recovered from aquatic environments receiving industrial wastewaters, plant products, fresh vegetables, food with a high content of sugars and acids, frozen orange juice concentrate, sugar cane wastes, living trees, plants, and plant by-products. They are commonly associated with wood, saw dust, and waters receiving industrial effluents from pulp and paper mills and textile finishing plants. Isolates have been described in forest environments, degrading kraft-lignin, tannic acid, pine bark, and condensed tannin, or from living or decaying wood and bark or composted wood.

Klebsiella can frequently be isolated from the root surfaces of various plants. *K. pneumoniae*, *K. oxytoca*, or *K. planticola* are capable of fixing nitrogen and are classified as associative nitrogen fixers.

Strains from plants certainly need to be reidentified in the light of present taxonomic schemes. Strains of *K. pneumoniae sensu stricto* that are associated with plants differ from those associated with serious human infections. These environmental *K. pneumoniae* strains are most often able to utilize 5-ketogluconate as sole carbon source and never have capsular types K1 to K6. Strains involved in serious infection do not utilize 5-ketogluconate and may have capsular types K1 to K6 as well as other capsular types (Grimont et al., 1991).

Capsular types K1, K2, and K5 were major causes of epidemic metritis in mares in England, whereas type K7 was associated with sporadic, opportunistic genital infection. Outbreaks of metritis in mare were due to type K2 in the United States and in France. The stallion plays an important role in the transmission of *K. pneumoniae*. Type K7 was found on the preputial skin of stallions and may be part of the normal bacterial flora in this location. Thus it is important to type *Klebsiella* isolated in the genital tract of horses to detect a stallion carrying an epidemic strain among other stallions carrying less pathogenic *K. pneumoniae* (Grimont et al., 1991).

Klebsiella have been frequently associated with bovine mastitis, and causes serious infections in other animals including rhesus monkeys, guinea pigs, or muskrats. Epidemics of fatal generalized infections among captive squirrel monkeys (*Saimiri sciureus*) in French Guyana and lemurs in a French zoo were due to *K. pneumoniae* K5 and K2, respectively. Immunization of the monkeys with the corresponding capsular polysaccharide is efficient in stopping the epidemic (Grimont et al., 1991).

Enrichment and Isolation Procedures

The detection, isolation, and enumeration in clinical, industrial, and natural environments can be facilitated by using a selective medium.

On agar plates, although colonies develop overnight, the characteristic elevated and mucoid appearance is observed after incubation for 48 h.

The ability to utilize citrate (Cooke et al., 1979) or *myo*-inositol (Legakis et al., 1976) has been applied to the formulation of selective media. Resistance of *Klebsiella* spp. to methyl violet (Campbell and Roth, 1975), double violet (Campbell et al., 1976), potassium tellurite (Tomas et al., 1986), and carbenicillin (Thom, 1970) has been used in selective media.

Thom (1970) developed a medium based on the MacConkey agar in which lactose is replaced by inositol (1% w/v), with the addition of 100 μg of carbenicillin per ml. Bagley and Seidler (1978) devised a similar medium with only 50 μg/ml carbenicillin. On this medium, about 95% of pink-to-red colonies were verified to be *Klebsiella* spp., whereas only 1% of yellow background colonies were *Klebsiella*.

Since about 10% of *Klebsiella* strains are susceptible to 50 μg/ml of carbenicillin, the antibiotic was replaced in the above formula by tellurite (K_2TeO_3, 3 μg/ml) (Tomas et al., 1986), which is a strong inhibitor of phosphate transport in *E. coli*. Minimal inhibitory concentrations of K_2TeO_3 were 100 or 200 μg/ml for *K. pneumoniae* subsp. *pneumoniae*, *K. oxytoca*, *K. planticola*, and *K. terrigena*, 10 μg/ml for *K. pneumoniae* subsp. *ozaenae*, and 1–3 μg/ml for other *Enterobacteriaceae* (Tomas et al., 1986). In a field test, 77% of pink-to-red colonies on MacConkey–inositol–potassium tellurite agar were confirmed as *Klebsiella* spp.; however, the efficiency of plating was about 1% (Dutka et al., 1987).

Bruce et al. (1981) devised an agar medium combining Koser citrate and raffinose (carbon sources) and ornithine and low pH (for ornithine decarboxylase). On acidic Koser citrate agar with ornithine and raffinose, *Klebsiella* strains grow as yellow mucoid colonies. Other *Enterobacteriaceae* either do not grow, or produce small colorless, pink, red, or orange colonies.

For the isolation of *K. pneumoniae* and *K. oxytoca* from human feces, Van Kregten et al. (1984) have developed a medium based on the presence of two carbon sources, citrate and inositol, without inhibitor. The medium consists of Simmons citrate agar with 1% inositol. *Klebsiella* spp. appear as yellow, dome-shaped, often mucoid colonies, whereas *E. coli* appears as tiny, watery colonies. Apart from some *Enterobacter* strains, no other of bacteria grow on the medium.

Wong et al. (1985) devised a minimal medium in which the carbon source is lactose and the nitrogen source is potassium nitrate. Inhibitory compounds were deoxycholate, neutral red, and crystal violet. On this medium, *K. pneumoniae* and *K. oxytoca* grow as convex, and 1–2 mm in diameter, rather mucoid pink-to-red colonies, or larger, more watery pale red colonies with a dark red center. Non-klebsiellae either fail to grow or form colorless colonies.

Maintenance Procedures

Klebsiella strains can be easily maintained at room temperature in meat extract semisolid agar, at −80°C in a broth medium with 10–50% (v/v) glycerol, or freeze-dried. *K. granulomatis* will not remain viable when stored at 5° or 37°C. At 25°C, viability of egg yolk cultures is maintained for 8–10 d.

Differentiation of the genus *Klebsiella* from other genera

See Table BXII.γ.193 of the family *Enterobacteriaceae* for characteristics that can be used to distinguish *Klebsiella* from other genera of the family. No strain of *Klebsiella* other than *K. mobilis* is motile.

Classically, a Gram-negative capsulated isolate that is nonmotile, aerogenic, Voges–Proskauer positive, lysine decarboxylase positive, ornithine decarboxylase negative, and arginine dihydrolase negative belongs in the genus *Klebsiella*. However, inclusion of *K. mobilis* and *K. ornithinolytica* makes this classical identification more difficult at the genus level. In the following discussion, the genus *Enterobacter* will be considered without *E. aerogenes*.

Carbon source utilization tests are essential. All *Klebsiella* strains (with the exception of *K. pneumoniae* subsp. *ozaenae* and subsp. *rhinoscleromatis*) utilize the following six substrates: D-arabitol, *myo*-inositol, palatinose, quinate, D-sorbitol, and sucrose. No *Enterobacter*, *Pantoea*, or *Erwinia* species utilizes all six of these substrates. In the genus *Serratia*, only *S. ficaria* would utilize all six substrates and also L-arabitol and *i*-erythritol, which no *Klebsiella* has the simultaneous ability to utilize. Furthermore, D-adonitol is utilized by all *Klebsiella* strains except environmental strains of *K. pneumoniae*. In the genus *Enterobacter*, D-adonitol is utilized only by some strains of *Enterobacter cloacae*. Some strains of *Pantoea* also utilize D-adonitol.

Taxonomic Comments

The first organism of the genus *Klebsiella* described was a capsulated bacillus isolated from patients with rhinoscleroma (von Frisch, 1882). Then Friedländer (1882) described a bacterium from lungs of a patient who had died of pneumoniae. The organism was subsequently named *"Hyalococcus pneumoniae"* (Schroeter, 1889). The genus *Klebsiella* was coined by Trevisan (1885) to honor the German microbiologist Edwin Klebs (1834–1913). In 1887 (Trevisan, 1887), the genus contained *Klebsiella pneumoniae* (Friedländer bacillus) and *K. rhinoscleromatis* (von Frisch's bacillus). *"Bacillus mucosus ozaenae"*, which Abel (1893) observed in nasal secretion of patients with ozena, was later included in the genus as *K. ozaenae* (Bergey et al., 1925).

The genus *Klebsiella* with three species lasted up to the eighth edition of the *Bergey's Manual of Determinative Bacteriology*.

Flügge (1886) described *"Bacillus oxytocus perniciosus"* from old milk. This organism was named *"Aerobacter oxytocum"* (Bergey et al., 1923) and *Klebsiella oxytoca* (Lautrop, 1956). For many years, the existence of this indole-positive species was questioned and it was often considered a biogroup of *K. pneumoniae* (Edwards and Ewing, 1972; Ørskov, 1974). DNA relatedness studies showed *K. oxytoca* to be clearly distinct from *K. pneumoniae* (Jain et al., 1974; Brenner et al., 1977).

K. planticola (Bagley et al., 1981) was proposed for strains isolated primarily from botanical and soil environments (Bagley et al., 1981). *K. planticola* is distinct from other *Klebsiella* species based on DNA relatedness (Woodward et al., 1979; Izard et al., 1981a).

K. terrigena (Izard et al., 1981a), was proposed for strains isolated mainly from aquatic and soil environments (Izard et al., 1981a). It is a distinct species according to DNA relatedness studies (Woodward et al., 1979; Izard et al., 1981a).

The species described as *K. trevisanii* (Ferragut et al., 1983) was shown to be synonymous with *K. planticola* by DNA–DNA hybridization (Gavini et al., 1986).

In the first edition of the *Bergey's Manual of Systematic Bacteriology*, four species were recognized: *K. pneumoniae*, *K. oxytoca*, *K. planticola*, and *K. terrigena*.

K. ozaenae and *K. rhinoscleromatis* cannot be separated from *K. pneumoniae* by DNA relatedness (Brenner et al., 1972c). For this reason, *K. ozaenae* and *K. rhinoscleromatis* were treated as subspecies of *K. pneumoniae* in the first edition of the *Bergey's Manual of Systematic Bacteriology* (Ørskov, 1974).

For many years, *K. pneumoniae* could not be objectively separated from an organism observed by Escherich (1885), named *"Bacterium lactis aerogenes"* (Kruse, 1896), transferred to genus *"Aerobacter"* as *"A. aerogenes"*, and finally as *Enterobacter aerogenes* (Hormaeche and Edwards, 1960b). Confusion occurred since both *K. pneumoniae* and *"Aerobacter aerogenes"* fermented many carbohydrates (often with gas production), gave a positive Voges–Proskauer reaction, and reacted with *Klebsiella* capsular antisera. When Møller (1955) introduced the decarboxylase tests, *K. pneumoniae* was defined as nonmotile and ornithine decarboxylase negative, whereas *"A. aerogenes"* was defined as motile or nonmotile and ornithine decarboxylase positive (Hormaeche and Edwards, 1958). Later, a new genus *Enterobacter* was formed (Hormaeche and Edwards, 1960b) to which *"A. aerogenes"* was transferred as *E. aerogenes*.

Nomenclatural confusion occurred when a biogroup of *K. pneumoniae* was named *"Klebsiella aerogenes"* (Taylor et al., 1956). Cowan et al. (1960) subdivided *K. pneumoniae sensu lato* into *K. pneumoniae* (*sensu stricto*), *"K. aerogenes"*, *"K. edwardsii* subsp. *edwardsii"*, and *" K. edwardsii* subsp. *atlantae"*. Authentic or typical strains of *K. pneumoniae*, *K. edwardsii*, and *"K. aerogenes"* cannot be differentiated by DNA relatedness or protein electrophoresis, and thus belong to a single species, *K. pneumoniae* (Brenner et al., 1972c; Jain et al., 1974; Ferragut et al., 1989).

These problems around the epithet *aerogenes* were due to a lack of authentic cultures. Neotypes have since been designated when no original type strain was available.

Enterobacter aerogenes is much closer to *Klebsiella* species than to *Enterobacter cloacae* (the type species of that genus) based on phenotypic traits and DNA relatedness (Bascomb et al., 1971; Brenner et al., 1972c; Steigerwalt et al., 1976; Izard et al., 1980). The transfer of *E. aerogenes* to the genus *Klebsiella* has been proposed (Bascomb et al., 1971). However, since the name *"Klebsiella aerogenes"* had been used for another organism, a new name, *Klebsiella mobilis*, was coined (Bascomb et al., 1971).

Nonmotile, encapsulated, ornithine decarboxylase positive strains were described under the name *Klebsiella ornithinolytica*

(Sakazaki et al., 1989a). Apart from ornithine decarboxylase test, these strains are biochemically undistinguishable from *K. planticola*, and are identical to *K. planticola* by DNA hybridization (Farmer et al., 1985a; D.J. Brenner, personal communication). Farmer et al. (1985a) questioned the validity of *K. ornithinolytica* as a species distinct from *K. planticola*. Some ornithine decarboxylase positive strains have been shown to belong in *K. pneumoniae* by DNA relatedness criteria (Lindh and Frederiksen, 1990).

Finally, *Calymmatobacterium granulomatis*, which has not been cultured on bacteriological media, has been transferred to the genus *Klebsiella* as *Klebsiella granulomatis*, mostly based on *rrs* sequences (Carter et al., 1999). Partial *rpoB* sequencing suggested that *K. granulomatis* is very close to *K. pneumoniae* (Drancourt et al., 2001) and *phoE* sequencing showed *K. granulomatis* close to *K. pneumoniae* subsp. *rhinoscleromatis* (Carter et al., 1999). Thus, there is presently no proof that *K. granulomatis* is a species distinct from *K. pneumoniae*, and instead there are arguments to make it part of *K. pneumoniae*.

Sequence data are increasingly used to suggest or support nomenclatural changes and some of these changes can be anticipated. The taxonomic significance of the three sequence clusters observed in *K. pneumoniae* or the two sequence clusters in *K. oxytoca* (Brisse and Verhoef, 2001) is still unknown, and DNA–DNA hybridization data are needed before a proposal can be made to design new species or subspecies. Since the phylogenetic tree obtained by *rrs* gene (encoding 16S rRNA) sequence comparison showed the genus *Klebsiella* to be split in at least two groups, a new genus, *Raoultella*, was proposed to contain *R. planticola* (type species), *R. ornithinolytica*, and *R. terrigena* (Drancourt et al., 2001). More sequencing work needs to be done to evaluate this proposal since partial *rpoB* sequence failed to group *Raoultella* species in a single cluster and these sequences were only 512 nucleotides long.

Differentiation of the species of the genus *Klebsiella*

Table BXII.γ.229 presents the characteristics differentiating the species and subspecies of *Klebsiella*.

List of species of the genus Klebsiella

1. **Klebsiella pneumoniae** (Schroeter 1886) Trevisan 1887, 94[AL] (*Hyalococcus pneumoniae* Schroeter 1886, 1952.)
pneu.mo′ni.ae. Gr. n. *pneumonia* pneumonia, inflammation of the lungs; M.L. gen. n. *pneumoniae* of pneumonia.

The characteristics are as described for the genus and as listed in Table BXII.γ.229. *K. pneumoniae* can be divided into three sequence clusters (Brisse and Verhoef, 2001) unrelated to the present subdivision in subspecies. *K. pneumoniae* is normally found in the intestinal tract of humans and animals. It may be isolated in association with several pathological processes in humans, e.g., community-acquired pneumonia or nosocomial urinary tract infection. Serotype K2 is the most common K-type isolated from patients with urinary tract infection, pneumonia, or bacteremia. In animals, *K. pneumoniae* may be isolated from metritis in mares, bovine mastitis, or generalized infections in captive monkeys. Environmental strains generally utilize more carbon sources than clinical strains, but often fail to utilize D-adonitol. Intraspecies DNA relative reassociation values among strains is ~80–90% (Brenner et al., 1972c) or 73–100% (Woodward et al., 1979).

The mol% G + C of the DNA is: 56–58 (T_m) (Seidler et al., 1975).

Type strain: ATCC 13883, CIP 82.9, DSM 30104, JCM 1662.

GenBank accession number (16S rRNA): X87276, Y17656, AB004753, AF130981.

a. **Klebsiella pneumoniae** *subsp.* **pneumoniae** (Schroeter 1886) Trevisan 1887, 94[AL] (*Hyalococcus pneumoniae* Schroeter 1886, 1952.)

Distinguished from the subspecies subsp. *ozaenae* and subsp. *rhinoscleromatis* by the characteristics listed in Table BXII.γ.229. Clinical strains may produce an extended-spectrum β-lactamase.

The mol% G + C of the DNA is: 56–58 (T_m) (Seidler et al., 1975).

Type strain: ATCC 13883, CIP 82.9, DSM 30104, JCM 1662.

GenBank accession number (16S rRNA): X87276, Y17656, AB004753, AF130981.

b. **Klebsiella pneumoniae** *subsp.* **ozaenae** (Abel 1893) Ørskov 1984c, 355[VP] (Effective publication: Ørskov 1984b, 463) (*Klebsiella ozaenae* (Abel 1893) Bergey, Harrison, Breed, Hammer and Huntoon 1925, 266; *Bacillus mucosus ozaenae* Abel 1893, 167; *Bacillus ozaenae* (Abel 1893) Lehmann and Neumann 1896, 204.)
o.zae′nae. L. fem. n. *ozaena* ozena; L. gen. n. *ozaenae* of ozena.

Distinguished from the subspecies subsp. *pneumoniae* and subsp. *ozaenae* by the characteristics listed in Table BXII.γ.229. Occurs in ozena and other chronic diseases of the respiratory tract.

The mol% G + C of the DNA is: not available.

Type strain: ATCC 11296, CIP52.211, JCM 1663, LMG 3113.

GenBank accession number (16S rRNA): Y17654, AF130982.

c. **Klebsiella pneumoniae** *subsp.* **rhinoscleromatis** (Trevisan 1887) Ørskov 1984c, 355[VP] (Effective publication: Ørskov 1984b, 464) (*Klebsiella rhinoscleromatis* Trevisan 1887, 95; *Bacterium rhinoscleromatis* (Trevisan 1887) Migula 1900, 352.)

rhi.no.scle.ro' ma.tis. M.L. adj. *rhinoscleromatis* pertaining to rhinoscleroma.

Distinguished from the subspecies subsp. *pneumoniae* and subsp. *ozaenae* by the characteristics listed in Table BXII.γ.229. Found in patients with rhinoscleroma.

The mol% G + C of the DNA is: not available.

Type strain: ATCC 13884, CIP 52.210, JCM 1664, LMG 3184.

GenBank accession number (16S rRNA): Y17657, AF130983.

2. **Klebsiella granulomatis** (Aragão and Vianna 1913) Carter, Bowden, Bastian, Myers, Sriprakash and Kemp 1999, 1698[VP] (*Calymmatobacterium granulomatis* Aragão and Vianna 1913, 221.)
gran.u.lo' ma.tis. L. dim. n. *granulum* a small grain; Gr. suff. *-oma* a swelling or tumor; M.L. n. *granuloma* a granuloma; M.L. gen. n. *granulomatis* of a granuloma.

Occurs in granuloma inguinale (donovanosis) lesions. The bacilli (Donovan bodies) are seen in large vacuolated macrophages found in dermal infiltrate of genital ulcerations. Grow in the yolk sac of developing embryo or in cell cultures (fresh mononuclear cells or Hep-2 cell line). No growth in bacteriological media. Type strain: No type culture is currently available.

The mol% G + C of the DNA is: not available.

GenBank accession number (16S rRNA): AF009171, AF010251, AF010252, AF010253.

3. **Klebsiella mobilis** Bascomb, Lapage, Willcox and Curtis 1971, 279[AL]*
mo' bi.lis. L. adj. *mobilis* movable, motile.

The characteristics are described in Table BXII.γ.229. This is the only motile species in the genus. Strains producing extended-spectrum β-lactamase occur as nosocomial pathogens. Occur in water, sewage, soil, dairy products, and the feces of humans and animals. Also an opportunistic pathogen.

The mol% G + C of the DNA is: 53–54 (Bd).

Type strain: ATCC 13048, CIP 60.86, DSM 30053, JCM 1235, LMG 2094.

GenBank accession number (16S rRNA): AB004748.

4. **Klebsiella oxytoca** (Flügge 1886) Lautrop 1956, 375[AL] (*Bacillus oxytocus perniciosus* Flügge 1886, 268.)
oxy.to' ca. Gr. *oxys* sour, acid; Gr. suff. *-tokos* bearer, producer; M.L. n. *oxytocus* acid-producer, spurious; M.L. adj. *oxytoca* (sic) acid-producing.

The characteristics are as described for the genus and as listed in Table BXII.γ.229. Present in the intestinal tract of humans and animals. Can be isolated from various pathological processes and from botanical and aquatic environments. *K. oxytoca* can be divided into two sequence clusters (Brisse and Verhoef, 2001). Encapsulated; typable with *Klebsiella* K antisera. The intraspecies DNA relative reassociation values were 75% in the study by Brenner et al. (1972c) and 95% (average value) in the study by Woodward et al. (1979).

The mol% G + C of the DNA is: 55–58 (T_m).

Type strain: ATCC 13182, CIP 103434, JCM 1665, LMG 3055.

GenBank accession number (16S rRNA): Y17655, AB004754, AF129440.

5. **Klebsiella planticola** Bagley, Seidler and Brenner 1982, 266[VP] (Effective publication: Bagley, Seidler and Brenner 1981, 109.)*
plan.ti' co.la. L. fem. n. *planta* a plant; L. suff. *-cola* dweller; M.L. fem. n. *planticola* plant-dweller.

The characteristics are as described for the genus and as listed in Table BXII.γ.229. Isolated mainly from botanical, aquatic, and soil environments. Three biovars have been described (Naemura et al., 1979). Encapsulated; typable with *Klebsiella* K antisera. The average intraspecies DNA relative reassociation value is above 75% (Woodward et al., 1979).

The mol% G + C of the DNA is: 53.9–55.4 (T_m) (Seidler et al., 1975).

Type strain: ATCC 33531, ATCC 33558, CIP 100751, DSM 3069, IFO 14939.

GenBank accession number (16S rRNA): X93215, Y17659, AB004755, AF129443.

6. **Klebsiella terrigena** Izard, Ferragut, Gavini, Kersters, De Ley and Leclerc 1981a, 125[VP]
ter.ri.ge' na. L. n. *terra* soil; L. suff. *gena* origin; M.L. n. *terrigena* from soil.

The characteristics are as described for the genus and as listed in Table BXII.γ.229. Isolated mainly from aquatic and soil environments. The average intraspecies DNA relative reassociation value is above 86% (Izard et al., 1981a).

The mol% G + C of the DNA is: 56.7 (T_m) (Izard et al., 1981a).

Type strain: ATCC 33257, CIP 80-07, DSM 2687, JCM 1687, LMG 3222.

GenBank accession number (16S rRNA): Y17658, AF129442.

Species Incertae Sedis

1. **Klebsiella ornithinolytica** Sakazaki, Tamura, Kosako and Yoshizaki 1989b, 495[VP] (Effective publication: Sakazaki, Tamura, Kosako and Yoshizaki 1989a, 205.)
or.ni.thi.no.ly' ti.ca. M.L. *ornithinum* ornithine, an amino acid; Gr. adj. *lyticus* dissolving; M.L. fem. adj. *ornithinolytica* ornithine dissolving.

The CDC group called Klebsiella Group 47 corresponds to this species (Sakazaki et al., 1989a). Physiological and nutritional characteristics are presented in Table BXII.γ.229. Isolated from clinical materials, including urine, sputa, stool, and pus. Can be found in food. Clinical significance unknown.

The mol% G + C of the DNA is: 57–58 (T_m) (Sakazaki et al., 1989a).

Type strain: ATCC 31898, CIP 103576, DSM 7464, JCM 6096.

GenBank accession number (16S rRNA): AF129441, AJ251467.

**Editorial Note: Klebsiella mobilis* Bascomb et al. 1971 and *Enterobacter aerogenes* Hormaeche and Edwards 1960b have the same type strain and therefore are homotypic synonyms.

**Editorial Note: Klebsiella trevisanii* Ferragut et al. 1983 (phenon K of Gavini et al., 1977) is a junior subjective synonym of *K. planticola* (Gavini et al., 1986).

Genus XVII. **Kluyvera** *Farmer, Fanning, Huntley-Carter, Holmes, Hickman, Richard and Brenner 1981b, 382[VP] (Effective publication: Farmer, Fanning, Huntley-Carter, Holmes, Hickman, Richard and Brenner 1981a, 927)*

J.J. Farmer III

Kluy' ve.ra. M.L. fem. n. *Kluyvera* named by Asai et al. (1956) to honor the Dutch microbiologist A.J. Kluyver, who made many contributions to microbial physiology and taxonomy.

Small rod-shaped cells, 0.5–0.7 × 2–3 μm, conforming to the general definition of the family *Enterobacteriaceae*. Gram negative. Motile, with peritrichous flagella. Contains the enterobacterial common antigen. Facultatively anaerobic. Catalase positive (weak). Oxidase negative. Nonpigmented. Ferment, rather than oxidize, D-glucose and other carbohydrates. Reduce nitrate to nitrite. **Positive for indole production, methyl red, citrate utilization (Simmons), ornithine decarboxylase, motility at 36°C, growth in the presence of cyanide (KCN test), malonate utilization, and esculin hydrolysis. Ferment D-glucose, lactose, sucrose, D-mannitol, salicin, L-arabinose, raffinose, L-rhamnose, maltose, D-xylose, trehalose, cellobiose, α-methyl-D-glucoside, melibiose, mucate, D-mannose, and D-galactose. Produce visible gas during fermentation. Produce large amounts of α-ketoglutaric acid during the fermentation of D-glucose.** Negative for Voges–Proskauer, H_2S production (TSI), urea hydrolysis, phenylalanine deaminase, arginine dihydrolase, gelatin hydrolysis (22°C), lipase (corn oil), DNase, and the fermentation of dulcitol, adonitol, *myo*-inositol, erythritol, and D-arabitol. Susceptible to colistin, sulfadiazine, gentamicin, kanamycin, tetracycline, and chloramphenicol (disk diffusion method on Mueller–Hinton agar); **resistant to carbenicillin; penicillin, ampicillin, and cephalothin**; variable susceptibility to nalidixic acid and streptomycin.

Some strains produce kluyveramycin, unusual reddish blue crystals of unknown composition. **Occur in human clinical specimens**, food, soil and sewage. Probably an occasional **opportunistic pathogen and a cause of extraintestinal infections of humans**.

The genus *Kluyvera* includes *Kluyvera ascorbata*, *K. cryocrescens*, and *K. georgiana*. There is also a fourth species with standing in nomenclature, *Kluyvera cochleae*, but it appears to be a synonym of *Enterobacter intermedius* (originally named *E. intermedium*; corrected by von Graevenitz, 1990).

The mol% G + C of the DNA is: 55.1–56.6.

Type species: **Kluyvera ascorbata** Farmer, Fanning, Huntley-Carter, Holmes, Hickman, Richard and Brenner 1981b, 382 (Effective publication: Farmer, Fanning, Huntley-Carter, Holmes, Hickman, Richard and Brenner 1981a, 927.)

Further descriptive information

Literature Since *Kluyvera* was described in 1956, there have been many reports in the literature; over 40 have been cataloged in MEDLINE and many others in BIOSIS. In addition to the genus and species names, "Enteric Group 8", *"K. citrophila"*, and *"K. noncitrophila"* should also be included as a search terms, although they are rarely used today.

The National Library of Medicine's Internet site Entrez (http://www.ncbi.nlm.nih.gov), which covers most of the sequence databases, includes full sequences of the 16S rRNA gene for *K. ascorbata*, *K. georgiana*, and *K. cochleae* (*Enterobacter intermedius*), and a partial sequences for *K. cryocrescens*. A search for the term *Kluyvera* yielded 29 sequences.

Problems in evaluating the literature Computer literature searches often yield articles such as "First case of bacteremia due to xx" or "Wound infections due to yy"; where "xx" and "yy" are newly described bacterial species. The reader should evaluate these reports very critically, with particular attention to the way that cultures were identified. Over half the cultures of new or unusual *Enterobacteriaceae* in these reports have been misidentified (Farmer unpublished). *Kluyvera* strains from two published studies were subsequently identified as *Serratia fonticola* (Enteric Reference Laboratory at CDC, unpublished).

Sources, strains, collections The original collection described by Farmer et al. (1981a) included isolates from body sites that are normally sterile such as blood (2 isolates) and urine (13). Strains were also from nonsterile body sites: intestine or feces (8), throat or sputum (40), and other or unspecified (10). Other isolates were from nonhuman sources or culture collections: cow (1), water (1), sewage (4), food (1), milk (1), soil (1), hospital sink (1), and unspecified or unknown (18). These other sources suggest ways that humans and animals might come in contact with the organism. The description of the genus was based on an unweighted tabulation of 193 *Kluyvera* strains from the Enteric Reference Laboratory's collection; 149 of *K. ascorbata*, 38 of *K. cryocrescens*, and six of *Kluyvera* species 3.

Occurrence in human feces The original report of Farmer et al. (1981a) listed eight isolates from human feces. All these presumably came from cases of diarrhea or intestinal infections, and were identified as *Kluyvera ascorbata*. Although clinical information that accompanied the cultures was limited, there was no suggestion of an etiological role for *Kluyvera*. Fainstein et al. (1982a) isolated strains of *Kluyvera* from patients with and without diarrhea, and in the title of their paper suggested that *Kluyvera* strains might have had a role in some of the diarrhea cases. Kay et al. (1990) isolated 28 *Kluyvera* strains during a 2-yr prospective case-control study of acute gastroenteritis in children younger that 2 years old, and concluded that *Kluyvera* did not appear to be a diarrheal pathogen. In summary, there is no strong evidence that *Kluyvera* strains can actually cause diarrhea or intestinal infections, but this issue warrants further study. The presence of *Kluyvera* in food and water is a possible source of these intestinal isolates.

Occurrence in extraintestinal human specimens: clinical significance Most of the *Kluyvera* strains have been from the respiratory tract. Forty strains from the original collection (Farmer et al., 1981a) were from throat or sputum. Clinical significance and the ability to actually cause infections are still being evaluated. Systematic study and additional case reports are needed. Schwach (1979) reported three isolates of Enteric Group 8 from upper respiratory tract specimens. The strains were in mixed culture and not detected in subsequent specimens; thus they were of doubtful clinical significance. Braunstein et al. (1980) reported two cases that yielded cultures identified as Enteric Group 8 (subsequently, both were identified as *K. ascorbata*). One of these was from the sputum of a 6-year-old boy with pulmonary tuberculosis, and was not considered clinically significant. A second isolate was from gallbladder drainage fluid of a 63-year-old

woman with acute pancreatitis. Based on chart review, this isolate was considered clinically significant. Of CDC's current collection of 144 *Kluyvera* strains, none has been isolated from spinal fluid, but five strains have been isolated from blood: three strains (two from France) of *K. ascorbata*, one strain of *K. cryocrescens* (a 3-month-old, at autopsy), and one of *Kluyvera* species group 3. Most of these were submitted with little or no patient information, so it was impossible to evaluate clinical significance. The five blood isolates and the growing number of literature reports (Aldová et al., 1985b; Wong, 1987; Luttrell et al., 1988; Thaller et al., 1988; Tristram and Forbes, 1988; Dollberg et al., 1990; Sierra-Madero et al., 1990; Yogev and Koszlowski, 1990; Sezer et al., 1996; Padilla et al., 1997) suggest that *Kluyvera* is more than a benign saprophyte. Most new species of *Enterobacteriaceae* have at least attained the status of "infrequent opportunistic pathogen". Based on present knowledge, this status also seems appropriate for *Kluyvera*. The respiratory tract has been the most common source for *Kluyvera*, but there is no strong evidence that it is clinically significant at this site (however, one isolate of *K. ascorbata* was from a lung at autopsy). The respiratory tract (particularly sputum) is notoriously difficult to evaluate for clinical significance. The urinary tract has been the next most common source, but it has also been difficult to document clinical significance (Tristram and Forbes, 1988).

Occurrence in other animals Bangert et al. (1988) identified strains as *Kluyvera* species along with other *Enterobacteriaceae* in a fecal culture survey of 47 captive raptors (the bird orders *Falconiformes* and *Strigiformes*).

Reporting of *Kluyvera* species Originally, Farmer et al. (1981a) were pessimistic that most clinical and public health laboratories could identify *Kluyvera* strains to species. They suggested that reference laboratories could attempt complete identification, but that clinical laboratories should not attempt the additional phenotypic testing with the addition of special tests. Normal identification methods should allow an identification to the genus level, with a report of "*Kluyvera* species". The addition of one new *Kluyvera* species, and seven new *Buttiauxella* species has made it even more difficult to identify cultures of *Kluyvera–Buttiauxella* to species. Further work is needed to find better tests for differentiation. In the meantime, a conservative approach would be to use terms such as "*Kluyvera* species", "*Buttiauxella* species", and "*Kluyvera–Buttiauxella* group" for cultures that cannot be definitively assigned a species name.

Accumulation of α-ketoglutaric acid Asai et al. (1956) assigned considerable importance to the fact that *Kluyvera* strains accumulated extremely large amounts of α-ketoglutaric acid during D-glucose fermentation. However, few other *Enterobacteriaceae* have been investigated for this property.

Enrichment and Isolation Procedures

Strain of *Kluyvera* are not difficult to grow and are typical *Enterobacteriaceae* in most respects. See the chapter on the family *Enterobacteriaceae* for general information on growth, plating media, working and frozen stock cultures, media and methods for biochemical testing, identification, computer programs, and antibiotic susceptibility.

Differentiation of the genus *Kluyvera* from other genera

Table BXII.γ.193 in the chapter on the family *Enterobacteriaceae* gives the results for *K. ascorbata*, *K. cryocrescens*, and *K. georgiana* in 47 biochemical tests normally used for identification (Farmer, 1999). There are no genus- or species-specific tests or sequences for the identification of *Kluyvera*. The best approach is to do a complete set of phenotypic tests (growth on plating media, biochemical tests, antibiogram, etc.) and compare the results with all the other named organisms in the family *Enterobacteriaceae*. This approach is described in more detail in the section on the family *Enterobacteriaceae*. The biochemical results of a test strain can be compared to all the organisms listed in Table BXII.γ.193 of that section. Several computer programs greatly facilitate analyzing the results.

Taxonomic Comments

Kluyvera is a genus with a turbulent history. Although the name was used in the literature from 1956 to 1980, the genus name, and the two original species names ("*K. citrophila*" and "*K. noncitrophila*") did not appear on the 1980 Approved Lists of Bacterial Names. The reasons for these omissions were never stated. Thus, *Kluyvera*, "*K. citrophila*", and "*K. noncitrophila*" lost standing in nomenclature. To resolve this nomenclatural problem, Farmer et al. (1981a) proposed a redefined genus *Kluyvera*.

The history of *Kluyvera* Asai et al., 1956 In 1956 and 1957, Asai and co-workers in Japan proposed the genus name *Kluyvera* for a group of "polarly flagellated" bacteria that produced large amounts of α-ketoglutaric acid during the fermentation of D-glucose. Five strains were originally studied, one from soil and four from sewage (Table BXII.γ.230). Two species names were proposed, "*K. citrophila*" and "*K. noncitrophila*", which were based on the difference among the strains in utilizing citrate as the sole source of carbon and energy (Asai et al., 1956). Asai and co-workers state (based on their interpretation of Kluyver and van Niel, 1936) that the genus was named to honor Professor A.J. Kluyver, who, with C.B. van Niel, in 1936 postulated that there may be a group of polarly flagellated organisms in the tribe *Pseudomonadeae* that have a mixed acid type of fermentation similar to *Escherichia* (called *Bacterium* in the paper). If such a group were to be discovered, it could be a separate genus, which would differentiate it from the genus *Aeromonas*, which has a butylene glycol fermentative pathway rather than a mixed acid pathway. Asai and co-workers thought they had discovered this postulated group of polarly flagellated organisms and named the group *Kluyvera* in honor of A.J. Kluyver for his many contributions to microbial metabolism and physiology. *Kluyvera* was classified in the tribe *Pseudomonadeae*, which at that time included nonfermentative genera, but also included the fermenters of the genus *Aeromonas*. Today, the family *Pseudomonadaceae* is restricted to bacteria that do not ferment glucose.

***Kluyvera* Asai et al., 1956 was "abolished" in 1962** In 1962, Asai and co-workers confirmed the observations of J.M. Shewan and Rudolph Hugh that all five of their *Kluyvera* strains actually had peritrichous rather than polar flagella (Asai et al., 1962). Thus, they proposed an alternative classification; the two species "*K. citrophila*" and "*K. noncitrophila*" were "transferred" to the genus *Escherichia* in the family *Enterobacteriaceae*. Thus, this alternative classification would result in the creation of two "new combinations"—"*Escherichia citrophila*" and "*Escherichia noncitrophila*"; however, these names were rarely used and did not appear on the 1980 Approved Lists of Bacterial Names.

History of the redefined genus *Kluyvera*: *Kluyvera* Farmer et al., 1981a The Enteric Reference Laboratory's interest in this group of organisms began in 1977 when the laboratory's

TABLE BXII.γ.230. Current nomenclature and classification (Farmer et al., 1981a) for strains originally proposed as *"Kluyvera citrophila"* and *"K. noncitrophila"*

Original name given by Asai et al. (1962)	Current (proposed) classification	ATCC number	Original strain designation	Source
"K. citrophila"	*K. ascorbata*	14236	6,β	Sewage, Japan
"K. citrophila"	*K. cryocrescens*	14237	84C,α	Soil, Tokyo, Japan
"K. citrophila"	*K. cryocrescens*	14238	11,γ	Sewage, Keihin District, Japan
"K. noncitrophila"	*K. cryocrescens*	14239	4	Sewage, Keihin District, Japan
"K. noncitrophila"	*K. cryocrescens*	14240	10	Sewage, Keihin District, Japan

STRAIN MATCHER computer programs listed over a dozen strains with almost identical biochemical reactions that had been reported as "unidentified". During this period, groups of unidentified *Enterobacteriaceae* were being defined, and this was the eighth group. Thus, the vernacular name "Enteric Group 8" was given to the group, and strains were then reported with this designation and included a comment that additional strains would be welcomed so the group could be further studied. Soon after Enteric Group 8 was defined, Holmes of the Computer Identification Laboratory, National Collection of Type Cultures (NCTC), England, reported that the NCTC collection had strains that were almost identical to our Enteric Group 8, and they had been cataloged under the name *Kluyvera* (unpublished). The NCTC stains of *Kluyvera* were then studied at CDC and the conclusions of Holmes were confirmed. Since then, Enteric Group 8 was thought of as a synonym of *Kluyvera*. The DNA–DNA hybridization studies of Fanning et al. (1979) defined two large species groups in *Kluyvera* and defined a third group of strains that became "*Kluyvera* species group 3", and was thought to represent one or more additional *Kluyvera* species. Although *Kluyvera* was "abolished" in 1962 (Asai et al., 1962), reports in the literature continued to use the name *Kluyvera*, probably because strains had been deposited in the American Type Culture Collection, NCTC, and other culture collections. The name *Kluyvera* was proposed as a redefined genus by Farmer et al. (1981a) because this was considered a better alternative than proposing a new genus. The main consideration was that the name *Kluyvera* was still being used in the literature, and that the genus *Kluyvera* was well represented in culture collections by established strains of long standing.

Phylogenetic position Based on both phenotype and DNA–DNA hybridization, Farmer et al. (1981a) thought that *Kluyvera* was a tight, well-defined genus of *Enterobacteriaceae*. Two 16S rDNA trees (Figure BXII.γ.198 in the section on *Budvicia* and Figure BXII.γ.189 in the chapter on the family *Enterobacteriaceae*) include *Kluyvera*. Unfortunately, the species of *Kluyvera* and *Buttiauxella* were not included in the 16S rDNA tree published by Spröer et al. (1999).

Additional species of *Kluyvera* There are probably several additional *Kluyvera* species. The Enteric Reference Laboratory's collection has 21 strains that were reported as "*Kluyvera* species", three as "possible-probable" *Kluyvera ascorbata*, three as *Kluyvera cryocrescens*, and two as "*Kluyvera–Buttiauxella* Group" (Enteric Reference Laboratory, 2000, unpublished). These 29 and the following strains need to be studied by techniques that measure evolutionary relatedness: the four additional strains included in *Kluyvera georgiana* by Müller et al. (1996); the three strains of *K. ascorbata* and five strains of *K. cryocrescens* that had divergence values in DNA–DNA hybridization experiments in the range 5–9 (see Table 4 of Farmer et al., 1981a); and all other "atypical strains" of *Kluyvera* and *Buttiauxella*. Detailed study of this collection would probably result in the definition of many new species.

Further studies needed New phenotypic and molecular tests are needed for the routine identification and differentiation of *Kluyvera*, *Buttiauxella*, and related organisms. The 16S rDNA sequences of all *Kluyvera* and *Buttiauxella* species need to be completed or repeated and new trees drawn. This could provide a useful way to identify strains and clarify relationships of the genera and species.

Differentiation of the species of the genus *Kluyvera*

The original two named species of *Kluyvera*, *K. ascorbata* and *K. cryocrescens*, had almost identical results in the 47 tests commonly used to identify cultures of *Enterobacteriaceae* (Farmer et al., 1981a; see Table BXII.γ.193 in the chapter on the family *Enterobacteriaceae*). However, these species can be differentiated by several simple phenotypic tests (Table BXII.γ.231). *K. georgiana* is also almost identical to *K. ascorbata* and *K. cryocrescens* in the 47 tests commonly used to identify cultures of *Enterobacteriaceae* (Farmer et al., 1981a), which is one of the reasons it was not originally named. At present there are no simple ways to differentiate it.

TABLE BXII.γ.231. Tests useful for differentiating the three *Kluyvera* species; and between *Kluyvera* and *Buttiauxella*[a]

Test or property	*K. ascorbata*	*K. cryocrescens*	*K. georgiana*	*Buttiauxella*
Ascorbate test	97	0	nd	nd
Growth and D-glucose fermentation at 5°C within 21 d	3	100	nd	nd
Zone of inhibition around carbenicillin and cephalothin (see Figure 4 of Farmer et al., 1981a)	Small	Large	nd	nd
Growth on cefsulodin-irgasan-novobiocin agar[b]	100	0	nd	nd
Minimum inhibitory concentration (MIC) for irgasan (μg/ml)[b]	>128	≤0.25	nd	nd
Lysine decarboxylase (Møller)	97	23	100	−
Gas production during the fermentation of D-glucose	93	95	17	+
Dulcitol fermentation	25	0	33	0
Indole production	92	90	100	−
Sucrose fermentation	98	81	100	0
Citrate utilization	96	80	100	d
Raffinose fermentation	98	100	100	d
α-Methyl-D-glucoside fermentation	98	95	100	−
Melibiose fermentation	99	100	100	d
Acetate utilization	50	86	83	0

[a]Symbols: +, most strains are positive; −, most strains are negative; d, species to species variation, but many strains are negative. Each number is the percentage positive after 2 d incubation at 36°C.

[b]The data for growth on CIN agar and the irgasan MIC are from Altwegg et al. (1986); the other data are from Farmer et al. (1981a) and Farmer (1999).

List of species of the genus Kluyvera

1. **Kluyvera ascorbata** Farmer, Fanning, Huntley-Carter, Holmes, Hickman, Richard and Brenner 1981b, 382[VP] (Effective publication: Farmer, Fanning, Huntley-Carter, Holmes, Hickman, Richard and Brenner 1981a, 927.)
a.scor.ba′ ta. ascorbate, a modern chemical term, a salt of ascorbic acid; M.L. fem. adj. *ascorbata* pertaining to ascorbate.

The characteristics are as described for the genus. See Table BXII.γ.193 in the chapter on the family *Enterobacteriaceae* for the results of 47 biochemical tests normally used for identification (Farmer, 1999). Occurs in human clinical specimens, water, sewage, and food. Probably an opportunistic pathogen of humans that is occasionally encountered in clinical microbiology laboratories. The type strain was isolated from human sputum.

The mol% G + C of the DNA is: 56.1–56.6 (Bd).

Type strain: ATCC 33433, CDC 0648-74.(holotype).

GenBank accession number (16S rRNA): AF176560.

Additional Remarks: The ATCC includes two other strains; ATCC 33434 and ATCC 14236 (Table BXII.γ.230).

2. **Kluyvera cryocrescens** Farmer, Fanning, Huntley-Carter, Holmes, Hickman, Richard and Brenner 1981b, 382[VP] (Effective publication: Farmer, Fanning, Huntley-Carter, Holmes, Hickman, Richard and Brenner 1981a, 927.)
cry.o.cres′ cens. Gr. n. *kryos* cold; L. fem. pres. part. *crescens* growing; M.L. fem. adj. *cryocrescens* growing in the cold; referring to the fact the cultures grow at 4–5°C.

The characteristics are as described for the genus. See Table BXII.γ.193 in the chapter on the family *Enterobacteriaceae* for the results of 47 biochemical tests normally used for identification (Farmer, 1999). Occurs in human clinical specimens, soil, water, sewage, and the hospital environment. Probably an opportunistic pathogen of humans that is rarely encountered in clinical microbiology laboratories.

The mol% G + C of the DNA is: 55.1 (Bd).

Type strain: ATCC 33435, CDC 2065-78 (holotype).

Additional Remarks: The ATCC includes six other strains, four of which are described in Table BXII.γ.230.

3. **Kluyvera georgiana** Müller, Brenner, Fanning, Grimont and Kämpfer 1996, 63[VP]
geor.gi.a′ na. M.L. fem. adj. *georgiana* pertaining to Georgia, U.S.A., where the characterization and redefinition of *Kluyvera* was done.

Synonym: *K. georgiana* and *Kluyvera* species group 3 of Farmer et al. (1981a) are similar in several ways, but are different in circumscription as described below.

The characteristics are as described for the genus. See Table BXII.γ.193 in the chapter on the family *Enterobacteriaceae* for the results of 47 biochemical tests normally used for identification (Farmer, 1999). Currently, it is not possible to completely differentiate *K. georgiana* from *K. ascorbata* and *K. cryocrescens* with simple tests (Table BXII.γ.231). The type strain was isolated from human sputum.

Phenotypic properties as originally given by Müller et al. (1996). The species includes the type strain but no other strains. Other strains named *K. georgiana* include CDC 2774-70 (ATCC 51703), CDC 2065-76 (ATCC 51702), CDC 4246-74, and CDC 3108-76 (Müller et al., 1996). However, no data are presented to show that these four strains are highly related to the type strain by either DNA–DNA hybridization

or phenotype (see the discussion below of *Kluyvera* species 3). Thus, there is a change in circumscription between the two species. In the future, additional strains that are highly related to the type strain should be included.

The mol% G + C of the DNA is: not determined.

Type strain: 189, ATCC 51603, CDC 2891-76, DSM 9409 (holotype).

Other Organisms

1. *Kluyvera cochleae* Müller, Brenner, Fanning, Grimont and Kämpfer 1996, 63^VP^

coch' le.ae. L. fem. gen. n. *cochleae* of a snail.

Müller et al. (1996) defined a fourth *Kluyvera* species, *Kluyvera cochleae*, which now appears to be a junior subjective synonym of *Enterobacter intermedius. K. cochleae* included two strains isolated from snails in Germany and one strain from a slug in Great Britain. In DNA–DNA hybridization experiments (Müller et al., 1996), the type strain of *K. cochleae* S3/1-49^T was labeled and was highly related (86–92% at 60°C with divergence values of 0.5–1.0) to the two other strains. It was 19–24% related to strains of *Buttiauxella*, but no relatedness values were given for its relationship to the type strains of the three *Kluyvera* species or to other *Enterobacteriaceae*.

Farmer (unpublished, see Farmer, 2003) studied the three strains of *K. cochleae* and found that they apparently metabolize D-glucose via the butanediol pathway (i.e., they are Voges–Proskauer positive). This is a very unlikely pathway to occur in *Kluyvera*, which was defined to be methyl red positive (well documented to accumulate large amounts of α-ketoglutaric acid) and Voges–Proskauer negative. Computer analysis of the phenotypic data indicated that the strains of *K. cochleae* were essentially identical to 10 reference strains of *Enterobacter intermedius* (Farmer, unpublished). *Enterobacter* is a genus that is well known to have the butanediol pathway of D-glucose metabolism (Voges–Proskauer positive). Later it was shown that the type strains of these two species have almost identical published 16S rRNA sequences. These observations led to further laboratory studies (Brenner and Steigerwalt, unpublished; Farmer, unpublished). By DNA–DNA hybridization, the type strains of the two species are very highly related (D.J. Brenner, personal communication).

To summarize, all current data indicate that *Kluyvera cochleae* and *Enterobacter intermedius* are different names for the same organism. The two species have different type strains, so they should be considered as subjective synonyms, with *Enterobacter intermedius* being the senior subjective synonym, since it was validly published first.

2. *"Kluyvera fluvialis"*

In an abstract, Gadaleta et al. (1996) from Buenos Aires, Argentina, described their work with "strain 21g" isolated from a polluted river. They determined its 16S rDNA sequence, compared it to the sequences of *K. ascorbata* and *K. cryocrescens*, and concluded " . . . the 21g strain is a member of an until now undescribed species of *Kluyvera* that we propose to be named *K. fluvialis*". Since the name *"Kluyvera fluvialis"* has not been effectively published or validly published, it lacks standing in nomenclature.

The vernacular name *Kluyvera* species group 3 was originally given by Farmer et al. (1981a) to five strains (2774-70, 2065-76, 2891-76, 4246-74, and 3108-76) that were 60–68% related (with divergence values of 9–12%) by DNA–DNA hybridization to strains of *K. ascorbata* and *K. cryocrescens* (see Table 4 in Farmer et al., 1981a). None of these strains were labeled and tested against the others to determine if they all belonged to the same species. However, the authors concluded that the five strains represented one or more additional species of *Kluyvera*. Because of its uncertain circumscription and the lack of simple tests to differentiate it from the two named *Kluyvera* species, they did not give it a scientific name, designate a type strain, or deposit strains in the American Type Culture Collection.

One of the strains (2891-76) was later designated as the type strain of *Kluyvera georgiana* by Müller et al. (1996) as described above. *K. georgiana* of Müller et al. (1996) also include the other four strains that Farmer et al. (1981a) included in *Kluyvera* species 3. However, no information is included in the paper of Müller et al. (1996) to show that these latter four strains are highly related to the type strain of *K. georgiana* by DNA–DNA hybridization or phenotype. The assignment of these four strains to *K. georgiana* or a new *Kluyvera* species awaits further study.

Genus XVIII. **Leclercia** *Tamura, Sakazaki, Kosako, and Yoshizaki 1987, 179^VP^ (Effective publication: Tamura, Sakazaki, Kosako, and Yoshizaki 1986, 183)*

CAROLINE M. O'HARA AND J.J. FARMER III

Le.clerc' i.a. M.L. fem. n. *Leclercia* named to honor H. Leclerc, a French bacteriologist, who first described and named this organism *Escherichia adecarboxylata* in 1962, and who made many other contributions to enteric bacteriology.

Small rod-shaped cells, conforming to the general definition of the family *Enterobacteriaceae*. Gram negative. Motile at 36°C and 25°C with peritrichous flagella. Facultatively anaerobic. Catalase positive. Oxidase negative. **Many strains produce a nondiffusible yellow pigment that may be weak and may be lost on storage and subculture.** Ferment, rather than oxidize, D-glucose and other carbohydrates. Reduce nitrate to nitrite. **Positive for indole production, methyl red, growth in the presence of cyanide, malonate utilization, esculin hydrolysis, ONPG, and the fermentation of lactose, D-mannitol, dulcitol, salicin, adonitol, L-arabinose, L-rhamnose, maltose, D-xylose, trehalose, cellobiose, erythritol, esculin, melibiose, D-arabitol, mucate, D-mannose, and D-galactose. Produce visible gas during fermentation.** Negative for Voges–Proskauer, citrate utilization (Simmons), H_2S production (TSI), phenylalanine deaminase, **lysine decarboxylase, arginine dihydrolase, ornithine decarboxylase**, gelatin hydrolysis (22°C), lipase (corn oil) production, DNase production, and the fermentation of *myo*-inositol, D-sorbitol, α-methyl-D-glucoside, and erythritol.

Most strains are susceptible to colistin, nalidixic acid, sulfadiazine, gentamicin, streptomycin, kanamycin, tetracycline, chloramphenicol, carbenicillin, cephaloridine, and ampicillin (disk diffusion method on Mueller–Hinton agar); **resistant to penicillin**.

Isolated from human clinical specimens that are normally sterile such as blood and urine. Also isolated from other clinical specimens such as sputum and wounds, usually in mixed culture. Probably an **opportunistic pathogen that occasionally causes extraintestinal infections** in humans. Occasionally occurs in human feces, but there is **no evidence that it causes diarrhea or intestinal infections**. Natural reservoirs and ecological niches are not completely defined, but has been isolated from water, food, milk, and other environmental samples. Appears to be important in the processing of "dry-cured" hams. A rarely isolated genus of *Enterobacteriaceae*.

The mol% G + C of the DNA is: 52–55.

Type species: **Leclercia adecarboxylata** (Leclerc 1962) Tamura, Sakazaki, Kosako, and Yoshizaki 1987, 179 (Effective publication: Tamura, Sakazaki, Kosako, and Yoshizaki 1986, 183) (*Escherichia adecarboxylata* Leclerc 1962, 737.)

Further descriptive information

Literature Since the genus was described in 1986, there have been a few reports in the literature; seven cataloged in MEDLINE and 18 cataloged in BIOSIS. These reports include reviews of new *Enterobacteriaceae*; human clinical specimens and infections; occurrence in animals, plants, food, water, and the environment; taxonomic studies; and studies on basic biology such as physiology-metabolism, biochemistry, and genetics.

***Leclercia* strains in reference laboratory collections** The original report by Tamura et al. (1986) described 58 isolates from human clinical specimens including blood, urine, sputum, and feces, and 27 isolates from nonhuman sources, including food, water, and the environment. However, they did not specify the number of isolates from each of these sources. Farmer et al. (1985a) described their studies with the type strain (isolated from water), and concluded that their collection also contained 6–10 isolates that were very similar. The CDC collection now includes 18 human isolates: blood (5), urine (1), wound (1), sputum (1), hand wound (1), leg wound (2), finger (1), ear (1), feces (3), and unspecified (2). It also includes 11 isolates from nonhuman sources or culture collections: intravenous fluid bottle (1), milk (1), environmental (1), and unspecified or unknown (8).

Occurrence in human clinical specimens Strains of *L. adecarboxylata* have been from a wide variety of human clinical specimens, but there have been few systematic clinical studies or case reports. Temesgen et al. (1997) found only five strains during 1984–1995 at the Mayo Clinic in Rochester, Minnesota, USA. In three cases it was isolated from wounds of the lower extremities, all in mixed culture. Another case was a pneumonia patient whose sputum yielded *L. adecarboxylata* along with other organisms. One patient had a culture of *Leclercia adecarboxylata* that was clinically significant. A 35-year-old woman with acute nonlymphocytic leukemia had undergone bone marrow transplantation. She developed bacteremia and fever while she was neutropenic, and *L. adecarboxylata* was isolated in pure culture from one of two sets of blood cultures.

Other cases of bacteremia have also been described. Daza et al. (1993) reported the case of a 45-year-old alcoholic who had severe abdominal pain, hypotension, tachycardia, and diaphoresis 6 hours after undergoing paracentesis for the removal of ascitic fluid. Four days after undergoing a laparotomy, he developed fever and had three blood cultures positive for *L. adecarboxylata*. Otani and Bruckner (1991) reported a case in an 8½-month-old with a history of congenital gastroschisis and intestinal atresia. He came to the emergency department with shaking chills and fever about 1 hour after total parenteral nutrition through a central line catheter. The blood culture from the central line was positive for *L. adecarboxylata*. Dudkiewicz and Szewczyk (1993) described one isolate of *L. adecarboxylata* in their series of 72 cases of bacterial endocarditis.

When *L. adecarboxylata* is isolated in mixed culture from specimens such as sputum and wounds, it is difficult to determine clinical significance. Martinez et al. (1998) reported its isolation from an ulcer exudate. However, the isolation of this organism from blood cultures suggests that it is at least an opportunistic pathogen. Additional studies and case reports are needed to better define its role as a human pathogen.

Occurrence in human feces Several collections have included isolates from feces (Tamura et al., 1986), which usually are from patients with diarrhea. Cai et al. (1992) described three patients in China with diarrhea whose fecal cultures were positive for *L. adecarboxylata*, but the authors could not demonstrate an etiological role. Although it has occasionally been isolated from feces, there is no evidence that *L. adecarboxylata* can actually cause diarrhea or infections of the intestinal tract.

Occurrence in animals, plants, food, water, and the environment In addition to sources previously mentioned, *L. adecarboxylata* (referred to as Enteric Group 41 by Bangert et al., 1988) also has been isolated from captive raptors (the bird order *Falconiformes*; the falcons) (Bangert et al., 1988). *L. adecarboxylata* appears to be important in the processing of "dry-cured" hams. It was the only species present at the end of the fast-curing process, and predominated along with some other *Enterobacteriaceae* at the end of the slow-curing process (Marin et al., 1996). These environmental reservoirs suggest additional ways that hospital and other patients can come in contact with *L. adecarboxylata*. If a blood culture from a patient on total parenteral nutrition is positive for *L. adecarboxylata*, all the liquids should be cultured as possible reservoirs.

Isolation, identification, culture preservation, phenotypic characterization Strains of *Leclercia adecarboxylata* grow well on media normally used in enteric bacteriology, and are typical *Enterobacteriaceae* in most respects. The typical yellow pigment is probably present in most cultures on initial isolation, but is easily lost. See the chapter on the family *Enterobacteriaceae* for general information on growth, plating media, working and frozen stock cultures, media and methods for biochemical testing, identification, and antibiotic susceptibility. Table BXII.γ.232 below summarizes the phenotypic characteristics of *L. adecarboxylata*. Also see Table BXII.γ.193 of the chapter on the family *Enterobacteriaceae* that has the tabulated biochemical reactions of *L. adecarboxylata* and other *Enterobacteriaceae*.

Taxonomic Comments

History Leclerc (1962) recognized a group that he referred to as "yellow-pigmented coliform bacteria" that was similar to *E. coli* in its IMViC reactions, but differed by producing a yellow pigment and fermenting many sugars. He proposed that it be recognized as a separate species in the genus *Escherichia*, *Escher-*

TABLE BXII.γ.232. Phenotypic characteristics of *Leclercia adecarboxylata* based on data from three different laboratories

Test or property	Study 1[a]	Study 2	Study 3
Number of strains studied	20	85	33

[a]Study 1, Izard et al. (1985); study 2, Tamura et al. (1986); study 3, Farmer (2003).

[b]The standard conditions used in each study; a different temperature or time for the final reading is indicated in parentheses. Abbreviations: TSI, triple sugar iron agar; KIA, Kligler iron agar; ONPG, O-nitrophenyl-β-D-galactopyranoside.

[c]Each number is the percentage of strains that are positive. Most positive reactions occur during the first 24 h. For a few tests in study there were not enough quantitative data, so these results are represented by symbols with the usual meaning stated in this *Manual*; nd, not determined.

ichia adecarboxylata. Ewing and Fife (1972) studied the type strain of *Escherichia adecarboxylata* and proposed a different classification. They classified it in their redefined species (which is now known to be heterogeneous) *Enterobacter agglomerans* as "a typical strain of biogroup G3".

Escherichia adecarboxylata* as a distinct group of *Enterobacteriaceae*; proposal of *Leclercia Several other investigators considered the taxonomic position of *E. adecarboxylata* and concluded that it is different from *Escherichia*, the *Enterobacter agglomerans*–*Erwinia* complex, and from other *Enterobacteriaceae* (see Table BXII.γ.233) (Gavini et al., 1983b; Sakazaki et al., 1983; Izard et al., 1985; Verdonck et al., 1987). The situation was clarified when Tamura et al. (1986) used DNA–DNA hybridization to study their collection of strains. They showed that *E. adecarboxylata* was different from other taxa of *Enterobacteriaceae*. The type strain of *E. adecarboxylata* was more than 70% related to eight other strains and was 64–66% related to two additional strains. It was only 32% related to the type strain of *Enterobacter agglomerans* and only 26% related to the type strain of *Escherichia coli*. Because it was distinct by both DNA–DNA hybridization and phenotype, they proposed a new genus *Leclercia* with one species *Leclercia adecarboxylata* to

include strains formerly classified as *Escherichia adecarboxylata*. Their proposal is an alternative classification that has been well accepted by the scientific community.

Phylogeny based on 16S rDNA sequencing Recently a complete 16S rDNA sequence of "strain LBV 449" (which is not the type strain) was deposited (GenBank accession number AJ276393) (De Baere et al., 2001). A 16S rRNA tree that includes *L. adecarboxylata* can be found in the chapter on the family *Enterobacteriaceae*. The 16S rDNA sequencing data agree with data from DNA–DNA hybridization experiments that *Leclercia* is distinct from other genera of *Enterobacteriaceae* (Tang et al., 1998). Unfortunately, *L. adecarboxylata* was not included in the tree published by Spröer et al. (1999).

Several sequences related to mercury resistance have also been deposited.

[a]See Farmer (2003) for a more detailed description of this "vernacular name". It is a term defined for practical identification in the clinical microbiology laboratory. It includes over a dozen DNA—DNA hybridization groups that were originally included in the species *Enterobacter agglomerans*, which is now known to be a heterogeneous species.

List of species of the genus Leclercia

1. **Leclercia adecarboxylata** (Leclerc 1962) Tamura, Sakazaki, Kosako, and Yoshizaki 1987, 179[VP] (Effective publication: Tamura, Sakazaki, Kosako, and Yoshizaki 1986, 183) (*Escherichia adecarboxylata* Leclerc 1962, 737; *Enterobacter agglomerans* biogroup G3 Ewing and Fife 1972, 10.)
a.de.car.box.y.la′ ta. Gr. adj. *a* without; M. Fr. n. *decarboxyl* removal of a molecule of carbon dioxide from an organic compound; *adecarboxylata* without decarboxylase activity; because it has negative reactions in lysine decarboxylase, ornithine decarboxylase and arginine dihydrolase; i.e., "triple decarboxylase negative".

The characteristics are as described for the genus; a more complete description is given in Table BXII.γ.232. Isolated from human clinical specimens, environmental samples, food, and water. Its clinical significance is not fully documented but its potential role as a pathogen is suggested by isolates from blood and similar specimens that are normally sterile. However, it may be colonizing rather than infecting nonsterile body sites. The isolates from food, drinking water, feces, and an intravenous fluid bottle suggest ways that humans come in contact with it. There is no evidence that it can cause diarrhea or intestinal infections. It should be considered a rarely isolated species of *Enterobacteriaceae*, and a possible opportunistic pathogen (extraintestinal infections only) for humans. The type strain was isolated from drinking water by Leclerc, 1962.

The mol% G + C of the DNA is: 52–55 (T_m).

Type strain: 1783, ATCC 23216, CIP 82.92, DSM 5077, HAMBI 1696, JCM 1667, LMG 2803.

Additional Remarks: The American Type Culture Collection includes 7 other strains of *L. adecarboxylata*, including four strains from "apple fruit".

Other Organisms

Currently *Leclercia* has only one species, but it will be interesting to see if future studies will change or clarify the current concept or circumscription of the genus. Tamura et al. (1986) included only one species in *Leclercia*; however, Table 2 of their paper includes strains 1523 and 363, which were only 66.2% and 64.2% related to the type strain by DNA–DNA hybridization; 70% is the usual cutoff point for the level of species. They did not include divergence values (ΔT_m), so it is more difficult to determine if these two strains are as related to the type strain as the other eight strains. The CDC collection contains five strains that were identified as "possible-probable" *Leclercia adecarboxylata* because their phenotypic characteristics were similar to, but different from, strains now included in the species. These five strains, the two of Tamura et al. (1986), and similar strains should be investigated as possible additional species of *Leclercia*.

Genus XIX. **Leminorella** *Hickman-Brenner, Vohra, Huntley-Carter, Fanning, Lowery, Brenner and Farmer 1985c, 375^{VP} (Effective publication: Hickman-Brenner, Vohra, Huntley-Carter, Fanning, Lowery, Brenner and Farmer 1985b, 235)*

J.J. Farmer III and Frances W. Brenner

Le.mi.no.rel′ la. M.L. dim. *-ella* ending; M.L. fem. n. *Leminorella* named to honor Leon Le Minor, a French microbiologist, for his many contributions to enteric bacteriology including the nomenclature, classification, and serotyping of *Salmonella*; lysogeny; metabolic plasmids; and new and rapid biochemical tests. The name also honors Simone Le Minor, who also made many contributions to enteric bacteriology as head of the National *Salmonella* Centre of France and for her research on *Serratia* serotyping.

Small rod-shaped cells, conforming to the general definition of the family *Enterobacteriaceae.* Gram-negative. **Nonmotile at 36°C and 25°C.** Contain the enterobacterial common antigen. Facultatively anaerobic. Catalase positive (strong and rapid). Oxidase negative. Nonpigmented. Ferment, rather than oxidize, D-glucose. Reduce nitrate to nitrite. **Inactive biochemically. Positive for H_2S production (TSI and PIA), tyrosine hydrolysis, and fermentation of L-arabinose, D-xylose, and L-tartrate.** Negative for indole production, Voges–Proskauer, urea hydrolysis, phenylalanine deaminase, lysine decarboxylase, arginine dihydrolase, ornithine decarboxylase, growth in the presence of cyanide (KCN test), malonate utilization, esculin hydrolysis, gelatin hydrolysis (22°C), lipase (corn oil), DNase, and the fermentation of lactose, sucrose, D-mannitol, salicin, adonitol, *myo*-inositol, D-sorbitol, raffinose, L-rhamnose, maltose, trehalose, cellobiose, α-methyl-D-glucoside, erythritol, melibiose, D-arabitol, glycerol, D-mannose, and D-galactose. Susceptible to colistin, nalidixic acid, sulfadiazine, gentamicin, kanamycin, tetracycline, chloramphenicol; **resistant to streptomycin, penicillin, ampicillin, carbenicillin, and cephalothin** (disk diffusion method on Mueller-Hinton agar).

Usually isolated from feces, but there is no evidence that strains cause diarrhea or intestinal infections. Some strains agglutinate in *Salmonella* diagnostic antisera, and **can be misidentified as being *Salmonella*. Rarely isolated from other clinical specimens.** Ecological niche may be the human intestinal tract since there are only a few isolates from other clinical specimens, and no reported isolates from animals, food, water or the environment. **A very rarely isolated genus of *Enterobacteriaceae*.**

The mol% G + C of the DNA is: not reported.

Type species: **Leminorella grimontii** Hickman-Brenner, Vohra, Huntley-Carter, Fanning, Lowery, Brenner and Farmer 1985c, 375 (Effective publication: Hickman-Brenner, Vohra, Huntley-Carter, Fanning, Lowery, Brenner and Farmer 1985b, 235.)

Further descriptive information

Literature Since the genus was described in 1985, there have been only a handful of reports in the literature, six cataloged in MEDLINE and 11 cataloged in BIOSIS. Except for the original report (Hickman-Brenner et al., 1985b), none of these has dealt specifically with *Leminorella.* The literature reports that have mentioned *Leminorella* include reviews and taxonomic studies of new *Enterobacteriaceae* (Schindler, et al., 1992; Gilchrist, 1995; Aleksic and Bockemühl, 1999); evaluation of commercial identification products or "kits" for *Enterobacteriaceae* (Kitch et al., 1994); and studies on physiology, metabolism, or biochemistry that included *Leminorella* strains (Bouvet and Grimont, 1987a; Satta et al., 1988; Bouvet et al., 1989; Grimont and Bouvet, 1989; Hodinka et al., 1991; Thaller et al., 1995; Hamana, 1996). In addition to the genus and species names, "Enteric Group 57" should be included as a search term in computerized literature searches, although it is rarely used today.

Sources and clinical significance Nine of the original *Leminorella* isolates were from feces, and two were from urine. Since the original paper in 1985, the CDC Enteric Reference Laboratory has received and identified nine additional human isolates, seven from feces and one each from urine and a decubitus wound. The clinical significance of *Leminorella* strains in these extraintestinal specimens is unknown, and further study and case reports are needed. Although strains of *Leminorella* have occasionally been isolated from feces of people with diarrhea, there is no evidence that it can actually cause diarrhea or intestinal infections. Its interest for clinical microbiology and public health appears to be more as a nuisance because *Leminorella* strains might be misidentified as *Salmonella* unless more complete biochemical and serological testing is done.

Original misidentification as *Salmonella* Several of the isolates from feces had been referred to the CDC's *Salmonella* reference laboratory because the strains agglutinated one or more *Salmonella* antisera. Presumably these tests were done with commercial antisera and with "live", rather than alcohol-treated, cultures, and the referring laboratory could not completely serotype the strain or confirm an identification as *Salmonella.* Four *L. grimontii* strains and one *L. richardii* strain have been reported to cross-react when tested at CDC with alcohol-treated antigens and CDC reference antisera. One of the strains agglutinated very weakly in O group B serum and in single factor O27 serum. The other strains did not agglutinate.

Isolation, identification, culture preservation, phenotypic characterization Strains of *Leminorella* grow on media normally used in enteric bacteriology, but they grow more slowly and are slower or more inactive biochemically than typical *Enterobacteriaceae.* One strain of *L. grimontii* and all four strains of *L. richardii* were negative for D-glucose fermentation after incubation for 24 h, but all became positive at 48 h (Hickman-Brenner et al., 1985b). On MacConkey agar at 24 h, strains appear as small colonies that are colorless (lactose negative). See the chapter on the family *Enterobacteriaceae* for general information on growth, plating media, working and frozen stock cultures, media and methods for biochemical testing, identification, computer programs, and antibiotic susceptibility.

Biochemical reactions Table BXII.γ.234 summarizes the biochemical reactions of the two *Leminorella* species. The tests useful for differentiation of *L. grimontii* and *L. richardii* are given in Table BXII.γ.235. Compared to other species of *Enterobacteriaceae*, strains of *Leminorella* are weak and inactive biochemically. One important characteristic is hydrogen sulfide production. Within 48 h on triple sugar iron agar, the species give an alkaline slant and a weak acid reaction in the butt with H_2S production.

Antibiotic susceptibility In their original description, Hickman-Brenner et al. (1985b) gave the zone sizes for each of the

TABLE BXII.γ.234. Biochemical reactions of *Leminorella grimontii* and *L. richardii* based on strains studied by DNA–DNA hybridization

Characteristic	*Leminorella grimontii*	*Leminorella richardii*

[a]These are the original strains that were studied by DNA–DNA hybridization and used by Hickman-Brenner et al. (1985b) to define the species.

[b]Each number gives the percentage positive after 2 d incubation at 36°C (unless a different time or temperature is indicated; phenylalanine, oxidase, and nitrate reduction are done only at 1 d). The cumulative % positive between 3 and 7 d is given for some tests in parentheses. Some of the percentages are slightly different from those given in the original descriptions (Hickman-Brenner et al., 1985b) and are based on tests results that were repeated after the original publication.

[c]TSI, triple sugar iron agar; PIA, peptone iron agar; ONPG, O-nitrophenyl-β-D-galactopynanoside.

11 strains with the 12 different antibiotics that have been used for many years in their reference laboratory as a aid in identification. There was little variation among the three *Leminorella* species, and all 11 strains were resistant to streptomycin, penicillin, ampicillin, carbenicillin, and cephalothin. Although this is not a unique pattern, the antibiogram can be a useful additional way of differentiating *Leminorella* from other genera of *Enterobacteriaceae*.

TABLE BXII.γ.235. Differentiation of *Leminorella grimontii* and *L. richardii*[a]

Test	Incubation time, days	*L. grimontii*	*L. richardii*
Methyl red	2	100	0
Citrate utilization (Simmons)	2	100	0
D-Glucose, acid production	1	83	0
D-Glucose, gas production	7	100	0
Dulcitol fermentation	2	83	0
Glucosaminidase activity[b]		100	0

[a]These data are based on results in Table BXII.γ.234 which included only strains that were documented to belong to these two species by DNA–DNA hybridization (Hickman-Brenner et al., 1985b). Each number gives the percentage positive at the specified indicated period; all the biochemical tests were done at 36°C.

[b]Data from Hodinka et al. (1991).

DNA, RNA, and protein sequences There is a full sequence (bases 1 to 1482) of the 16S rRNA gene of *L. grimontii* listed in GenBank (Spröer et al., 1999).

A 16S rDNA tree that includes *Leminorella grimontii* can be found in the chapter on the family *Enterobacteriaceae* (Fig. BXII.γ.189). The 16S rDNA sequencing data agree with data from DNA–DNA hybridization that *Leminorella* is distinct from other genera of *Enterobacteriaceae*. In the tree, *Pragia fontium* is the closest relative, in agreement with the tree published by Spröer et al. (1999) with respect to these two genera being on a distinct branch. However, the two trees differ in the placement of other organisms.

Differentiation of the genus *Leminorella* from other genera

Strains of *Leminorella* can be distinguished because they do not ferment D-mannose, but hydrolyze tyrosine, much like strains of *Proteus*; however, they are negative for urea hydrolysis and phenylalanine deaminase. They differ from *Salmonella* because they are lysine and ornithine decarboxylase negative and do not ferment D-sorbitol. Also see Table BXII.γ.193 of the chapter on the family *Enterobacteriaceae*), which gives the percentage positive for 47 biochemical tests done at the Enteric Reference Laboratories at CDC with standard media and methods. These tests have proved useful for identification and for differentiating *Leminorella* from other species in the family.

Taxonomic Comments

History and discovery In 1980 one of us (JJF, unpublished) noticed two H_2S^+ strains that seemed to be distinct from other *Enterobacteriaceae*, and coded these as a "possible new group of *Enterobacteriaceae*" in the laboratory's master computer database. In 1981 diagnostic culture 1944-81 was received and studied in more detail (Hickman-Brenner et al., 1985b). It was from a stool culture of a 7-month-old patient in Hawaii with gastroenteritis. The culture had a low identification score for other *Enterobacteriaceae* in the computer program GEORGE (Farmer et al., 1985a). However, the computer program STRAIN MATCHER listed nine additional strains that had been reported as "unidentified" that were very similar biochemically. Several of these strains had been sent to CDC because they reacted weakly in *Salmonella* antisera. Five strains had been sent as *Salmonella*, or with a diagnosis of suspected salmonellosis or diarrhea; two were sent as "possible

Citrobacter"; and one was a "suspect H_2S^+ *Shigella*" (Hickman-Brenner et al. 1985b). The vernacular name Enteric Group 57 was coined in 1981 (Hickman-Brenner and Farmer, unpublished; see Farmer et al., 1985a) for the original group of 10 strains, and the taxonomic position of the group was unknown. Enteric Group 57 was simply thought of as being a unique group of H_2S-producing strains that was being confused with *Salmonella* in some reference laboratories. An 11th strain was received in 1982.

Proposal of the genus *Leminorella* Hickman-Brenner et al. (1985b) used DNA–DNA hybridization (hydroxyapatite, $^{32}PO_4$) to further characterize Enteric Group 58. Strain 1944-81^T was labeled and was highly related (77–97% at 60°C with divergence values of 0–0.5%) to five other Enteric Group 58 strains. Strain 1944-81 was only 3–16% related to other species of *Enterobacteriaceae*. Because it was distinct from all *Enterobacteriaceae* by both DNA–DNA hybridization and phenotype, it was given a scientific name. The group of six strains was named *Leminorella grimontii*, which was designated as the type species for the genus *Leminorella*. Five other strains were 32–60% related to 1944-81, so strain 0978-82 was chosen from this group and tested by DNA hybridization against all 11 strains. Three strains were 93–94% related to strain 0978-82 with divergence values of 0.5–1.0. This group of four strains was named *Leminorella richardii*. The remaining strain 3346-72 was 60% and 40% related to strains 1944-81 and 0978-82, respectively. It was considered to be a third *Leminorella* species, that was closer to *L. grimontii*, and was given the vernacular name "*Leminorella* species 3". Since there was only one strain, it was not given a scientific name. Although *Leminorella* species 3 was distinct by DNA hybridization, it could not be distinguished from *L. grimontii* by simple tests (Hickman-Brenner et al., 1985b). Since the original report in 1985, additional strains of *Leminorella* have been studied biochemically, but not by DNA–DNA hybridization. *Leminorella* and its two named species gained standing in nomenclature in July 1985, when the names appeared on Validation List 18 (Hickman-Brenner et al., 1985c).

Problems in routine identification In the original publication DNA hybridization was used to divide the strains into two named species, and a description was written based on this clear separation (Tables BXII.γ.234 and BXII.γ.235). Unfortunately, *Leminorella* species 3 cannot be distinguished from *L. grimontii* with simple tests (Hickman-Brenner et al., 1985b). This strain illustrates the difficulty in identifying *Leminorella* cultures to the species level without the benefit of DNA–DNA hybridization. Since the original report in 1985, the Enteric Reference Laboratory has received 10 additional strains of *Leminorella*. Based on the differential reactions listed in Table BXII.γ.235, five of these were identified as *L. grimontii*; one as a "possible-probable" *L. grimontii* and four as *L. richardii*. Five of the strains identified as *L. grimontii* had at least one test that was in disagreement with the composite results in Table BXII.γ.234. The strains identified as *L. richardii* were more typical, and agreed with the definition given in Table BXII.γ.235, except that one strain had one atypical reaction. Thus, the identification of new strains of *Leminorella* to the genus level is probably correct, but the identification to the species level is more tentative and needs confirmation by DNA–DNA hybridization or other methods. Enzyme profiles (Hodinka et al., 1991) and whole-cell protein patterns (Schindler et al., 1992) appear promising for differentiation. Further study and better and simpler methods are needed to assist routine identification.

Further Reading

Hickman-Brenner, F.W., M.P. Vohra, G.P. Huntley-Carter, G.R. Fanning, V.A.I. Lowery, D.J. Brenner and J.J. Farmer III. 1985. *Leminorella*, a new genus of *Enterobacteriaceae*: identification of *Leminorella grimontii* sp. nov. and *Leminorella richardii* sp. nov. found in clinical specimens. J. Clin. Microbiol. *21*: 234–239.

List of species of the genus Leminorella

1. **Leminorella grimontii** Hickman-Brenner, Vohra, Huntley-Carter, Fanning, Lowery, Brenner and Farmer 1985c, 375^{VP} (Effective publication: Hickman-Brenner, Vohra, Huntley-Carter, Fanning, Lowery, Brenner and Farmer 1985b, 235) *gri.mon′ ti.i.* M.L. gen. n. *grimontii* named to honor Patrick Grimont and Francine Grimont, French microbiologists at the Pasteur Institute for their many contributions to enteric bacteriology.

   The characteristics are as given for the genus. The biochemical reactions are given in more detail in Table BXII.γ.234, and tests for the differentiation of *L. grimontii* and *L. richardii* are given in Table BXII.γ.235. Isolated from human feces, but there is no evidence that it can cause diarrhea or intestinal infections. Rarely isolated from other clinical specimens. Its clinical significance in these extraintestinal specimens needs further study. One isolate was from mouse feces. The type strain was isolated from the feces of a 7-month-old child with gastroenteritis.

   The mol% G + C of the DNA is: not reported.

   Type strain: ATCC 33999, CDC 1944-8, DSM 5078.

   GenBank accession number (16S rRNA): AJ233421.

   Additional Remarks: The American Type Culture Collection includes four other strains documented to be *L. grimontii* by DNA–DNA hybridization: ATCC 43006 (CDC 3257-77), from human feces, California; ATCC 43005 (CDC 3244-76), from human urine of an 80-year-old woman with a urinary tract infection, Hawaii; ATCC 43007 (CDC 3595-77), from urine of a 9-year-old girl, Pennsylvania; and ATCC 43008 (CDC 0301-79), from mouse feces, Maryland.

2. **Leminorella richardii** Hickman-Brenner, Vohra, Huntley-Carter, Fanning, Lowery, Brenner and Farmer 1985c, 375^{VP} (Effective publication: Hickman-Brenner, Vohra, Huntley-Carter, Fanning, Lowery, Brenner and Farmer 1985b, 235.) *ri.char′ di.i.* M.L. gen. n. *richardii* named to honor Claude Richard, a French microbiologist at the Pasteur Institute for his many contributions to enteric bacteriology.

   The characteristics are as given for the genus. The biochemical reactions are given in more detail in Table BXII.γ.234, and the differentiation of *L. richardii* from *L. grimontii* is given in Table BXII.γ.235. Isolated from human feces, but there is no evidence that it can cause diarrhea or intestinal infections. Nonhuman strains have not been reported. The type strain was isolated from the feces of a patient in Texas who had diarrhea. She also had systemic lupus erythematosus, and was on corticosteroid therapy. No other enteric pathogens were present.

The mol% G + C of the DNA is: not reported.

Type strain: ATCC 33998, CDC 0978-82.

Additional Remarks: The American Type Culture Collection includes three other strains documented to be *L. richardii* by DNA–DNA hybridization; all were from human feces in the USA: ATCC 43009 (CDC 598-78), Indiana; ATCC 43010 (CDC 2209-80), Pennsylvania; and ATCC 43011 (CDC 2502-80), Texas.

Other Organisms

1. "Leminorella species 3"

In addition to the two named species of *Leminorella*, Hickman-Brenner et al. (1985b) also described a third species. Since there was only one strain, and because it could not be differentiated from *L. grimontii* by phenotypic tests, they gave it the vernacular name " *Leminorella* species 3".

The reference strain, ATCC 43012, was isolated from the human feces, Georgia, USA. This is the only strain of species 3, and we suggest that it be designated the type strain if species 3 is given a scientific name.

Deposited strain: ATCC 43012, CDC 3346-72.

Strains studied since 1985 have been reported without the benefit of DNA hybridization. One strain (1201-84) was reported as a "possible-probable" *Leminorella grimontii*. Five were reported as *L. grimontii* because they were more active biochemically. However, four of these had one or more atypical test results for this species. All new strains of *Leminorella* should be studied by DNA hybridization or other methods to determine their correct taxonomic position.

Genus XX. **Moellerella** *Hickman-Brenner, Huntley-Carter, Saitoh, Steigerwalt, Farmer and Brenner 1984c, 355^{VP} (Effective publication: Hickman-Brenner, Huntley-Carter, Saitoh, Steigerwalt, Farmer and Brenner 1984a, 462)*

J.J. Farmer III and Frances W. Brenner

Moe.ller.el′ la. M.L. dim. ending *-ella*; M.L. fem. n. *Moellerella* named to honor Vagn Møller for his contributions to enteric bacteriology, especially for Moeller media for the determination of lysine decarboxylase, ornithine decarboxylase, and arginine dihydrolase, that are widely used for the identification of *Enterobacteriaceae*.

Small rod-shaped cells, conforming to the general definition of the family *Enterobacteriaceae*. Contain the enterobacterial common antigen. Gram negative. Nonmotile. Facultatively anaerobic. Catalase positive. Oxidase negative. Nonpigmented. Ferment, rather than oxidize, D-glucose and other carbohydrates. Reduce nitrate to nitrite. **Positive for methyl red, citrate utilization (Simmons), ONPG, and the fermentation of lactose, sucrose, adonitol, raffinose, melibiose, D-arabitol, D-mannose, and D-galactose.** Negative for indole production, Voges–Proskauer, H_2S production (TSI), urea hydrolysis, phenylalanine deaminase, lysine decarboxylase, arginine dihydrolase, ornithine decarboxylase, motility at 36°C, malonate utilization, esculin hydrolysis, gelatin hydrolysis (22°C), lipase (corn oil), and DNase, and the fermentation of dulcitol, salicin, *myo*-inositol, D-sorbitol, L-arabinose, L-rhamnose, D-xylose, trehalose, cellobiose, α-methyl-D-glucoside, erythritol, glycerol, and mucate. No visible gas produced during fermentation.

Most strains are susceptible to nalidixic acid, gentamicin, streptomycin, kanamycin, chloramphenicol, and cephalothin (disk diffusion method on Mueller-Hinton agar); **resistant to colistin, penicillin, ampicillin, and carbenicillin**. Variable susceptibility to sulfadiazine and tetracycline. Rarely isolated from human clinical specimens that are normally sterile. Most isolates have been from human feces, but there is **no evidence that it actually causes diarrhea or intestinal infections**. Natural reservoirs and ecological niches are not known. Can occur in water and food. **A rarely isolated genus of *Enterobacteriaceae* that is probably an opportunistic pathogen.**

The mol% G + C of the DNA is: not determined.

Type species: **Moellerella wisconsensis** Hickman-Brenner, Huntley-Carter, Saitoh, Steigerwalt, Farmer and Brenner 1984c, 355 (Effective publication: Hickman-Brenner, Huntley-Carter, Saitoh, Steigerwalt, Farmer and Brenner 1984a, 462.)

Further descriptive information

Literature Since *Moellerella* was described in 1984, there have been only a few reports in the literature, 11 cataloged in MEDLINE and 12 cataloged in BIOSIS. In addition to the genus and species names, "Enteric Group 46" should also be included as a search term in computerized literature searches, although it is rarely used today. The literature reports with *M. wisconsensis* include reviews and taxonomic studies of new *Enterobacteriaceae* (Farmer et al., 1985a; Richard, 1989; Gilchrist, 1995; Pokhil, 1996; Aleksic and Bockemühl, 1999); evaluation of commercial identification products or "kits" for *Enterobacteriaceae* (Gonzalez et al., 1986; Kitch et al., 1994); and surveys or comparisons of the family *Enterobacteriaceae* for metabolic pathways (Bouvet et al., 1989), acid phosphatases (Thaller et al., 1995), siderophores (Rabsch and Winkelmann, 1991), and polyamines (Hamana, 1996).

Occurrence in human feces Strains of *M. wisconsensis* were first recognized because of six strains submitted to CDC from Wisconsin; all were from human feces. Eight of the nine original cultures described by Hickman-Brenner et al. (1984b) were from feces and the other one was from water. Most isolates of *M. wisconsensis* have been from people with diarrhea, but there is no evidence that the strains are actually causing diarrhea or intestinal infections (Hickman-Brenner et al., 1984a). Marshall et al. (1986) reported the isolation of three strains of *M. wisconsensis* from 400 stool specimens screened for this organism with the aid of a new selective medium, developed in their laboratory. There was one report of *M. wisconsensis* isolation in the U.K., but its etiological role was not established in any of the diarrhea cases.

The interest of *M. wisconsensis* to clinical microbiology and public health laboratories may be more as a possible nuisance because strains have been picked as "suspect *Salmonella*" or "suspect *Yersinia*". More complete biochemical and serological testing should easily rule out these incorrect identifications.

Occurrence in extraintestinal human specimens Wallet et al. (1994) reported the isolation of *M. wisconsensis* from a bronchial aspirate of a patient with inhalation pneumonia. It was from an autopsy culture of a patient admitted in a deep coma following cardiac arrest. They concluded that the origin of the organism may have been from digestive secretions that inoculated the lower respiratory tract. This was the first isolate of *M. wisconsensis* from a human source other than stool or gallbladder. Wittke et al. (1985) reported the isolation of *M. wisconsensis* from the infected gallbladder of a 71-year-old man with typical signs of acute cholecystitis. Equal numbers of enterococci were also isolated. Serum from the patient taken on the 24th day after cholecystectomy did not contain agglutinating antibodies to heated or unheated suspensions of *M. wisconsensis*, providing negative evidence for its pathogenic role. Ohanessian et al. (1987) reported the isolation of *M. wisconsensis* along with *Hafnia alvei* from the infected gallbladder of a 77-year-old woman with coronary cardiac failure and gallstones. In 1985 the CDC's Enteric Reference Laboratory received the first isolate from human blood.

Clinical significance of human isolates The clinical significance and the ability of *M. wisconsensis* to actually cause infections should be carefully evaluated in cases that yield this new organism. Systematic study and good case reports are needed. The isolates described above suggest that it is probably an opportunistic pathogen with only a slight capacity to cause extraintestinal infections in humans.

Occurrence in other animals Bangert et al. (1988) isolated *M. wisconsensis* and other *Enterobacteriaceae* in a fecal culture survey of 47 captive raptors (the bird orders *Falconiformes* and *Strigiformes*). Giordano-Dias et al. (1997) reported isolates from the sandfly *Lutzomyia longipalpis* (*Diptera*: *Psychodidae*) maintained in the laboratory.

Occurrence in food and water One of the original nine strains reported by Hickman-Brenner et al. (1984a) was from a routine drinking water sample from a South Dakota (USA) town that did not chlorinate its water. Cabadajova and Kudrna (1988) of the Czech Republic isolated five strains of *M. wisconsensis* from food, but could not show an etiological role in relation to the corresponding human diarrhea cases.

Isolation, identification, culture preservation, phenotypic characterization Strains of *Moellerella* are not difficult to grow, and are typical *Enterobacteriaceae* in most respects. See the chapter on the family *Enterobacteriaceae* for general information on growth, plating media, working and frozen stock cultures, media and methods for biochemical testing, identification, computer programs, and antibiotic susceptibility. Strains grow on media normally used in enteric bacteriology. On MacConkey agar, colonies of *M. wisconsensis* are bright red with precipitated bile around them, and thus are indistinguishable from *Escherichia coli* colonies (Hickman-Brenner et al., 1984a). Marshall et al. (1986) reported the enhanced isolation of *M. wisconsensis* from stool specimens with a selective medium developed in their laboratory that contained bacitracin and polymyxin.

Biochemical reactions and differentiation from other *Enterobacteriaceae* Table BXII.γ.193 in the chapter on the family *Enterobacteriaceae* gives the results for *Moellerella* in 47 biochemical tests normally used for identification (Farmer, 1999). There are no genus- or species-specific tests or sequences for the identification of *Moellerella*. The best approach is to do a complete set of phenotypic tests (growth on plating media, biochemical tests, antibiogram, etc.) and compare the results with all the other named organisms in the family *Enterobacteriaceae*. This approach is described in more detail in the section on the family *Enterobacteriaceae*. The biochemical results of a test strain can be compared to all the organisms listed in Table BXII.γ.193 in that chapter. Several computer programs greatly facilitate analyzing the results.

Antibiotic susceptibility In their original description, Hickman-Brenner et al. (1984a) gave the zone sizes for each of the nine strains around 12 different antibiotics (the standard "antibiogram" that has been used for many years in their reference laboratory as an aid in identification). There was some variation among the strains, but all were resistant to colistin and penicillin. Although this is not a unique pattern, the antibiogram can be a useful additional way of differentiating *M. wisconsensis* from other species of *Enterobacteriaceae*.

Taxonomic Comments

Discovery and DNA–DNA hybridization In 1980 the vernacular name Enteric Group 46 was applied (Hickman-Brenner et al., 1984b) to a group of strains that had been studied at the Centers for Disease Control, and most had originally been sent from the Wisconsin State Laboratory of Hygiene. The strains were characterized biochemically and were phenotypically distinct from all of the described organisms in the family *Enterobacteriaceae*. By DNA–DNA hybridization the strains were 78–97% related to the type strain, with divergence values (ΔT_m) of 0–1.5. Other *Enterobacteriaceae* were only 2–32% related. Because Enteric Group 46 was distinct by both DNA–DNA hybridization and phenotype, a new genus *Moellerella* with a single species, *Moellerella wisconsensis*, was proposed (Hickman-Brenner et al., 1984a).

List of species of the genus Moellerella

1. **Moellerella wisconsensis** Hickman-Brenner, Huntley-Carter, Saitoh, Steigerwalt, Farmer and Brenner 1984c, 355[VP] (Effective publication: Hickman-Brenner, Huntley-Carter, Saitoh, Steigerwalt, Farmer and Brenner 1984a, 462.)
wis.con.sen′sis. M.L. fem. adj. *wisconsensis* pertaining to the state of Wisconsin, U.S.A., where most of the original strains were isolated.

The characteristics are as given for the genus and are summarized in Table BXII.γ.193 in the chapter on the family *Enterobacteriaceae.* Isolated from human feces but rarely from extraintestinal specimens, also isolated from animals, water, and food. The type strain was isolated from the stool culture of a 16-year-old girl in Wisconsin.

The mol% G + C of the DNA is: not determined.

Type strain: ATCC 35017, CDC 2896-78, DSM 5076.

Additional Remarks: The American Type Culture Collection includes four other strains, all from human feces.

Genus XXI. **Morganella** *Fulton 1943, 81[AL]*

J. Michael Janda and Sharon L. Abbott

Mor.ga.nel′la. M.L. dim. ending *-ella*; M.L. fem. n. *Morganella* named after H. de R. Morgan, who first studied the organism.

Straight rods, 0.6–0.7 × 1.0–1.7 µm. Gram negative. Motile by means of peritrichous flagella. Facultatively anaerobic. **Oxidative deamination of various amino acids including L-phenylalanine and L-tryptophan** (Singer and Volcani, 1955). **Urease positive. Indole positive** (Penner, 1984). Relatively few carbohydrates fermented. **Ornithine decarboxylase positive. Acid produced from D-mannose but not D-xylose. Gelatin not degraded.** The genus *Morganella* presently resides in the class *Gammaproteobacteria* in the family *Enterobacteriaceae*, based upon DNA hybridization data and not rDNA sequencing (Stackebrandt et al., 1988). 16S rDNA sequence data are presently unavailable.

The mol% G + C of the DNA is: 50 (Falkow et al., 1962).

Type species: **Morganella morganii** (Winslow, Kliger and Rothberg 1919) Fulton 1943, 81 (*Bacillus morgani* (sic) Winslow, Kliger and Rothberg 1919, 481; *Proteus morganii* (Winslow, Kliger and Rothberg 1919) Yale 1939b, 435.)

Further descriptive information

M. morganii displays morphologic characteristics typical of members of the *Enterobacteriaceae* appearing as short, straight rods. Capsules not produced (McKell and Jones, 1976). Peritrichous flagella with normal and curly curvature have been described (Leifson et al., 1955). Normal flagella have a wavelength of 2.09–2.36 µm with an amplitude of 0.51 µm. Curly flagella possess a shorter periodicity (1.14–1.18 µm) and amplitude (0.37–0.40 µm). Strains often express multiple fimbriae consisting of morphologically thin (outside diameter [o.d.] 4–5 nm) and thick forms (o.d. 7–8 nm) on the same cell (Old and Adegbola, 1982). The ultrastructure of *M. morganii* has not been investigated to any extent.

The peptidoglycan of *M. morganii* is O-acetylated at the C-6 hydroxyl group of *N*-acetylmuramyl residues (Clarke, 1993). The degree of O-acetylation ranges from 43.0–49.6% and appears responsible for resistance to muramidase (lysozyme) activity. The major fatty acids present in *M. morganii* lipopolysaccharide are 3-hydroxytetradecanoic ($C_{14:0\ 3OH}$), tetradecanoic ($C_{14:0}$), hexadecanoic ($C_{16:0}$), and dodecanoic ($C_{12:0}$) acids (Vasyurenko and Chernyavskaya, 1990). Cellular fatty acid analysis of morganellae reveals hexadecanoic acid as the dominant peak with octadecenoic acid ($C_{18:1}$) and methylenehexadecanoic acid ($C_{16:0\ ante}$) as additional major peaks (Vasyurenko and Chernyavskaya, 1990). The presence of detectable amounts of dodecanoic acid separates morganellae from *Proteus* and *Providencia.* Histamine, cadaverine, and diaminopropane are the predominant polyamines synthesized under defined conditions (Hamana, 1996).

Half of all morganellae grown in broth culture show uniform turbidity with ring or pellicle formation (McKell and Jones, 1976). Growth occurs between 4 and 45°C. On nutrient agar, *M. morganii* produces smooth transparent colonies with an entire edge. Pigmentation not observed (McKell and Jones, 1976). On nonselective media, most morganellae appear as nonhemolytic, buff-colored, convex colonies, 2–3 mm in diameter after overnight incubation at 35–37°C (Janda and Abbott, 1998a). Hemolysis on blood agar may be detected by prolonged incubation (48–72 h). On media containing an aromatic amino acid such as phenylalanine agar an almond-like odor may be emitted (Müller, 1986a). Because most strains are sucrose- and lactose-negative they appear as colorless colonies on selective media such as MacConkey's, xylose-lysine-desoxycholate, eosin-methylene blue, and Salmonella–Shigella agar. Some strains are highly pleomorphic producing multiple morphovars on media such as Salmonella–Shigella agar (Janda and Abbott, 1998a).

Morganellae possess a number of metabolic features almost exclusively associated with members of the tribe *Proteeae* (*Morganella*, *Proteus*, and *Providencia*). Oxidative deamination of certain amino acids (e.g., phenylalanine deaminase) to form keto acids that then react with ferric compounds yielding chromogenic products is a unique characteristic of this tribe (Singer and Volcani, 1955; Ewing, 1986a). On DL-tryptophan agar, *Morganella* produces a reddish-brown melanin-like compound with a molecular weight ≤12,000 (Polster and Svobodová, 1964; Müller, 1986a). *M. morganii* also degrades L-tyrosine crystals incorporated

into solid media within 24 h, presumably mediated via a tyrosine phenol-lyase (Sheth and Kurup, 1975). All proteeae, including *M. morganii*, produce extracellular bacteriolytic enzymes capable of degrading cell wall components of *Escherichia coli* and *Pseudomonas aeruginosa*. This reaction presumably occurs through extracellular secretion of a peptidoglycan-hydrolase (Branca et al., 1996). Like *Proteus*, morganellae elaborate a type II glycerol dehydrogenase that distinguishes these taxa from *Providencia* (type III); 1,3-propanediol dehydrogenase is not produced (Bouvet et al., 1995a).

The genus is biochemically homogeneous. Indole formed. Nitrates reduced. The methyl red test is positive. The Voges–Proskauer test is negative. Lysine decarboxylase activity is variable. Growth in KCN broth. Citrate, acetate, malonate, and mucate not utilized. Hydrolysis of urea. No H_2S produced on triple sugar iron (TSI) agar slants, although upon prolonged incubation (>24 h) a slight blackening at the junction may occur due to small amounts of a reddish-brown pigment being produced (Janda and Abbott, 1998a).

Acid with gas from D-glucose fermentation. Anaerobic fermentation of D-mannose. Fermentation of glycerol and trehalose is variable (Siboni, 1976). No fermentation of adonitol, L-arabinose, cellobiose, dulcitol, α-methyl-D-glucoside, *m*-inositol, lactose, maltose, D-mannitol, melibiose, raffinose, L-rhamnose, salicin, sucrose, and D-xylose.

Deoxyribonuclease, ribonuclease, alkysulfatase, arylsulfatase, lipase, lecithinase, hyaluronidase, and protease activities not produced. Chitin, elastin, pectin, mucin, and fibrin are not degraded (Janda et al., 1996b). Alkaline and acid phosphatase, leucine arylamidase, and naphthol-AS-BI-phosphohydrolase positive.

Morganella exhibits 20% relatedness to core members of the *Enterobacteriaceae* in DNA hybridization studies (Brenner et al., 1978). All *M. morganii* studied constituted a single DNA relatedness group. The average relatedness of 18 strains was 90% in 60°C reactions and 85% in 75°C reactions with <1% divergence (Brenner et al., 1978). Biochemically aberrant morganellae, exhibiting either the lysine decarboxylase-positive or ornithine decarboxylase-negative phenotype, were subsequently found to be highly related to classic *M. morganii* using the lysine decarboxylase-positive strain, CDC 1274-75, as the source of labeled DNA (Hickman et al., 1980). Hybridization studies indicated 73–92% relatedness in 60°C reactions and 79–96% relatedness in 75°C reactions.

Morganella strains harbor between one and four extrachromosomal elements ranging from 35–60 MDa (Cornelis et al., 1981; Janda et al., 1996b). Plasmids in *Morganella* that confer antibiotic resistance belong to compatibility groups N, FI, and FII (Hedges et al., 1973). Additionally, lactose fermentation and lysine decarboxylation are attributable to plasmid carriage (Le Minor and Coynault, 1976; Cornelis et al., 1981). A bacteriophage typing scheme using seven phages defined 14 lytic patterns, but plaques produced are poorly developed (Schmidt and Jeffries, 1974). Phages are lytic only for *Morganella* and have not been found to attack *Proteus* or *Providencia* (Coetzee, 1963). A bacteriocin (morganocin) system detecting both morganocin production and sensitivity revealed 33 types in 45 serologically distinct strains of *Morganella* (Senior and Vörös, 1989).

The antigenic schema of *Morganella* consists of 77 serotypes with 44 somatic (O), 4 capsular (K), and 38 flagellar (H) antigens (Vörös and Senior, 1990). In 1990, 11 additional O types were added, extending the number of somatic antigens to 55 (Vörös and Senior, 1990). Passive hemagglutination can be used to determine the O antigen (Penner and Hennessy, 1979b).

Morganella is generally resistant to ampicillin, extended-spectrum penicillins, first-generation cephalosporins, and cefoxitin. Antimicrobial agents to which strains are susceptible include third-generation cephalosporins, aztreonam, quinolones, tobramycin, and chloramphenicol. Variable resistance has been demonstrated for gentamicin, amikacin, imipenem, and tetracycline. Disk diffusion testing may be unreliable for some cephems (Biedenbach et al., 1993).

Although isolated more often from urine than other sources, *Morganella* is an uncommon cause of urinary tract infection (UTI) (Janda and Abbott, 1998a). It is often isolated as a colonizer in cases of bacteriuria in patients undergoing long-term catheterization (Mobley and Warren, 1987). Bacteremia is rare, usually occurring in immunocompromised patients; 70% of cases are acquired nosocomially (Janda and Abbott, 1998a). Surgical patients are affected most often, with the focus of infection being wounds. Urinary tract infections are not a common source for bacteremias (McDermott and Mylotte, 1984).

M. morganii produce mannose-sensitive hemagglutinins (MSHA) (Coetzee et al., 1962); electron micrographs of MSHA strains show perifimbriation but with denser polar aggregations. Catecholate- or hydroxymate-type siderophores used for iron acquisition are not produced (Drechsel et al., 1993). However, α-keto acids generated by L-amino acid deaminases produced by *M. morganii* can form ferric complexes that are sufficiently stable to transport iron (Drechsel et al., 1993). *M. morganii* can also use exogenous siderophores (ferrichromes, rhizoferrin, and citrate) for iron acquisition. *M. morganii* strains producing heat labile enterotoxin have been reported in a group of Swedish travelers with diarrhea (Jertborn and Svennerholm, 1991). Approximately 50% of morganellae produce a cell-free hemolysin related to the α-hemolysin of *E. coli* (Koronakis et al., 1987). The cytoplasmic location of urease and its low activity optimum of pH 5.5 in *M. morganii* allows the organism to survive under acidic conditions when other urease-positive, Gram-negative rods die (Young et al., 1996a). However, *M. morganii* grows more slowly and is less efficient in producing alkaline conditions in the urine than *P. mirabilis*, which is a more frequent cause of UTIs (Senior, 1983).

Enrichment and Isolation Procedures

Morganellae may be recovered from specimens from sterile body sites using routine enteric isolation media. Both smooth and rough morphovars may be present. For fecal specimens, MacConkey agar with methyl blue and phenolphthalein diphosphate may be helpful (Janda and Abbott, 1998a). When testing for human intestinal carriage, Rustigian and Stuart (1945) reported increases in *Morganella* recovery of 1.8–10% using tetrathionate or selenite enrichment broth prior to plating on media.

Maintenance Procedures

Morganella strains may be maintained at room temperature in agar deeps, especially motility agar, for several months. For long-term storage cultures should be frozen and maintained at −70°C.

Differentiation of the genus *Morganella* from other genera

See the genus *Proteus*, Table BXII.γ.254, for characteristics that can be used to differentiate *Morganella* from other related genera of *Enterobacteriaceae*.

List of species of the genus Morganella

1. **Morganella morganii** (Winslow, Kliger and Rothberg 1919) Fulton 1943, 81[AL] (*Bacillus morgani* (sic) Winslow, Kliger and Rothberg 1919, 481; *Proteus morganii* (Winslow, Kliger and Rothberg 1919) Yale 1939b, 435.)
mor.ga'ni.i. M.L. gen. n. *morganii* of Morgan; named after H. de R. Morgan, a British bacteriologist who first studied the organism.

The description is the same as that for the genus. Trehalose negative, susceptible to tetracycline See Tables BXII.γ.236 and BXII.γ.237 for other characteristics.

Occurs in the feces of humans, dogs, other mammals, and reptiles. Opportunistic human pathogens.

The mol% G + C of the DNA is: 50 (T_m).

Type strain: ATCC 25830, DSM 30164, IFO 3848, NCIB 235.

a. **Morganella morganii** *subsp.* **morganii** *subsp. nov.* (Winslow, Kliger and Rothberg 1919) Fulton 1943, 81[AL] (*Bacillus morgani* [sic] Winslow, Kliger and Rothberg 1919, 481; *Proteus morganii* (Winslow, Kliger and Rothberg 1919) Yale 1939b, 435.)

Distinguished from subsp. *sibonii* by positive trehalose reaction and resistance to tetracycline. See Table BXII.γ.236 for other characteristics.

The mol% G + C of the DNA is: 50 (T_m).

Type strain: ATCC 25830, DSM 30164, IFO 3848, NCIB 235.

b. **Morganella morganii** *subsp.* **sibonii** *subsp. nov.* Jensen, Frederiksen, Hickman-Brenner, Steigerwalt, Riddle and Brenner 1992, 619[VP]
si.bo'ni.i. L. gen. n. *sibonii* of Siboni, named after Knud Siboni, a Danish microbiologist who first recognized trehalose-fermenting *Morganella morganii*.

Distinguished from subsp. *morganii* by characteristics in Table BXII.γ.236. The above subspecies designations were created in keeping with the recommendation that "genetically close organisms that diverge in phenotype" be given subspecies status; DNA relatedness data for these strains indicated the creation of subspecies as opposed to species.

The mol% G + C of the DNA is: 50.

Type strain: 8103-85, ATCC 49948.

TABLE BXII.γ.236. Characteristics of *Morganella morganii*[a,b]

Characteristic	*Morganella morganii* subsp. *morganii*	*Morganella morganii* subsp. *sibonii*
Indole	+	d
Voges–Proskauer	−	−
Utilization of Simmons citrate, malonate, mucate, acetate	−	−
Urease	+	+
H_2S production (triple sugar iron agar)	d	−
Phenylalanine deaminase	+	+
O-Nitrophenyl-β-galactopyranoside (ONPG) hydrolysis	D	−
Møeller amino acid decarboxylases:		
Lysine decarboxylase	d	d
Arginine dihydrolase	−	−
Ornithine decarboxylase	d	d
Motility	+	d
Gelatin liquefication 22°C	−	−
Growth in potassium cyanide (KCN)	+	d
NO_3^- reduction to NO_2^-	+	+
Corn oil lipase	−	−
Deoxyribonuclease	−	−
Acid production from:		
Glucose, D-mannose	+	+
Trehalose, adonitol, D-arabitol	−	+
L-Arabinose, cellobiose, dulcitol, erythritol, *myo*-inositol, lactose, maltose, mannitol, α-methylglucoside, melibiose, raffinose, rhamnose, salicin, *D*-sorbitol, sucrose, D-xylose	−	−
Tetracycline susceptibility	+	−

[a]For symbols see standard definitions; temperature of reactions, 36 ± 1°C. All reactions are for 48 h.

[b]Adapted from Farmer (1995) and Jensen et al. (1992).

TABLE BXII.γ.237. Identification of *Morganella morganii* biogroups[a,b]

Characteristic	Biogroup						
	A	B	C	D	E	F	G
Acid production from:							
Trehalose	−	−	−	−	+	+	+
Glycerol	+[c]	d	+[c]	−	−	d[c]	d[c]
Møeller amino acid decarboxylase:

[c]Positive at 3–7 d.

Genus XXII. **Obesumbacterium** *Shimwell 1963, 759*[AL]

J.J. Farmer III and Don J. Brenner

O.be' sum.bac.te' ri.um. L. neut. adj. *obesum* fat; L. neut. n. *bacterium* rod; M.L. neut. n. *Obesumbacterium* a fat, rod-shaped bacterium.

Pleomorphic rods 0.8–2.0 × 1.5–100 µm (short, "fat" rods predominate when grown in beer wort with live yeasts; long pleomorphic rods usually predominate when grown in most bacteriological media; some strains have been reported to display a branching cell morphology), conforming to the general definition of the family *Enterobacteriaceae*. Gram negative. **Nonmotile.** Facultatively anaerobic. Slow growing, forming colonies <0.5 mm in diameter on ordinary plating media at 24 h. Optimal growth temperature is 25–32°C; **growth at 37°C is comparatively poor**. **Acid formed from D-glucose and D-mannose; very few other carbohydrates are fermented.** Gas formation during fermentation appears to be variable (original description says gas is produced, but none of the strains studied produced gas). **Lysine decarboxylase is positive.** Nitrate is reduced to nitrite. **Many biochemical tests normally used for differentiation of *Enterobacteriaceae* are negative or delayed positive** (3–7 d at 36°C). **One of only three genera** (along with *Hafnia* and *Pragia*) **in *Enterobacteriaceae* to contain only gluconate dehydrogenase** in its D-glucose oxidation pathway (Bouvet et al., 1989). **Occurs as a brewery contaminant** that can survive and grow in the presence of live yeasts during beer production. Not isolated from human clinical specimens; no evidence of pathogenicity for humans or animals. The genus has a single species, *O. proteus*, with two defined biogroups (1 and 2). The description of the genus above is a "composite description" based on data for both biogroups. However, the two biogroups are actually distinct species that are phenotypically different and only distantly related by DNA–DNA hybridization (Brenner, 1981). *O. proteus* biogroup 1 is actually a biogroup of *Hafnia alvei* (Brenner, 1981), and will be referred to as *H. alvei* biogroup 1 (Farmer et al., 1985a) in this chapter.

The mol% G + C of the DNA is: 48–49.

Type species: **Obesumbacterium proteus** (Shimwell and Grimes 1936) Shimwell 1963, 759 (*Flavobacterium proteum* (sic) Shimwell and Grimes 1936, 348.)

Further descriptive information

Obesumbacterium, as a member of *Enterobacteriaceae*, belongs to the *Gammaproteobacteria*. Shimwell's original description of an organism he called *"Flavobacterium proteum"* centered on its cellular morphology (Shimwell, 1936; Shimwell and Grimes, 1936). He noted that it appeared as plump rods 0.8–1.2 × 1.5–4 µm when grown in wort media or when taken directly from breweries during fermentation. This morphology had no doubt led to the term "short fat rod of pitching yeasts", which had been used in breweries for many years. Shimwell (1936) also noted much pleomorphism when the organism was grown in laboratory media that were alkaline or neutral. Chains of up to 100 µm were observed under these conditions.

SDS-PAGE protein fingerprints differentiate *H. alvei* biogroup 1 (*O. proteus* biogroup 1) from *O. proteus* biogroup 2 (Fernandez et al., 1993), as do plasmid profiles, ribotyping, enteric repetitive intergenic consensus (ERIC)-PCR (Prest et al., 1994), and random amplified polymorphic DNA (RAPD) profiles (Savard et al., 1994). Plasmid profiling, ERIC-PCR, and RAPD profiles successfully differentiated between isolates of *O. proteus* biogroup 2 (Prest et al., 1994; Savard et al., 1994).

A number of reports discuss the ecology of *Obesumbacterium* in breweries (Shimwell, 1936, 1948, 1963, 1964; Shimwell and Grimes, 1936; Strandskov et al., 1953; Case, 1965). Unfortunately, no distinction has been made between biogroups 1 and 2, so it is usually impossible to determine whether these two biogroups (which are really distinct species, one of which does not belong *Obesumbacterium*; see Taxonomic Comments, below), are different in their ecology, distribution, and other factors. Future studies in breweries should resolve this problem, but only if the two distinct biogroups are differentiated. This approach was used by van Vuuren (1978) in South African breweries.

Changes in brewery practices have eliminated many bacterial contaminants that were once carried along with pitching yeasts; thus *Obesumbacterium* is isolated much less frequently than in the past (F.G. Priest, personal communication). This fact may hamper future studies on the organism.

Enrichment and Isolation Procedures

Quantitative recovery of *O. proteus* from samples of ale yeast was best after 3 d incubation at 25°C on universal beer agar and Wallerstein Laboratories' differential medium, containing cycloheximide to inhibit yeast growth, intermediate on wort agar and yeast mannitol (YM) (Difco) agar, and unsatisfactory on MacConkey agar and membrane lauryl sulfate agar (Fernandez et al., 1993).

Maintenance Procedures

Long-term storage can be accomplished by quick freezing at −80°C in yeast extract peptone dextrose broth supplemented with 15% glycerol (Fernandez et al., 1993), or in 10% skim milk.

Taxonomic Comments

Obesumbacterium was first proposed as a genus by Shimwell in 1963 (Shimwell, 1963, 1964) to accommodate the organism known as *"Flavobacterium proteus"* (Shimwell and Grimes, 1936), which was called *"Flavobacterium proteum"* in the original proposal (Shimwell and Grimes, 1936). The specific epithet *"proteus"* was chosen because the organism has a very pleomorphic cell morphology depending upon the particular growth conditions (Shimwell, 1936, 1948, 1964). The organism was first named in 1936 when Shimwell was doing studies on the "short fat rods of pitching yeasts". He gave an adequate description (based on the available techniques) of the organism, but much of his description is not helpful in identifying it. Shimwell deposited a pure culture of *"F. proteus"* (isolated from yeast of Beamish and Crawford's Brewery, Cork, Ireland) in the National Collection of Type Cultures (NCTC), England. However, when Shimwell's own culture was "lost", he wrote the NCTC and found they had also "lost" this culture (unpublished letter of 27 February 1964 from J.L. Shimwell to E.F. Lessel of the ATCC). Thus it appears that no culture has survived from those originally studied by Shimwell in writing his description of *"F. proteus"*. The strain most studied is apparently ATCC 12841 (NCIB 8771; strain 42 of Strandskov and Bockelmann), which, until 1980 was only a reference strain (*Bergey's Manual of Determinative Bacteriology*, 8th ed.). This strain was isolated from lager and ale yeasts and deposited by the Shaefer

Brewing Co. (Strandskov and Bockelmann, 1955). This strain was given status, without comment, as the type strain (neotype) of *O. proteus* when the Approved Lists of Bacterial Names were issued in 1980.

There is confusion whether the current type strain of *O. proteus* is the same organism that Shimwell studied and named *"F. proteus"*. In 1956, the NCTC sent three cultures (numbers 42, 2, and 41), isolated and described by Strandskov and Bockelmann (1955), to Shimwell to examine and determine whether he thought they were *"F. proteus"*. For no. 42 (the current type strain of *O. proteus*) he concluded: "This is almost certainly an authentic strain. Its morphology is almost exactly that of my original isolation, namely thick (up to 2 or more μm), long (up to 100 μm or more) filaments etc. together with the usual short fat rods in fair numbers". The properties of these strains include indole, acetylmethylcarbinol, H_2S and starch, all negative; nitrite from nitrate, positive. However, probably hundreds of Gram-negative bacteria would answer to this description. Indeed, the species is very poorly characterized biochemically, its main characteristic being its extremely large cell size, and its almost incredible pleomorphism, by means of which (taken in conjunction with its presence in a brewery fermentation) it can readily be identified. In cataloguing any of the strains I suggest that no. 42 could be safely named *F. proteus*; no. 2 a little doubtfully, and no. 41 very doubtful indeed" (unpublished letter of 7 June 1956 from J.H. Shimwell to W.S. Greaves of the NCTC). Thus the current concept of *O. proteus* based on its type strain ATCC 12841 (no. 42) is not incompatible with *"F. proteus"* as defined by Shimwell based on strains that no longer exist. Unfortunately, Shimwell's original description of *"F. proteum"* fits both *H. alvei* biogroup 1 (*O. proteus* biogroup 1) and *O. proteus* biogroup 2, so it is uncertain which of these latter two organisms (or perhaps both) was originally studied by Shimwell (1936). It is even possible that it was neither since Shimwell described *"F. proteum"* as a producer of gas during fermentation of carbohydrates, but neither *H. alvei* biogroup 1 nor *O. proteus* biogroup 2 produce gas (Priest et al., 1973; see also Table BXII.γ.193 in the chapter on the family *Enterobacteriaceae*.

"F. proteus" had been known for many years as a brewery contaminant that can survive and grow in the presence of live yeasts during beer production. Because it fermented D-glucose and other carbohydrates, it was incompatible with a redefined genus *Flavobacterium* that was limited to oxidative rather than fermentative bacteria. Its removal from *Flavobacterium* was subsequently confirmed by Bauwens and De Ley (1981), who used DNA–rRNA hybridization to show that *"F. proteus"* was not closely related to other *Flavobacterium* species. Shimwell (1963, 1964) formed the new genus *Obesumbacterium* for *"F. proteus"* because its phenotypic properties and ecological niche differed from those of other genera. He did not assign *Obesumbacterium* to a family, but its properties (see also Table BXII.γ.193 in the chapter on the family *Enterobacteriaceae*) are compatible with those of the family *Enterobacteriaceae*.

Priest et al. (1973) determined the phenotypic properties and did DNA–DNA relatedness studies on 19 strains of *O. proteus*, including 16 brewery isolates. They defined two biogroups, which had the same mol% G + C content of DNA, 48.0–48.5. They also proposed that *O. proteus* be reclassified in the genus *Hafnia* where its citation would be *"H. protea"* (Shimwell and Grimes, 1936) Priest, Somerville, Cole and Hough 1973. The new combination could have been proposed as *"Hafnia proteus"*, since *"proteus"* is a substantive that need not agree in gender with its genus. This change in classification was accepted to some extent, but in reality both *O. proteus* and *"H. protea"* have, until recently, been rarely used in the literature. Most of the existing citations have been in journals related to brewing. The name *"Hafnia protea"* lost standing in nomenclature on 1 January 1980, because it did not appear on the Approved Lists of Bacterial Names; however, *Obesumbacterium* and *O. proteus*, with its type strain ATCC 12841, have standing in nomenclature since they did appear on the lists.

The classification of *Obesumbacterium* was clarified by Brenner and co-workers (1981), who used DNA–DNA hybridization to determine the relatedness of *O. proteus* biogroups 1 and 2 to each other and to other *Enterobacteriaceae*. *O. proteus* biogroup 1 was very highly related to *Hafnia alvei*, and it was concluded that this biogroup is a synonym of *H. alvei*. It can best be thought of as the pleomorphic, KCN-negative, nonmotile, non-gas-producing, salicin-positive, L-arabinose-negative, L-rhamnose-negative, maltose-negative, D-xylose-negative, β-galactosidase-negative biogroup of *H. alvei* that has adapted to the brewery environment. This adaptation to the brewery environment was noted by Shimwell and Grimes (1936) in the original description of *"F. proteus"*: "The organism sometimes failed to grow in dilute media, probably owing to its having become accustomed to the more concentrated nature of beer-wort in the brewery." This adaptation has presumably made the organism very "sluggish" in its metabolic activities, as is reflected in its slow growth rate and diminished activity in the tests normally done for identification of *Enterobacteriaceae*. The classification of *O. proteus* biogroup 1 as *H. alvei* is further strengthened by the fact that strains of *O. proteus* biogroup 1 (but not biogroup 2) are lysed (Farmer, 1984a; Table BXII.γ.238) by the *Hafnia*-specific bacteriophage 1672 described by Guinée and Valkenburg (1968).

Van Vuuren et al. (1981) studied 10 cultures of "*Hafnia alvei-Obesumbacterium proteus*" isolated from South African lager-beer breweries. One of their five distinct biogroups (based on API 20E biochemical profiles) was very active biochemically and more like typical cultures of *H. alvei*. The other four biogroups were progressively less biochemically active with the least active group more like *O. proteus*. Based on phenotypic and DNA relatedness data (Brenner, 1981), Farmer et al. (1985a) proposed that *O. proteus* biogroup 1 and biochemically inactive strains of *H. alvei* isolated from breweries be classified in a single taxon. They proposed the names " *Hafnia alvei* biogroup 1" and " *Hafnia alvei* brewery biogroups" to aid in the recognition and identification of these strains adapted to the brewery environment. *H. alvei*, *H. alvei* biogroup 1, and *O. proteus* biogroup 2 have been listed as separate taxa in the CDC's master biochemical chart of *Enterobacteriaceae* since 1985. Based on these data, it appears that biogroups intermediate between typical *H. alvei* and *O. proteus* biogroup 1 may occur in breweries. A complete set of biochemical tests (Table BXII.γ.238, also see Table BXII.γ.193 in the chapter on the family *Enterobacteriaceae*) and lysis by the *Hafnia*-specific bacteriophage are needed to characterize isolates from breweries that resemble *Hafnia/Obesumbacterium*.

O. proteus biogroup 2 is different biochemically from *H. alvei* biogroup 1 and from *H. alvei* (Table BXII.γ.238). In DNA–DNA relatedness studies *O. proteus* biogroup 2 was only 25–30% related to *H. alvei* biogroup 1 (Brenner, 1981). In fact, its closest relative is *Escherichia blattae* to which it was 60–65% related. Thus *O. proteus*

TABLE BXII.γ.238. Differentiation of *Obesumbacterium proteus* biogroup (BG) 2, *Hafnia alvei*, and *Hafnia alvei* biogroup 1 (*Obesumbacterium proteus* biogroup 1)[a]

Characteristic	Incubation time (d)	*O. proteus* BG 2	*Hafnia alvei* wildtype	*Hafnia alvei* BG 1 [b]
Lysis by the *Hafnia*-specific bacteriophage of Guinée and Valkenburg (1968)	1	−	+	+
Strong rapid catalase[c]		−	+	+
Voges–Proskauer (22°C)	4	−	+	+
Acid production from:				
D-Mannitol	10	−	+	+
Salicin	7	−	[−]	+
D-Xylose	7	+	+	−
Esculin hydrolysis	7	−	[−]	+

[a]Symbols: +, positive for 90–100% of strains; [−], positive for 11–25% of strains; −, positive for 0–10% of strains.

[b]Formerly known as *O. proteus* biogroup 1.

[c]Strains of *O. proteus* biogroup 2 are catalase positive but the reaction is weak and takes 10–30 seconds. Strains of wild-type *H. alvei* and of *H. alvei* biogroup 1 give a very strong and rapid (1 second) catalase reaction. This is a very simple way to differentiate between strains of *H. alvei* and *O. proteus* biogroup 2.

biogroup 2 should not be included in the same species or in the same genus as *H. alvei* biogroup 1.

The type strain of *O. proteus* is ATCC 12841 (NCIB 8771). It was listed as *"H. protea"* in the 14th edition of the ATCC catalog, and has been listed as *O. proteus* in the 15th to 19th editions. This culture is lysed by the *Hafnia*-specific bacteriophage 1672, is methyl red negative, D-mannitol negative, salicin positive (6 d), maltose negative, D-xylose negative, esculin positive (7 d), and ONPG negative. Thus from Table BXII.γ.238 it clearly belongs to *H. alvei* biogroup 1, although it is somewhat more inactive or slower in its biochemical reactions than other strains. *H. alvei* biogroup 1 can be logically considered as a series of inactive biogroups of *H. alvei*. However, if it were classified as a named subspecies it could cause serious nomenclatural problems in *Hafnia* because it has priority over *H. alvei*. Since the name *Obesumbacterium* has traditionally been well known in the brewing industry, which seems to be the ecological niche for this organism, the most practical solution at present is to continue use of the names *H. alvei* biogroup 1 and *O. proteus* biogroup 2 until all the taxonomic problems are resolved and a "final" nomenclature and classification can be proposed after careful analysis.

Since *O. proteus* is now known to be a heterogeneous species, it is essential to append "biogroup 2" to the name that will correspond to the second distinct species shown by DNA–DNA hybridization and biochemical tests. Unless this is done, the intended meaning of *O. proteus* is unclear. We recommend that the term *O. proteus* biogroup 1 be discontinued, and replaced by *H. alvei* biogroup 1.

O. proteus biogroup 2 is a unique genomospecies (DNA hybridization group); however, since its type strain is in a different hybridization group than that of *H. alvei*, the species and the genus (since it is the type species of the genus) would be invalid because it is a junior synonym of *H. alvei*. To rectify this, a new type strain would have to be designated. A Request for an Opinion to do this would have to be made to the Judicial Commission. If the request were granted, the genus *Obesumbacterium* and the species *O. proteus* would again be valid under the rules of nomenclature of the Bacteriologic Code. Other alternatives remain since, based on its DNA–DNA relatedness to *Escherichia blattae*, *O. proteus* could be classified in the genus *Escherichia*. Placing it in this genus would be a simple matter—designating a new type strain and describing a new combination: *"Escherichia proteus"*. An alternative would be to classify *E. blattae* and *O. proteus* biogroup 2 together, either in a redefined genus *Obesumbacterium* or as a new genus. The results from 16S rDNA sequencing (not currently available), should be helpful in deciding on the most logical classification.

List of species of the genus Obesumbacterium

1. **Obesumbacterium proteus** (Shimwell and Grimes 1936) Shimwell 1963, 759[AL] (*Flavobacterium proteum* (sic) Shimwell and Grimes 1936, 348.)
pro' te.us. Gr. masc. n. *proteus* the ancient Greek sea-god noted for being able to change his form at will; Gr. masc. n. *proteus* pleomorphic.

Obesumbacterium proteus is really two different species, which can be differentiated by phenotypic tests (Table BXII.γ.238) and DNA–DNA relatedness tests. The type strain has the properties of *H. alvei* (*O. proteus*) biogroup 1 (see Taxonomic Comments, above). The description of *O. proteus* biogroup 2 is as given for the genus and as listed in Table BXII.γ.193 in the chapter on the family *Enterobacteriaceae*. Occurs in breweries where it grows in beer-wort along with yeasts early in the fermentation. There is no evidence that it is pathogenic for humans or animals.

The mol% G + C of the DNA is: 48–49 (Bd).

Type strain: 42 of Strandskov and Bockelmann (1955), ATCC 12841, DSM 2777, NCIB 8771.

GenBank accession number (16S rRNA): AJ233422.

Additional Remarks: Strain No. 42 belongs to *H. alvei* (O. proteus) biogroup 1. Therefore, at present there is no valid type strain for *O. proteus* biogroup 2—the true representative of the species. Strains 520, 531, and 580 of Priest et al. (1973) belong to *O. proteus* biogroup 2 by DNA–DNA hybridization and are phenotypically typical (Table BXII.γ.238). Thus, they should be considered as the candidates for the proposed type strain.

Genus XXIII. **Pantoea** *Gavini, Mergaert, Beji, Mielcarek, Izard, Kersters and De Ley 1989b, 343^VP emend. Mergaert, Verdonck and Kersters 1993, 171*

Patrick A.D. Grimont and Francine Grimont

Pan.toe'a. Gr. adj. *pantoios* of all sorts and sources; M.L. fem. n. *Pantoea* [bacteria] from diverse [geographical and ecological] sources.

Straight rods, 0.5–1.3 × 1.0–3.0 μm. Nonencapsulated. Nonsporeforming. Some strains form symplasmata. **Most strains are motile and are peritrichously flagellated.** Gram negative. Colonies on nutrient agar are smooth, translucent, and more or less convex with entire margins or heterogenous in consistency and adhering to the agar. **Colonies are yellow, pale beige to pale reddish yellow, or nonpigmented. Facultatively anaerobic. Oxidase negative. Glucose dehydrogenase and gluconate dehydrogenase are produced** and are active without an added cofactor. Acid is produced from the fermentation of D-fructose, D-galactose, trehalose, and D-ribose. Most strains are **Voges–Proskauer positive. Lysine and ornithine are not decarboxylated.** Urease negative. Pectate is not degraded. H_2S is not produced from thiosulfate. Optimum temperature 30°C. *N*-acetyl-D-glucosamine, L-aspartate, D-fructose, D-galactose, D-gluconate, D-glucosamine, D-glucose, L-glutamate, glycerol, D-mannose, D-ribose, and D-trehalose are utilized as sole sources of carbon and energy. 5-Aminovalerate, benzoate, caprate, caprylate, *m*-coumarate, ethanolamine, gentisate, glutarate, histamine, 3-hydroxybenzoate, 4-hydroxybenzoate, 3-hydroxybutyrate, itaconate, maltitol, D-melezitose, 1-*O*-methyl-α-D-glucoside, palatinose, 3-phenylpropionate, propionate, L-sorbose, tricarballylate, tryptamine, D-turanose, and L-tyrosine are not utilized as sole sources of carbon and energy. *Pantoea* spp. are isolated from plants, seeds, fruits, soils, water, and from humans (urine, blood, wounds, internal organs), and animals. Some strains are (or have been thought to be) phytopathogenic.

The mol% G + C of the DNA is: 49.7–60.6.

Type species: **Pantoea agglomerans** (Ewing and Fife 1972) Gavini Mergaert, Beji, Mielcarek, Izard, Kersters and De Ley 1989b, 343 (*Enterobacter agglomerans* (Beijerinck 1888) Ewing and Fife 1972, 10.)

Further descriptive information

Much of our knowledge about the characteristics of the genus *Pantoea* was acquired when all *Pantoea*, *Leclercia* and related bacteria were called *Enterobacter agglomerans*. Therefore, in this chapter, we will refer to *Pantoea agglomerans* when this precise species is meant and to the *Enterobacter agglomerans* complex when there is insufficient taxonomic information. Older data refer to *Erwinia herbicola* or the "herbicola group". Strains in the *Enterobacter agglomerans* complex (or *Erwinia herbicola* or the "herbicola group") may or may not belong to the genus *Pantoea*.

Phylogenetic treatment Of the 124 strains of the *Enterobacter agglomerans* complex analyzed by DNA–DNA hybridization by Brenner et al. (1984a), 90 formed 13 distinct DNA groups. The remaining 34 strains did not fit any of these groups. The synonymy between these groups and named species is given in Table BXII.γ.239.

Comparison of *rrs* gene (encoding 16S rRNA) sequences showed the genus *Pantoea* (represented by *Pantoea agglomerans*, *Pantoea ananatis*, and *Pantoea stewartii*) to constitute a monophyletic cluster distinct from clusters corresponding to the genera *Erwinia*, *Pectobacterium*, *Brenneria*, and other genera of the *Enterobacteriaceae* (Hauben et al., 1998a). When all DNA groups from Brenner et al. (1984a) and named *Pantoea* species are studied

TABLE BXII.γ.239. Correspondence between DNA relatedness groups, phenons, and nomenspecies in the *Enterobacter agglomerans* complex.

Gavini et al., 1983b	Brenner et al., 1984a	Verdonck et al., 1987	Nomenspecies (older synonyms)

E4	VII	(26)	Close to *Leclercia adecarboxylata* and *Enterobacter cloacae*

[a]( ) : parentheses indicate partial correspondence.

by *rrs* and *rpoB* sequence comparisons, the following congruent clusterings are obtained:

a. *P. agglomerans* (DNA group XIII), *P. ananatis* (DNA group VI), *P. stewartii*, and DNA group V cluster together.
b. DNA groups I and II and a cluster containing *Pantoea dispersa* (DNA group III) and DNA group IV branch with the above-mentioned cluster to constitute a monophyletic *Pantoea* cluster.
c. *Pantoea citrea*, *Pantoea terrea*, and *Pantoea punctata* constitute a discrete cluster that joins the *Pantoea* cluster at a lower level.
d. *E. agglomerans* DNA groups VII, VIII, IX, X, XI, and XII branch away from the *Pantoea* cluster (unpublished data).

More taxonomic work is needed to justify the assignment of *P. citrea*, *P. terrea*, and *P. punctata* to the genus *Pantoea*.

Cell morphology Symplasmata are sausage-shaped zoogloeal masses of bacteria observed by phase contrast microscopy in hanging drop preparations from the water of syneresis in glucose nutrient agar slopes after 24 h incubation (Graham and Hodgkiss, 1967). Symplasmata have been observed in bacteria now reclassified in the genus *Pantoea* (*"Bacterium herbicola"*, *Erwinia lathyri*, *Erwinia uredovora*, and *Erwinia milletiae*) (Graham and Hodgkiss, 1967). The epithet *"agglomerans"* probably refers to symplasmata (Beijerinck, 1888).

Nutrition and growth conditions Best results are obtained when *Pantoea* cultures are incubated at 30°C. Most strains grow at 37°C on plating media, but some cultures fail to grow or only produce microcolonies. A few isolates can grow on brilliant green or bismuth sulfite agar media and can produce light growth of colonies that range from very small to 2.0 mm in diameter. Many strains produce mucoid colonies at 37°C, and most cultures do so when the media are incubated at room temperature, about 25°C.

On nutrient agar, anaerogenic strains of the *E. agglomerans* complex (*Pantoea* spp.) form mucoid colonies, smooth and irregularly round colonies, or rough and wrinkled colonies that are difficult to remove with a platinum wire. This latter aspect is what led to the description of "biconvex bodies", which can be observed with a low power stereoscopic binocular microscope in 2 or 3 day-old colonies. These bodies appear to be granular structures analogous to symplasmata or down-growths of the colonies into the medium (Graham and Hodgkiss, 1967).

P. agglomerans, *P. stewartii*, and *P. ananatis* colonies are usually yellow pigmented; *P. dispersa* is often pigmented; and *P. citrea*, *P. punctata*, and *P. terrea* are never pigmented. Yellow pigmentation of *P. agglomerans* may be weak at 37°C.

In Biotype-100 strips (BioMerieux, Craponne, France) or in a minimal medium containing ammonium sulfate as the nitrogen source, the following compounds serve as sole carbon sources for most strains: *N*-acetyl-D-glucosamine, L-aspartate, D-fructose, D-galactose, D-gluconate, D-glucosamine, D-glucose, L-glutamate, glycerol, D-mannose, D-ribose, and D-trehalose.

Most strains cannot utilize the following substrates as sole carbon and energy sources: 5-aminovalerate, benzoate, caprate, caprylate, *m*-coumarate, ethanolamine, gentisate, glutarate, histamine, 3-hydroxybenzoate, 4-hydroxybenzoate, 3-hydroxybutyrate, itaconate, maltitol, D-melezitose, 1-*O*-methyl-α-D-glucoside, palatinose, 3-phenylpropionate, propionate, L-sorbose, tricarballylate, tryptamine, D-turanose, and L-tyrosine.

Metabolism Most cultures produce acid from sucrose and therefore yield acid throughout in tubes of triple sugar iron agar. *P. agglomerans* gives negative reactions in all three decarboxylase tests.

Under aerobic conditions, all *Pantoea* species produce gluconate from D-glucose in the presence of iodoacetate due to a glucose dehydrogenase, without added pyrroloquinoline quinone (PQQ) (Bouvet et al., 1989). A reducing compound, 2-ketogluconate, is also produced from gluconate due to a gluconate dehydrogenase (Bouvet et al., 1989). 2,5-Diketogluconate is produced from 2-ketogluconate by *Pantoea citrea*, *P. punctata*, and *P. terrea* (Kageyama et al., 1992).

Pantoea species are negative for the following tests: H_2S production from thiosulfate, tetrathionate reduction, tributyrin and corn oil hydrolysis, and β-glucuronidase.

Mutants, plasmids, phages and phage typing, bacteriocins *Pantoea agglomerans* strain Eh318 produces two antibiotics (pantocin A and B) that inhibit *Erwinia amylovora in vitro* (Wright et al., 2001). *Erwinia herbicola* produces two lipopeptide antibiotics, herbicolicin A and B, which are active against sterol-containing fungi (Greiner and Winkelmann, 1991). Four antibiotics, agglomerins A, B, C, and D, were isolated from the culture broth of a strain identified as *Enterobacter agglomerans*; these antibiotics are active against a wide variety of anaerobic bacteria *in vitro* (Shoji et al., 1989).

The eight bacteriocin-producing *Enterobacter cloacae* strains used to type *E. cloacae* isolates by bacteriocin susceptibility are useful in typing isolates identified as *Enterobacter agglomerans* (Bauernfeind and Petermüller, 1984).

Antigenic structure The principal antigens in most strains studied under the name *E. agglomerans* (*Erwinia herbicola*) are uncharged capsular polysaccharides. These antigens are not removed from the cells by heating at 100°C for 30 min (Slade and Tiffin, 1984). Most members of the "herbicola group" are motile, but there is no report on the antigenic structure of the flagella (Slade and Tiffin, 1984). Most strains produce antigenically similar high molecular weight acidic polysaccharides.

Two schemes of serotyping have been proposed for *Erwinia herbicola*. Muraschi et al. (1965) used immunodiffusion and antigens extracted by aqueous ether and classified 55 isolates into 7 serotypes, although "some cultures were mixtures of more than one serotype". A second scheme was established by Slade (cited by Slade and Tiffin, 1984), using laboratory strains. This scheme has not been used to type new isolates.

Pathogenicity Strains of the *E. agglomerans* complex may occur in clinical samples (blood, wounds, sputum, urine), often with dubious clinical significance (von Graevenitz, 1970; Gilardi and Bottone, 1971; Pien et al., 1972). In some cases (Cooper-Smith and von Graevenitz, 1978; von Graevenitz and Palermo, 1980), clinical significance has been demonstrated. In an Ohio hospital, *E. agglomerans* accounted for four of 58 episodes of *Enterobacter* bacteremia and one of 42 cases of nosocomial bacteremia (Watanakunakorn and Weber, 1989). In 1970, *E. agglomerans* was implicated in a United States-wide and a Canadian outbreak of septicemia caused by contaminated closures on bottles of infusion fluids. Twenty-five hospitals were involved with 378 cases and 40 deaths (Maki et al., 1976).

Strains identified as *Pantoea agglomerans* have been isolated from joint fluid of patients with arthritis following injuries with plant thorns, wood slivers, or wooden splinters (Flatauer and Khan, 1978; Olenginski et al., 1991; de Champs et al., 2000).

A case of metastatic endophthalmitis caused by a strain identified as *Enterobacter agglomerans* was reported. One day following

internal hemorrhoidal ligation, the patient developed anterior uveitis, followed by panophthalmitis and loss of vision (Zeiter et al., 1989).

Enterobacter agglomerans was isolated from the blood of a patient with cotton fever, a benign febrile leukocytic syndrome seen in intravenous narcotic abusers. The strain was also isolated from cotton that the patient had used to filter heroin (Ferguson et al., 1993). *Enterobacter agglomerans* is known to heavily colonize cotton and cotton plants.

Antibiotic sensitivity Most *E. agglomerans* strains are naturally resistant to ampicillin and cephalothin and susceptible to many antibiotics including aminoglycosides, carbenicillin, cefamandole, cefuroxime, and cefoxitine. Resistance to carbenicillin may occur.

Pathogenesis Contaminated medicinal agents can be sources of outbreaks. Maki and Martin (1975) showed that strains identified as *E. agglomerans* (as well as strains of *E. cloacae* and *Serratia marcescens*) multiplied in 5% dextrose solution at 25°C better than did other members of the *Enterobacteriaceae*. A single tested strain of *E. agglomerans* was devoid of hemagglutinin (Adegbola and Old, 1983a). *E. agglomerans* strains produce aerobactin. Two of nine strains of *E. agglomerans* produced a hydroxamate compound other than aerobactin (Reissbrodt and Rabsch, 1988). In another study, strains identified as *Enterobacter agglomerans* produced hydroxamate siderophores identified as ferrioxamine E. The strains had also multiple siderophore receptors in the outer membrane (Berner et al., 1988).

The lipopolysaccharide from strains identified as *E. agglomerans* (commonly found in cotton dust) can bind to the pulmonary lipid-proteinaceous lining material (surfactant) and alter its surface tension properties (DeLucca et al., 1988). This binding in the lung may change the physiological properties of surfactant and be a possible mechanism for the pathogenesis of byssinosis, an occupational respiratory disorder caused by the inhalation of cotton dust (DeLucca et al., 1988).

Ecology The *Enterobacter agglomerans* complex is ubiquitous in the environment. This complex predominates on the leaf and bract of pre- and postsenescent cotton plants (DeLucca and Palmgren, 1986). The main species of Gram-negative bacteria in cotton dusts found in mills is *E. agglomerans* (Haglind et al., 1981). The following occurrences have been reviewed by Slade and Tiffin (1984). Strains of the *Enterobacter agglomerans* complex are found on the aerial surfaces of plants and within healthy plant tissues and seeds. Nitrogen fixing strains have been found in the rhizosphere of wheat and sorghum. In fact, these bacteria are typical of the innermost part of the rhizosphere of wheat (Kleeberger et al., 1983). Nitrogen-fixing strains identified as *Enterobacter agglomerans* have also been isolated from gut of the wood-eating termite *Coptotermes formosanus* (Potrikus and Breznak, 1977). Strains of this complex have been isolated from water, paper mill process water, soil and decaying wood. They are frequently isolated from damaged plant tissues and lesions, although they are rarely considered pathogenic. A pathogenic role has been shown in some instances. Strains named *Erwinia milletiae* produce β-indolyl acetic acid (a plant hormone) causing galls on some plants in Japan (reviewed by Slade and Tiffin, 1984). Some strains initiate freezing of buffer solutions (which would normally freeze at temperatures below −10°C) at about −4°C. This ice-nucleating property plays a critical role in causing frost damage on plants (Kozloff et al., 1983; Lindow et al., 1978).

Pink disease of pineapple, caused by *Pantoea citrea*, is characterized by a dark coloration on fruit slices after autoclaving (Cho et al., 1980). This coloration is initiated by the oxidation of glucose to gluconate, then the oxidation of gluconate to 2-ketogluconate, and finally the production of 2,5-diketogluconate. The latter appears to be responsible for the dark color characteristic of the pink disease of pineapple (Pujol and Kado, 2000).

Some strains of the *Enterobacter agglomerans* complex are associated with stalk and leaf necrosis of onion (Hattingh and Walters, 1981). Strains originally named *Erwinia uredovora* (now *Pantoea ananatis*) attack the uredia of rust (*Puccinia* spp.) on wheat, oats and rye (Pon et al., 1954; Dye, 1969b).

Stewart's bacterial wilt is a disease of corn (*Zea mays*) caused by *Pantoea stewartii* subsp. *stewartii*. On corn seedlings at the three- to five-leaf stage, the disease is characterized by water-soaked lesions on leaves, leading to stunted plants with severe yield reductions in susceptible corn hybrids (Dillard and Kline, 1989; Wilson et al., 1994). The corn flea beetle, *Chaetocnema pulicaria*, is the overwintering host and vector of *P. stewartii*, and the abundance of the primary inoculum is related to corn flea beetle populations. Many countries ban import of seed corn unless it is certified free of *P. stewartii*. A ligase chain reaction assay has been proposed for the detection of *P. stewartii* in infected plant and vector material (Wilson et al., 1994).

P. stewartii subsp. *stewartii* produces an extracellular heteropolysaccharide capsule, which plays several roles in the development of Stewart's wilt on sweet corn. The capsule provides a barrier that protects the bacterium against plant host defense factors (Braun, 1982; Beck von Bodman and Farrand, 1995). It also partially contributes to the induction of water-soaking symptoms early in the development of Stewart's wilt, and it obstructs the free flow of water in the host vascular system, causing necrosis and wilting during the systemic phase of the infection (Braun, 1982; Beck von Bodman and Farrand, 1995). *P. stewartii* subsp. *stewartii* synthesizes *N*-(-3-oxohexanoyl)-L-homoserine lactone, which is an autoinducer for capsular polysaccharide biosynthesis and *P. stewartii* pathogenicity (Beck von Bodman and Farrand, 1995).

A strain identified as *Pantoea agglomerans* was isolated from necrotic spots in the leaves of a beach pea (*Lathyrus maritimus*) that grew on the shorelines of Newfoundland, Canada. The bacterium produced cellulase and amylase and was a plant wound parasite (Khetmalas et al., 1996).

Some strains of the *E. agglomerans* complex have been used for biological control of plant pathogens (such as *Erwinia amylovora* or *Xanthomonas oryzae*), either by competition for nutrients, acid production, bacteriocin production or phage production (reviewed by Slade and Tiffin, 1984). *Pantoea agglomerans* CFA-2 is effective for the biological control of postharvest pear diseases due to *Botrytis cinerea*, *Penicillium expansum*, and *Rhizopus stolonifer* (Nunes et al., 2001).

Pantoea agglomerans in fecal pellets of locusts produces large amounts of guaiacol and small amounts of phenol, both of which are components of the locust cohesion pheromone (Dillon et al., 2002).

Enrichment and Isolation Procedures

All media designed for the isolation of *Enterobacteriaceae* can be used for the isolation of *Pantoea* species: MacConkey agar, Drigalski lactose agar, Hektoen agar, deoxycholate lactose citrate agar, etc. *Pantoea* strains can also grow on media for general use, such as blood agar, nutrient agar, tryptic soy agar, bromocresol

purple lactose agar, etc. Media specifically selective for *Pantoea* strains are not available.

A differential medium, lysine-ornithine-mannitol agar containing vancomycin, was proposed for the isolation of *Pantoea agglomerans*. It yields colorless colonies from mannitol-negative strains, yellow colonies from mannitol-positive, ornithine- and lysine-decarboxylase negative strains, and greenish-blue colonies from mannitol-positive strains that produce one or both decarboxylases (Bucher and von Graevenitz, 1982).

Maintenance Procedures

Strains are initially grown on tryptic soy agar at their optimum temperature. They are then inoculated by stabbing a maintenance medium[1] designed for maintenance of *Enterobacteriaceae* and related organisms. The cultures are then stored at room temperature in a dark, dry place.

Cultures may be also preserved by freeze-drying. Freeze-drying is the best procedure for preservation of pigmented strains.

Differentiation of the genus *Pantoea* from other genera

Enterobacter strains that are negative for lysine and ornithine decarboxylases and arginine dihydrolase and that may or may not produce a yellow pigment were formerly identified as *Enterobacter agglomerans*. The genus *Pantoea* is a subset of the *Enterobacter agglomerans* complex. Species of *Pantoea* are able to oxidize D-glucose to D-gluconate (glucose dehydrogenase activity) without added pyrroloquinoline quinone, and D-gluconate to 2-ketogluconate (gluconate dehydrogenase activity). In addition, they cannot utilize phenylacetate, and most strains can utilize *myo*-inositol.

Taxonomic Comments

The genus *Erwinia* has long been a depository for plant-associated members of the family *Enterobacteriaceae*. Several species of this genus were found to be phenotypically similar to *Enterobacter* species (*Erwinia herbicola*, *Erwinia ananatis*, *Erwinia uredovora*, *Erwinia milletiae*, *Erwinia dissolvens*, and *Erwinia nimipressuralis*) (Lelliott, 1974; Lelliott and Dickey, 1984), or highly related to *Enterobacter* species by DNA hybridization (*Erwinia dissolvens* and *Erwinia nimipressuralis*) (Steigerwalt et al., 1976).

The (invalid) name *"Bacterium herbicola aureum"* was introduced by Düggeli (1904) and *"Bacterium herbicola"* is attributed to Löhnis (1911). The species was transferred to the genus *Erwinia* as *E. herbicola* by Dye (1964). It has always been considered a saprophyte associated with plants (epiphyte).

The earliest synonym of *Erwinia herbicola*, represented by an extant culture, is *"Pseudomonas trifolii"* (Hüss 1907) shown by Dye (1964) to be identical with *Erwinia herbicola*. Unfortunately, the epithet *"trifolii"* did not appear in the Approved Lists, although it had priority over the epithet *herbicola*.

Manns and Taubenhaus (1913) described *"Bacillus lathyr"* as the cause of streak disease of sweet peas (now attributed to a virus). The species was transferred to the genus *Erwinia* as *E. lathyri* by Holland (1920).

"Bacillus milletiae" was described by Kawakama and Yoshida (1920) as causing galls on millet. The species was transferred to the genus *Erwinia* as *E. milletiae* by Magrou (1937).

"Bacillus ananas" was isolated from bacterial fruitlet brown-rot of pineapple in the Philippines by Serrano (1928). It is given as *Erwinia ananas* Serrano 1928 on the Approved Lists of Bacterial Names (Skerman et al., 1989).

"Xanthomonas uredovorus" was isolated from uredia of cereal rusts (Pon et al., 1954) and reclassified in the genus *Erwinia* by Dye (1963c).

Graham (1958) reported that the pathogenic properties of *E. ananas* and *E. milletiae* are doubtful and that culturally and biochemically these species were indistinguishable from *E. lathyri*.

Dye (1969b) proposed a classification of the "herbicola group" containing *Erwinia herbicola* subsp. *herbicola* (18 species names were listed as synonyms including *E. herbicola*, *E. lathyri*, and *E. milletiae*), *Erwinia herbicola* subsp. *ananas*, *E. uredovora* and *E. stewartii*.

"Pseudomonas stewartii" was isolated by Smith (1898) from Stewart's sweet corn wilt and was transferred to *Erwinia* as *E. stewartii* by Dye (1963b).

After studying many cultures of the "herbicola-lathyri" group, including clinical isolates, Ewing and Fife (1972) exhumed an old work by Beijerinck (1888) describing *"Bacillus agglomerans"*, a bacterium that formed what might have been symplasmata. Although no culture was available, a new combination, *Enterobacter agglomerans* (Beijerinck) Ewing and Fife 1972, was proposed for the "herbicola-lathyri" group on the argument of priority. However, the Approved Lists gave the name as *Enterobacter agglomerans* Ewing and Fife 1972, thus losing the connection with Beijerinck (1888). The other synonyms found in the Approved Lists are *Erwinia herbicola* (Löhnis 1911) Dye 1964 and *Erwinia milletiae* (Kawakama and Yoshida 1920) Magrou 1937.

E. agglomerans is a very complex group of bacteria, which may cause opportunistic infections. The name covers many (20 to 40) genomic groups (Brenner et al., 1984a) or phena (Gavini et al., 1983b; Verdonck et al., 1987). In addition to this diversity, strains of the *E. agglomerans* complex are not closely related to *E. cloacae* (the type species of the genus *Enterobacter*) by DNA relatedness. Some groups in this complex have been designated as new genera (*Rahnella aquatilis*, *Ewingella americana*, *Leclercia adecarboxylata*). There is an apparent confusion in the literature, and a close examination of published papers for the presence of commonly studied strains is needed to extract convergent pieces of information. A table relating phena and DNA groups has been created after such a literature analysis (Table BXII.γ.239).

The numerical study of Gavini et al. (1983b), based on 169 strains, yielded five phena (A to E). Phenon A corresponded to *Erwinia carotovora*. Phenon B, which included strains of the *Enterobacter agglomerans* complex, was split into nine smaller phena (B1 to B9). Phenon B4 contained the type strains of *Erwinia herbicola* and *Erwinia milletiae*. Phenon B8 contained the type strain of *Erwinia ananas* and a reference strain of *Erwinia uredovora*. Phenon C corresponded to *Rahnella aquatilis*. Phenon D was split into three smaller phena (D1 to D3), with phenon D2 corresponding to *Enterobacter sakazakii*. Phenon E was split into five smaller phena (E1 to E5), with phenon E5 containing strains previously identified as *Escherichia adecarboxylata* (now *Leclercia adecarboxylata*).

A larger numerical study (Verdonck et al., 1987), based on 529 strains and including many type and reference strains, distributed 66 strains of the *Enterobacter agglomerans* complex into 21 phena. The correspondence between phena from both studies

1. Maintenance medium (g/liter): Bacto-peptone (Difco), 10.0, NaCl, 5.0: Bacto-agar (Difco), 10.0; pH 7.4. The medium should be dispensed into small (9.5–10 × 90 mm) screw-capped tubes.

(Gavini et al., 1983b; Verdonck et al., 1987) is given in Table BXII.γ.239.

The DNA relatedness work of Brenner et al. (1984a) revealed the extreme genomic diversity of the *Enterobacter agglomerans* complex: of 124 strains studied, 90 fell into 13 DNA groups (I to XIII) and 34 strains did not fit into any group. Furthermore, four groups (V, XI, XII, and XIII) were heterogeneous with respect to $\Delta(T_m)$ values. An interesting finding was that aerogenic strains and anaerogenic strains were not found in the same hybridization group.

Lind and Ursing (1986) identified 52 of 86 clinical isolates with *Enterobacter agglomerans sensu strictu* by DNA hybridization. In the same study, they demonstrated the synonymy of *Enterobacter agglomerans*, *Erwinia herbicola*, and *Erwinia milletiae*. This synonymy was confirmed by Beji et al. (1988) who, in addition, identified DNA group XIII (Brenner et al., 1984a) with *Enterobacter agglomerans sensu strictu*.

To separate *Enterobacter agglomerans/Erwinia herbicola* from the genera *Enterobacter* and *Erwinia*, a new genus, *Pantoea*, was proposed with *P. agglomerans* as the type species (Gavini et al., 1989b). The epithet *agglomerans* was retained because it was believed to have priority over epithet *herbicola*. Strains of DNA group III (Brenner et al., 1984a) or phenon 8 (Verdonck et al., 1987) were proposed as a new species, *Pantoea dispersa* (Gavini et al., 1989b). The DNA groups closest to *Pantoea agglomerans* are DNA groups II, III, IV, V, and VI (Lind and Ursing, 1986). It is interesting that strains of group II to VI and XIII are characterized by the presence of a glucose oxidation pathway that produces 2-ketogluconate from glucose (Bouvet et al., 1989). This finding has been extended to DNA group I (P.A.D. Grimont, unpublished observations). Thus, the genus *Pantoea* can be envisioned to include DNA groups I, II, IV, V, and VI in addition to groups XIII (*P. agglomerans*) and III (*P. dispersa*).

Erwinia ananas (Serrano 1928) corresponds to group VI of Brenner et al. (1984a) and was transferred to the genus *Pantoea* as *P. ananas* (Mergaert et al., 1993). The name was corrected to *P. ananatis* by Trüper and De' Clari, 1997). *Erwinia uredovora* belongs to that species.

Erwinia stewartii was included in the genus *Pantoea* as *P. stewartii* subsp. *stewartii* (Smith 1898) Mergaert et al. 1993. *P. stewartii* subsp. *indologenes* was a new subspecies composed of strains phenotypically different from *Erwinia stewartii* (and *P. stewartii* subsp. *stewartii*) and resembling *P. ananatis*. However, DNA hybridization and sequence studies indicate that both subspecies should belong to the same species.

The three species (*Pantoea punctata*, *P. citrea*, and *P. terrea*) described by Kageyama et al. (1992) have the ability to oxidize 2-ketogluconate to 2,5-diketogluconate. These species differ from the other *Pantoea* species in several biochemical or nutritional characteristics. Their phylogenetic position is as a branch on the border of the *Pantoea* cluster.

DNA group XI (Brenner et al., 1984a) was identified with *Escherichia adecarboxylata* by DNA relatedness (Izard et al., 1985). *Escherichia adecarboxylata* was transferred to a new genus *Leclercia*, as *L. adecarboxylata* (Tamura et al., 1986). DNA group VII (Brenner et al., 1984a) was close to (but distinct from) *Escherichia adecarboxylata* (*Leclercia adecarboxylata*) (Izard et al., 1985). In our laboratory, strains of DNA group VII were indistinguishable from strains of phenon E4 (Gavini et al., 1983b) by carbon source utilization tests (P.A.D. Grimont, unpublished observations). Thus, DNA group VII is a good candidate as a new species of *Leclercia*.

DNA group VIII (Brenner et al., 1984a) was 64% related to *Enterobacter persicina* (a close relative of *Erwinia rhapontici*).

DNA group IX (Brenner et al., 1984a) is identical with *Enterobacter cowanii* based on nutritional tests and *rpoB* sequence analysis (unpublished data).

More work is needed to characterize unclassified strains of the *E. agglomerans* complex.

DIFFERENTIATION OF THE SPECIES OF THE GENUS *PANTOEA*

The characteristics of named or unnamed species of *Pantoea* are given in Table BXII.γ.240 . The results of carbon source utilization tests given in Table BXII.γ.240 are mostly unpublished observations (P.A.D. Grimont and E. Ageron).

The genus *Pantoea* can be divided into two groups of species: (1) the *Pantoea* core group with *P. agglomerans*, *P. dispersa*, *P. ananatis* , and *P. stewartii* and (2) the "Japanese" group with *P. citrea*, *P. punctata*, and *P. terrea*. Species of the core group utilize the following substrates as sole carbon sources which the "Japanese" group cannot utilize: D-alanine, L-alanine, *myo*-inositol, DL-lactate, 1-*O*-methyl-β-D-glucoside, and L-serine. Furthermore, all species of the core group utilize L-arabinose and D-mannitol, whereas two species of the "Japanese" group fail to utilize these substrates. Species of the core group are negative for arginine dihydrolase and 2-ketogluconate dehydrogenase, whereas two species of the "Japanese" group are positive for arginine dihydrolase and all three species are positive for 2-ketogluconate dehydrogenase.

List of species of the genus Pantoea

1. **Pantoea agglomerans** (Ewing and Fife 1972) Gavini Mergaert, Beji, Mielcarek, Izard, Kersters and De Ley 1989b, 343[VP] (*Enterobacter agglomerans* (Beijerinck 1888) Ewing and Fife 1972, 10.)

   ag.glo' mer.ans. L. v. *agglomerare* to form into a ball; L. part. adj. *agglomerans* forming into a ball (referring to the occurrence of symplasmata bacteria in aggregates surrounded by a translucent sheath in anaerogenic strains).

   The species has all the characteristics given for the genus. Cells may form symplasmata. Strains grow well on nutrient agar at 30°C but not at 44°C. Some strains grow slowly at 4 or 41°C. The biochemical and nutritional characteristics are shown in Table BXII.γ.240. Key characteristics are: alkaline reaction in malonate broth; utilization of D-glucuronate and D-tartrate as sole carbon sources; inability to utilize *meso*-erythritol, gentiobiose, 5-ketogluconate, D-me-

[a]Symbols: +, 90–100% of strains positive in 1–2 days; (+), 90–100% of strains positive in 1–4 days; −, 90–100% of strains negative in 4 days; d, positive in 1–4 days; (d), positive in 3–4 days; ND, no data.

libiose and D-raffinose as sole carbon sources; and no production of indole and 2-ketogluconate dehydrogenase.

Isolated from plants, flowers, seeds, vegetables, water, soil and foodstuffs. Some strains are of human (wounds, blood, urine, internal organs) and animal origin. Some strains (synonym, *Erwinia milletiae*) have been reported to cause galls on *Wisteria floribunda* and *Wisteria japonica*; some strains cause galls on *Gypsophyla paniculata*, and some strains cause stalk and leaf necrosis on onion plants.

The mol% G + C of the DNA is: 55.1–56.8 (T_m).

Type strain: ATCC 27155, CCUG 539, CFBP 3845, CIP 57.51, DSM 3493, ICMP 12534, JCM 1236, LMG 1286, NCTC 9381.

GenBank accession number (16S rRNA): AB004691, AJ233423.

2. **Pantoea ananatis** corrig. (Serrano 1928) Mergaert, Verdonck and Kersters 1993, 170[VP] (*"Bacillus ananas"* Serrano 1928, 271; *Erwinia ananas* (sic) Serrano 1928; *Pantoea ananas* (sic) Mergaert, Verdonck and Kersters 1993, 170.)
a′na.na.tis. M.L. n. *ananas* generic name of the pineapple.

The species has all the characteristics given for the genus. The biochemical and nutritional characteristics are given in Table BXII.γ.240. Key characteristics are: indole production; no alkaline reaction in malonate broth; utilization of gentiobiose, D-glucuronate, 5-ketogluconate, lactose, lactulose, D-melibiose, 1-*O*-methyl-α-galactoside, protocatechuate, quinate and D-raffinose as sole carbon sources; utilization of D-sorbitol by most strains; and no utilization of *meso*-erythritol and D-tartrate.

Strains formerly classified as *Erwinia uredovora* show a stronger proteinase activity and produce a DNase.

The mol% G + C of the DNA is: 53.6–56.4 (T_m).

Type strain: ATCC 33244, CFBP 3612, CIP 105207, LMG 2665, NCPPB 1846.

GenBank accession number (16S rRNA): U80196.

3. **Pantoea citrea** Kageyama, Nakae, Yagi and Sonoyama 1992, 209[VP]
ci′tre.a. M.L. adj. *citrea* of citrus.

The cell morphology and colonial morphology are as given for the genus. The cells are nonmotile. Either nicotinic acid or nicotinamide is required for growth. Good growth occurs at 20–34°C; no growth occurs at 41°C. Colonies grown on nutrient agar at 30°C for 2 d are pale beige to pale reddish yellow. Physiological and nutritional characteristics are presented in Table BXII.γ.240. Key characteristics are: production of 2-ketogluconate dehydrogenase; positive arginine dihydrolase reaction; hydrolysis of ONPG but not esculin; utilization of L-arabinose, *meso*-erythritol, maltose, and D-tagatose as sole carbon and energy sources; and no utilization of gentiobiose. Isolated from mandarin oranges.

The mol% G + C of the DNA is: 49.7 (HPLC).

Type strain: SHS 2003, ATCC 31623, CIP 105599, CCUG 30156, DSM 13699.

4. **Pantoea dispersa** Gavini, Mergaert, Beji, Mielcarek, Izard, Kersters and De Ley 1989b, 344[VP]
dis.per′sa. L. v. *dispergere* to spread, to scatter; L. fem. part. adj. *dispersa* spread, scattered.

The species has all the characteristics of the genus. Strains grow well on nutrient agar at 30 and 41°C but not at 44°C or 4°C. Key characteristics are: no alkaline reaction in malonate broth; utilization of *meso*-erythritol, gentiobiose, D-glucuronate and 5-ketogluconate as sole carbon sources; no utilization of D-melibiose, D-raffinose, and D-tartrate as sole carbon sources; and no production of indole and 2-ketogluconate dehydrogenase. Isolated from plant surfaces, seeds, humans, and the environment.

The mol% G + C of the DNA is: 56.5–60.6 (T_m).

Type strain: ATCC 14589, CCUG 25232, CIP 103338, DSM 30073, LMG 2603.

5. **Pantoea punctata** Kageyama, Nakae, Yagi and Sonoyama 1992, 209^{VP}
punc.ta′ta. L. n. *punctum* a point; M.L. adj. *punctata* full of points.

The cell morphology and colonial morphology are as given for the genus. Cells are nonmotile. Either nicotinic acid or nicotinamide is required for growth. Good growth occurs at 20–34°C; no growth occurs at 41°C. Colonies grown on nutrient agar at 30°C for 2 d are pale beige to pale reddish yellow. Yellow pigment is not produced on nutrient agar. Physiological and nutritional characteristics are presented in Table BXII.γ.240. Key characteristics are: production of 2-ketogluconate dehydrogenase; positive arginine dihydrolase reaction; hydrolysis of esculin by some strains; no hydrolysis of ONPG; utilization of gentiobiose as a sole source of carbon and energy; and no utilization of L-arabinose, *meso*-erythritol, maltose, and D-tagatose. Isolated from mandarin oranges.

The mol% G + C of the DNA is: 50.0–50.3 (HPLC).

Type strain: SHS 2006, ATCC 31626, CIP 105598, DSM 13700.

6. **Pantoea stewartii** (Smith 1898) Mergaert, Verdonck and Kersters 1993, 170^{VP} (*"Pseudomonas stewartii"* Smith 1898, 422; *Erwinia stewartii* (Smith 1898) Dye 1963b, 504.)
stew.art′i.i. M.L. en. n. *stewartii* of Stewart; named after F.C. Stewart.

The species has all the characteristics given for the genus, except that some strains produce a capsular polysaccharide. The species is divided into two subspecies that differ strongly in vigor. Previous information about the characteristics of *Erwinia stewartii* applies only to *P. stewartii* subsp. *stewartii*, not to *P. stewartii* subsp. *indologenes*, which can hardly be differentiated from *P. ananatis* by biochemical and nutritional properties. Common characteristics of the species are listed in Table BXII.γ.240. Key characteristics are: production of a yellow pigment; no alkaline reaction in malonate broth; no reduction of nitrate to nitrite; acid production from L-arabinose, sucrose, and D-mannitol but not from D-sorbitol; utilization of L-alanine, L-arabinose, *myo*-inositol, DL-lactate, D-mannitol, D-melibiose, 1-*O*-methyl-α-galactoside, 1-*O*-methyl-β-galactoside, 1-*O*-methyl-β-D-glucoside, D-raffinose, L-serine, sucrose, *meso*-tartrate, and D-xylose as sole sources of carbon and energy; and no utilization of *meso*-erythritol and D-sorbitol. Isolated from *Zea mays*, several other grasses, *Ananas comosus*, and beetles.

The mol% G + C of the DNA is: 53.6–56.4 (T_m).

Type strain: ATCC 8199, CIP 104005, DSM 30176, LMG 2715, NCPPB 2295.

a. **Pantoea stewartii** *subsp.* **stewartii** (Smith 1898) Mergaert, Verdonck and Kersters 1993, 170^{VP} (*"Pseudomonas stewartii"* Smith 1898, 422; *Erwinia stewartii* (Smith 1898) Dye 1963b, 504.)

The biochemical and nutritional characteristics are given in Table BXII.γ.240. A few strains grow at 4°C. Some strains grow at 37°C, but no strains grow at 41°C. Key characteristics are: lack of motility; no production of indole; no hydrolysis of esculin; no acid production from D-arabitol, cellobiose, *myo*-inositol, lactose, maltose, L-rhamnose and salicin; and no utilization of D-arabitol, betaine, citrate, D-glucuronate, 5-ketogluconate, maltose, 3-*O*-methyl-D-glucose, protocatechuate, quinate, and D-saccharate as sole carbon and energy sources.

Causative agent of Stewart's bacterial wilt of corn, a vascular disease of *Zea mays*. Also isolated from the insect vector, the corn flea beetle *Chaetocnema pulicaria*.

The mol% G + C of the DNA is: 54.6–55.1 (T_m).

Type strain: ATCC 8199, CIP 104005, DSM 30176, LMG 2715, NCPPB 2295.

GenBank accession number (16S rRNA): Z96080.

b. **Pantoea stewartii** *subsp.* **indologenes** Mergaert, Verdonck and Kersters 1993, 171^{VP}
in.do.lo′gen.es. M.L. n. *indolum* indole; Gr. n. *gennao* to produce; M.L. adj. *indologenes* indole producing.

The biochemical and nutritional characteristics are given in Table BXII.γ.240. Many strains grow at 4 and 37°C and some strains grow at 41°C, but few strains grow at 44°C. Key characteristics are: motility; production of indole; hydrolysis of esculin; acid production from D-arabitol, cellobiose, *myo*-inositol, lactose, maltose, D-rhamnose and salicin; and utilization of L-arabitol, betaine, citrate, D-glucuronate, 5-ketogluconate, maltose, 3-*O*-methyl-D-glucose, protocatechuate, quinate and D-saccharate as sole carbon and energy sources.

Thought to cause leaf spot on foxtail millet (*Setaria italica*) and pearl millet (*Pennisetum americanum*) and rot of *Ananas comosus*. Also isolated from cluster bean (*Cyamopsis tetragonolobus*).

The mol% G + C of the DNA is: 56.4 (T_m).

Type strain: ATCC 51785, CIP 104006, LMG 2632.

GenBank accession number (16S rRNA): Y13251.

7. **Pantoea terrea** Kageyama, Nakae, Yagi and Sonoyama 1992, 210^{VP}
ter′re.a. L. n. *terra* soil; L. adj. *terrea* of soil.

The cell morphology and colonial morphology are as given for the genus. The cells are motile by means of one or two lateral flagella. Colonies grown on nutrient agar at 30°C for 2 d are pale beige to pale reddish yellow. Yellow pigment is not produced on nutrient agar. Physiological and nutritional characteristics are presented in Table BXII.γ.240. Key characteristics are: production of 2-ketogluconate dehydrogenase; negative arginine dihydrolase reaction; hydrolysis of esculin but not ONPG; and no utilization of L-arabinose, *meso*-erythritol, gentiobiose, maltose, and D-tagatose as sole carbon and energy sources. Isolated from soil in Japan

The mol% G + C of the DNA is: 51.0–51.9 (HPLC).

Type strain: SHS 2008, ATCC 31628, CCUG 30161, CIP 105600, DSM 13701.

Genus XXIV. **Pectobacterium** *Waldee 1945, 469*[AL] *emend. Hauben, Moore, Vauterin, Steenakcers, Mergaert, Verdonck and Swings 1999a, 1*

Lysiane Hauben, Frederique Van Gijsegem and Jean Swings

Pec.to.bac.te' ri.um. Gr. dim. neut. n. *bakterion* a small rod; M.L. neut. n. *Pectobacterium* a pectolytic bacterium.

Straight rods, 0.5–1.0 × 1.0–3.0 μm, rounded ends; occur singly or in pairs. Gram-negative. Motile by peritrichous flagella. Fermentative. Facultatively anaerobic. Optimum growth temperature, 27–30°C; maximum temperature for growth is 40°C. Oxidase negative. Catalase positive. Acid is produced from ***N*-acetylglucosamine**, fructose, D-galactose, D-glucose, D-mannose, L-rhamnose, D-ribose, salicin, and sucrose but not from adonitol, L-arabitol, D-lyxose, α-methylmannoside, L-sorbose, starch, or D-tagatose. Utilize acetate, arbutin, fructose, fumarate, D-galactose, D-glucose, glycerol, malate, D-mannitol, mannose, β-methylglucoside, ribose, salicin, succinate, and sucrose but not adipate, benzoate, betaine, butanol, gallate, methanol, oxalate, propionate, or sorbose as carbon and energy-yielding sources. Utilize L-alanine, allantoin, γ-aminobutanic acid, ammonium chloride, arginine, asparagine, asparaginic acid, citrulline, glucosamine, glutamine, L-glutaminic acid, glutathione, glycine, glycylglycine, histidine, leucine, L-methionine, phenylalanine, L-serine, L-tryptophan, tyrosine, and urea, but not anthranilic acid, betaine, choline, cysteamine, hydroxyproline, kynureninic acid, quinolinic acid, sarcosine, spermidine, spermine, trigonelline, or trimethylammonium as nitrogen sources. No decarboxylases are formed for arginine, lysine or ornithine. Do not possess tryptophan deaminase or urease. **Hydrolyze esculin but not starch.**

The species of the genus *Pectobacterium* comprise a distinct phylogenetic group, as determined by 16S rRNA gene sequence comparisons, and are characterized by 17 signature nucleotides (Table BXII.γ.223 in Genus *Erwinia*).

Pectobacterium species cause plant diseases that include blights, cankers, die back, leaf spots, wilts, discoloration of plant tissues, and especially soft rots variously described as stalk rot, crown rot, stem rot, or fruit collapse. Ingress by the pathogen generally occurs through natural openings and wounds. Soft rot is characterized by the breakdown of the plant cell wall, leading to maceration of the parenchyma, loss of electrolytes, and cell death. Pectinases and pectate lyases are mainly responsible for these symptoms.

The mol% G + C of the DNA is: 50.5–56.1.

Type species: **Pectobacterium carotovorum** (Jones 1901) Waldee 1945, 469 emend. Hauben, Moore, Vauterin, Steenackers, Mergaert, Verdonck and Swings 1999a, 1 (*Erwinia carotovora* (Jones 1901) Bergey, Harrison, Breed, Hammer and Huntoon 1923, 171; *Bacillus carotovorus* Jones 1901, 12.)

Further descriptive information

Metabolic features are the same as for the genus *Erwinia*. Decarboxylases for arginine, lysine, or ornithine are not present except in a few (usually 5% or less) strains of *Pectobacterium carotovorum* and *Pectobacterium chrysanthemi*.

Pectate lyases are produced by all species except by *Pectobacterium cypripedii*. Cellulases (Cx) are produced by strains of *P. carotovorum*, *P. carotovorum* subsp. *atrosepticum*, and *P. chrysanthemi* (El-Helaly et al., 1979). *P. carotovorum* and *P. chrysanthemi* produce pectinases, cellulases, hemicellulases, and proteases (Garibaldi and Bateman, 1973; Bertheau et al., 1984; Collmer and Keen, 1986; Ried and Collmer, 1986; Wandersman et al., 1986; Willis et al., 1987). *P. carotovorum* produces an endopolygalacturonase (Lei et al., 1985; Willis et al., 1987) as well. The genes encoding these enzymes that have been mapped are located on the chromosome (Chatterjee et al., 1981; Hugouvieux-Cotte-Pattat et al., 1996). In most *Pectobacterium* species, production of the plant cell wall degrading enzyme pectin lyase (Pnl) is activated by DNA-damaging agents such as mitomycin C (MC), nalidixic acid, and UV light (Liu et al., 1994b).

Naturally occurring plasmids have been detected in strains of *P. carotovorum* and *P. chrysanthemi*, and plasmids from bacteria other than *Pectobacterium* have been introduced into strains of the foregoing *Pectobacterium* species (Lacy and Leary, 1979; Chatterjee and Starr, 1980). Plasmid-mediated transfer of chromosomal genes by conjugation also has been reported for strains of *P. carotovorum* and *P. chrysanthemi*.

Plasmid pULB113 (Van Gijsegem and Toussaint, 1982) mediates chromosomal mobilization and R-prime formation in *P. carotovorum* and *P. chrysanthemi* (Chatterjee et al., 1985).

Virulent or temperate phages have reported to be active against strains of *P. carotovorum* (Chapman et al., 1951; Faltus and Kishko, 1980; Pirhonen and Palva, 1988; Gross et al., 1991; Toth et al., 1993) and *P. chrysanthemi* (Paulin and Nassan, 1978). Bacteriocinogeny or production of bacteriocin-like substances has been noted for strains of *P. carotovorum* (Itoh et al., 1978), *P. chrysanthemi* (Echandi and Moyer, 1979), and *Pectobacterium* species from sugar beet (Stanghellini et al., 1977). Bacteriocin-resistant mutants of *P. chrysanthemi* have been isolated (Expert and Toussaint, 1985).

Lipopolysaccharide defective mutants of *P. carotovorum* (Pirhonen and Palva, 1988) and genetically engineered kanamycin resistant strains of *P. carotovorum* (Scanferlato et al., 1989; Orvos et al., 1990) have been isolated.

Antisera prepared against live or heat-killed cells, nonpurified or purified immunogens have been used for the differentiation or identification of all *Pectobacterium* species except *P. cypripedii* (Schaad, 1979). Serogroups have been determined for *P. carotovorum* (De Boer et al., 1979) and *P. chrysanthemi* (Samson and Nassan-Agha, 1978; Yakrus and Schaad, 1979).

More recently, a conductimetric assay was developed for automated detection of *P. carotovorum* subsp. *atrosepticum*, *P. carotovorum* subsp. *carotovorum*, and *P. chrysanthemi* (Fraaije et al., 1996a, 1997), and a luminescence-based assay is available for the detection of *P. carotovorum* (Grant et al., 1992; McLennan et al., 1992).

A strain of *P. carotovorum* subsp. *carotovorum* was found to produce the antibiotic 1-carbapen-2-em-3-carboxylic acid (Bainton et al., 1992b).

16S rDNA sequence analyses of the species of the genus *Pectobacterium* by Kwon et al. (1997) and Hauben et al. (1998a) agree very well, except for the type strain of *P. cypripedii*, and situate the genus *Pectobacterium* within the *Enterobacteriaceae*, closely related to the genera *Pantoea*, *Erwinia*, *Brenneria*, and *Enterobacter* (Fig. BXII.γ.201 and Table BXII.γ.223 of the genus *Erwinia*). The sequence of the type strain of *P. cypripedii*, sequenced by Kwon et al. (1997) (ATCC 29267) and Hauben et al. (1998a) (LMG 2657), differ in 53 nucleotides. The sequence reported by Hauben et al. (1998a) places *P. cypripedii* in the *Pectobacterium* cluster.

Enrichment and Isolation Procedures

The isolation procedure is the same as for the genus *Erwinia*.

The isolation of some *Pectobacterium* species can be facilitated by use of selective-differential media, but such media are usually not necessary. Selective media have been developed for the isolation of pectolytic bacteria (Kelman and Dickey, 1980). The crystal violet pectate (CVP)[1] medium is commonly used. Miller-Schroth (Miller and Schroth, 1972) medium modified by replacement of most of the agar by sodium polypectate selectively allows the growth of pectolytic species. NaOH (105%) and MOPS (3-(-*N*-morpholino)propanesulfonic acid; 0.4%) are added to raise the pH and buffer the medium (Pierce and McCain, 1992). *P. chrysanthemi* strains isolated from plants grow well on LB medium[2].

Maintenance Procedures

Stock cultures of *Pectobacterium* species should be grown on standard media of choice at 25–30°C. The cultures can be maintained for short-term storage in a refrigerator (4–5°C); some strains of *P. chrysanthemi* are nonviable after 3–4 weeks at 4°C, but remain viable for longer periods when stored at 12°C. Long-term preservation is the same as for the genus *Erwinia*.

Differentiation of the genus *Pectobacterium* from other genera

Characteristics that differentiate *Pectobacterium* from the genera *Erwinia*, *Pantoea*, and *Brenneria* are given in Table BXII.γ.223 of the genus *Erwinia*. Apart from their pectolytic nature, it is very difficult to differentiate them phenotypically; genomic methods are recommended for differentiation.

Taxonomic Comments

The species of the genus *Pectobacterium* were formerly classified under *Erwinia*. We refer the reader to the taxonomic comments section of the genus *Erwinia* for a discussion on this issue.

Strains of *P. chrysanthemi* have been isolated from numerous plant species and cultivars (Dickey, 1981). Six pathovars (pathovar *chrysanthemi*, pathovar *dianthicola*, pathovar *dieffenbachiae*, pathovar *paradisiaca*, pathovar *parthenii*, and pathovar *zeae*) have been designated for *P. chrysanthemi* (Dye et al., 1980). The relationship between pathogenicity, phenotypic properties and serological reactions of strains of the pathovars is not clear (Samson and Nassan-Agha, 1978; Yakrus and Schaad, 1979; Dickey, 1981; Thomson et al., 1981).

Differentiation of the species of the genus *Pectobacterium*

The differential characteristics of the species of *Pectobacterium* are given in Tables BXII.γ.241, BXII.γ.242, BXII.γ.243, and BXII.γ.244. Only a small number (eight) of strains of *P. cypripedii* have been studied.

List of species of the genus Pectobacterium

1. **Pectobacterium carotovorum** (Jones 1901) Waldee 1945, 469[AL] emend. Hauben, Moore, Vauterin, Steenackers, Mergaert, Verdonck and Swings 1999a, 1 (*Erwinia carotovora* (Jones 1901) Bergey, Harrison, Breed, Hammer and Huntoon 1923, 171; *Bacillus carotovorus* Jones 1901, 12.)
ca.ro.to′ vo.rum. L. n. *carota* carrot; L. v. *voro* to devour; M.L. adj. *carotovorum* carrot-devouring.

The characteristics are as described for the genus and as listed in Tables BXII.γ.241, BXII.γ.242, BXII.γ.243, and BXII.γ.244. Causes rotting, particularly of storage tissues, of a wide variety of plants and causes a vascular and parenchymal disease (blackleg) of potato plants. The small diffusible autoinducer signal molecule *N*-(β-ketocaproyl) homoserine lactone (KHL) acts as a molecular control signal for the expression of genes controlling carbapenem antibiotic biosynthesis (Bainton et al., 1992a). The *pnl* gene, encoding pectin lyase (Ohnishi et al., 1991), and the *peh* gene, encoding polygalacturonase (Peh) (Lei et al., 1992) of *P. carotovorum*, have been located and characterized.

Subspecies can be differentiated by (1) PCR with primers Y1 (5′-TTACCGGACGCCGAGCTGTGGCGT-3′) and Y2 (5′-CAGGAAGATGTCGTTATCGCGAGT-3′), annealing at 65°C, and (2) restriction fragment length polymorphism (RFLP) of a *pel* gene identifying *P. carotovorum* subsp. *atrosepticum* and *P. carotovorum* subsp. *wasabiae* strains (Darrasse et al., 1994b). The pectate lyase (*pel*) genes I and III were characterized by Nikaido et al. (1985) and Yoshida et al. (1991), respectively. RAPD-PCR can differentiate *P. carotovorum* subsp. *carotovorum* and *P. carotovorum* subsp. *atrosepticum* (Maki-Valkama and Karjalainen, 1994; Parent et al., 1996) and a DNA probe, isolated from a genomic library, can differentiate the subspecies *P. carotovorum* subsp. *carotovorum*, *P. carotovorum* subsp. *atrosepticum*, and *P. carotovorum* subsp. *betavasculorum* (Ward and De Boer, 1990).

The bacteriocin carotovoricin was identified (Itoh et al., 1982) and the gene *recA*, which is required for its induction (Zink et al., 1985, Zhao and McEntee, 1990). Monoclonal antibodies were developed for detection of *P. carotovorum* subsp. *carotovorum*, *P. carotovorum* subsp. *atrosepticum*, and *P. carotovorum* subsp. *betavasculorum* (Ward and De Boer, 1989; Murray et al., 1990a; Vernon-Shirley and Burns, 1992). *Drosophila melanogaster* Meigen and *Drosophila rucksii* Coquillett can function as vectors for *P. carotovorum* subsp. *carotovorum* and *P. carotovorum* subsp. *atrosepticum* (Brewer et al., 1981).

The mol% G + C of the DNA is: 50.5–53.1 (T_m, Bd).
Type strain: ATCC 15713, NCPPB 312, ICMP 5702.

a. **Pectobacterium carotovorum** *subsp.* **carotovorum** (Jones 1901) Waldee 1945, 469[AL] (*Erwinia carotovora* subsp. *carotovora* Bergey, Harrison, Breed, Hammer and Huntoon 1923, 171.)

Characteristics distinguishing this subspecies from the other *Pectobacterium carotovorum* subspecies are indicated in Table BXII.γ.243.

The production of extracellular enzymes such as pectate lyase (Pel), polygalacturonase (Peh), cellulase (Cel), and protease (Prt) is activated by the cell density (quorum)-sensing signal, *N*-(3-oxohexanoyl)-L-homoserine lactone (HSL), and/or CarR (Barras et al., 1994). *RmsA*, a global repressor gene, controls the production of these

1. CVP medium consists of 1N NaOH, 4.5 ml; 10% $CaCl_2 \cdot H_2O$, 3 ml ; Bacto-agar, 1.5 g; $NaNO_3$, 1 g; Bacto-yeast extract, 0.05 g; blended with 300 ml boiling distilled water for 15 s, to which 15 g sodium polypectate and 200 ml boiling distilled water is added and blended (Cuppels and Kelman, 1974; Woodward and Robinson, 1990).

2. LB medium consists of (per l distilled water) tryptone, 10 g; yeast extract, 5 g; NaCl, 10 g.

enzymes and tissue macerating ability (Bainton et al., 1992b; Cui et al., 1995; McGowan et al., 1995; Mukherjee et al., 1996). The gene *aepA* (activator of extracellular protein production) controls the production of pectolytic enzymes Pel, Peh, Cel, and Prt (Liu et al., 1993c; Murata et al., 1994), and the *out* gene cluster encoding the proteins of the type II or general secretory pathway (GSP) apparatus is required for secretion of pectinases and cellulases (Reeves et al., 1993; Thomas et al., 1997). The *pnlA* gene, encodes DNA damage-inducible pectin lyase (Chatterjee et al., 1991) and *rdgB* encodes a transcriptional factor that specifically interacts with the pectin lyase structural gene *pnlA* promoter/regulatory region (Liu et al., 1997e). The *pnlA* gene is activated by DNA-damaging agents like RecA, RdgA, and RdgB. RdgA and RdgB also control bacteriocin production, phage release, and cell lysis (Barras et al., 1994).

A pleiotrophic reduced virulence (Rvi-negative) mutant was found to be defective in flagella assembly proteins (Mulholland et al., 1993). Several monoclonal antibodies have been produced against *P. carotovorum* subsp. *carotovorum* strains that can be used for identification and detection by Ouchterlony double diffusion (ODD), indirect immunofluorescence (IIF), and enzyme-linked immunosorbent assay (ELISA) (Alarcon et al., 1995), and for detection by reverse passive hemagglutination (RPH) (Koehm and Eggers-Schumacher, 1995).

Pseudomonas fluorescens strains are antagonistic (biological control agent) to *P. carotovorum* subsp. *carotovorum* (El Hendawy et al., 1998). Causes rotting, particularly of storage tissues, of a wide variety of plants, e.g., mushroom (*Agaricus* sp.), century plant (*Agave* sp.), mustard (*Brassica campestris*, *B. nigra*, and *B. juncea*), Chinese cabbage (*Brassica chinensis*), cauliflower (*Brassica oleracea* var. *botrytis*), cabbage (*Brassica oleracea* var. *capitata*), Brussels sprouts (*Brassica oleracea* var. *gemmifera*), broccoli (*Brassica oleracea* var. *italica*), turnip (*Brassica rapa* var. *rapa*), and ornamental plants. Larger fleshy organs are particularly susceptible and, once infected, they usually become softened to a pulp very quickly.

The mol% G + C of the DNA is: 50.5–53.1 (T_m, Bd).

Type strain: ATCC 15713, DSM 30168, LMG 2404.

GenBank accession number (16S rRNA): Z96089, U80197.

b. **Pectobacterium carotovorum** *subsp.* **atrosepticum** (van Hall 1902) Hauben, Moore, Vauterin, Steenackers, Mergaert, Verdonck and Swings 1999a, 1[VP] (Effective publication: Hauben, Moore, Vauterin, Steenackers, Mergaert, Verdonck and Swings 1998a, 393) (*Erwinia carotovora* subsp. *atroseptica* (van Hall 1902) Dye 1969a, 81; *Bacillus atrosepticus* van Hall 1902, 134.)
at.ro.sep' ti.cum. L. adj. *ater* black; Gr. adj. *septicus* producing a putrefaction; M.L. adj. *atrosepticum* producing a black rot.

Characteristics distinguishing this subspecies from the other *P. carotovorum* subspecies are indicated in Table BXII.γ.243. Several regions of the bacterial DNA of *P. carotovorum* subsp. *atrosepticum* seem to be subspecies-specific and can be used for identification by (1) genomic subtraction of DNA probes (Darrasse et al., 1994a);

EcoRI digest of a cloned library (Ward and De Boer, 1994).

Several monoclonal antibodies have been produced against *P. carotovorum* subsp. *atrosepticum* strains that can be used for identification and detection in cell suspensions as well as in plant material by (1) ODD (Alarcon et al., 1995); (2) IIF with a sensitivity of up to 240 cells/ml (De Boer and McNaughton, 1987; Gorris et al., 1994; Alarcon et al., 1995); (3) ELISA with a sensitivity of up to 10^3 cells/ml tuber peel extract (Jones et al., 1993; Gorris et al., 1994; Alarcon et al., 1995; Basalp et al., 1995; Hyman et al., 1995; Pérombélon and Hyman, 1995); (4) immunofluorescence (IF) cell staining with a sensitivity of up to 10^5 cells/ml tuber peel extract (Fraaije et al., 1996b); (5) immunofluorescence colony staining (Gorris et al., 1994; Pérombélon and Hyman, 1995; Schober and Van Vuurde, 1997); and (6) slide agglutination test (McLeod and Pérombélon, 1992).

Causes a vascular and parenchymal disease (blackleg) of potato (*Solanum tuberosum*), cauliflower (*Brassica oleraceae* var. *botrytis*), tomato (*Lycopersicon esculentum*), and cabbage (*Brassica oleracea* var. *capitata*), and a storage rot of potato tubers. Bases of stems are blackened, rotted, and slimy. Plants wilt and are stunted or die. The soft rot may affect various parts of the plant, particularly the tubers in storage.

The mol% G + C of the DNA is: 51.3–53.1 (T_m, Bd).

Type strain: ATCC 33260, NCPPB 549, LMG 2386.

GenBank accession number (16S rRNA): Z96090.

c. **Pectobacterium carotovorum** *subsp.* **betavasculorum** (Thomson, Hildebrand and Schroth 1981) Hauben, Moore, Vauterin, Steenackers, Mergaert, Verdonck and Swings 1999a, 1[VP] (Effective publication: Hauben, Moore, Vauterin, Steenackers, Mergaert, Verdonck and Swings 1998a, 393) (*Erwinia carotovora* subsp. *betavasculorum* Thomson, Hildebrand and Schroth 1981, 1040.)

be.ta.vas.cu.lo′ rum. L. n. *beta* beet; L. n. *vasculum* vascular tissue; M.L. pl. gen. n. *betavasculorum* of the beet's vascular tissues.

Characteristics distinguishing this subspecies from the other *Pectobacterium carotovorum* subspecies are indicated in Table BXII.γ.243. Strain Ecb168 was found to produce an antibiotic that suppresses growth of *P. carotovorum* subsp. *carotovorum* (Costa and Loper, 1994). Causes soft rot and vascular necrosis of sugar beet (*Beta vulgaris*) and, after artificial inoculation, of potato stems.

The mol% G + C of the DNA is: 54.4–54.7 (T_m, Bd).

Type strain: ATCC 43762, NCPPB 2795, LMG 2466.

GenBank accession number (16S rRNA): U80198, Z96091.

d. **Pectobacterium carotovorum** *subsp.* **odoriferum** (Gallois, Samson, Ageron and Grimont 1992) Hauben, Moore, Vauterin, Steenackers, Mergaert, Verdonck and Swings 1999a, 1[VP] (Effective publication: Hauben, Moore, Vauterin, Steenackers, Mergaert, Verdonck and Swings 1998a, 394) (*Erwinia carotovora* subsp. *odorifera* Gallois, Samson, Ageron and Grimont 1992, 586.)

o.do.r.i′ fe.rum. L. masc. adj. *odoriferum* bringing odors, fragrant.

Characteristics distinguishing this subspecies from the other *Pectobacterium carotovorum* subspecies are indicated in Table BXII.γ.243. Grow on nutrient agar, producing colonies that are about 2.5 mm in diameter after 48 h at 25°C and also on yeast peptone dextrose (YPDA) medium (3 g/l yeast extract, 5 g/l peptone, 5 g/l dextrose, 15% agar). Colonies are circular, grayish (to yellowish on media containing sucrose or gelatin), slightly domed, and semitranslucent. Causes odorous soft rot of chicory (*Cichorium intybus* L.). The disease typically results in water-soaked, translucent, wet rot of the etiolated leaves. The development of slimy rot in witloof chicories is always associated with the production of a sweet, ripe, banana-like odor.

The mol% G + C of the DNA is: unknown.

Type strain: CFBP 1878, LMG 17566.

GenBank accession number (16S rRNA): AJ223407.

e. **Pectobacterium carotovorum** *subsp.* **wasabiae** (Goto and Matsumoto 1987) Hauben, Moore, Vauterin, Steenackers, Mergaert, Verdonck and Swings 1999a, 1[VP] (Effective publication: Hauben, Moore, Vauterin, Steenackers, Mergaert, Verdonck and Swings 1998a, 393) (*Erwinia carotovora* subsp. *wasabiae* Goto and Matsumoto 1987, 132.)
wa.sa' bi.a.e. L. gen. n. *wasabiae* of wasabi (*Eutrema wasabi*), name of host plant.

Characteristics distinguishing this subspecies from the other *Pectobacterium carotovorum* subspecies are indicated in Table BXII.γ.243. Colonies on yeast extract-peptone agar plates at 28°C are white, transparent, circular with entire margins, convex, and 1.0–2.0 mm in diameter after 24 h. Growth on yeast extract-peptone agar slants is moderate, white, and butyrous, with high viability. Abundant growth is obtained on yeast extract-peptone agar slants supplemented with glucose or on potato-glucose agar slants, although viability on these media is poor. Causes soft rot and an internal black discoloration on slices of wasabi rhizomes and, after artificial inoculation, also on potato tubers, carrot and radish roots, midribs of chinese cabbage and intact wasabi, and tomato and tobacco plants.

The mol% G + C of the DNA is: 51.4–51.7 (T_m).

Type strain: ATCC 43316, ICMP 9121, LMG 8444.

GenBank accession number (16S rRNA): U80199, AJ223408.

2. **Pectobacterium cacticida** (Alcorn, Orum, Steigerwalt, Foster, Fogleman, and Brenner 1991) Hauben, Moore, Vauterin, Steenackers, Mergaert, Verdonck and Swings 1999a, 1[VP] (Effective publication: Hauben, Moore, Vauterin, Steenackers, Mergaert, Verdonck and Swings 1998a, 394) (*Erwinia cacticida* (Hori 1911) Dye 1969a, 93; *Erwinia cypripedii* Alcorn, Orum, Steigerwalt, Foster, Fogleman, and Brenner 1991, 210.)
cac.ti.ci' da. Gr. n. *kaktos* prickly plant; Gr. v. *cid* to kill; L. adj. *cacticida* cactus killing.

The characteristics are as described for the genus and as listed in Tables BXII.γ.241 and BXII.γ.242. Colonies grown on PDP (40 g potato dextrose agar (Difco), 5 g agar, 20 g peptone, 1 l distilled water, pH 7.2) for 24 h at 30°C are small, smooth, glistening, circular, entire, slightly convex, ivory, and translucent, and frequently have striations. They produce a distinct odor and become opaque, off-white, and butyrous with age. Causes soft rot of *Opuntia* (cactus) fruits and pads. After artificial inoculation, also causes soft rot of saguaro, organ pipe, senita cacti, tomato fruits, potato slices, and slices of carrot roots.

The mol% G + C of the DNA is: 50.8–51.7 (T_m).

Type strain: ATCC 49481, LMG 17936, ICPB EC186.

GenBank accession number (16S rRNA): AJ223409.

3. **Pectobacterium chrysanthemi** (Burkholder, McFadden and Dimock 1953) Brenner, Steigerwalt, Miklos and Fanning 1973b, 205[AL] emend. Hauben, Moore, Vauterin, Steenackers, Mergaert, Verdonck and Swings 1999a, 1 (*Erwinia chrysanthemi* Burkholder, McFadden and Dimock 1953, 526.)
chrys.an' the.mi. M.L. n. *Chrysanthemum* generic name; M.L. gen. n. *chrysanthemi* of chrysanthemums.

The characteristics are as described for the genus and as listed in Tables BXII.γ.241 and BXII.γ.242.

Colonies on potato–glucose agar (pH 6.5) (ATCC culture medium 97) are characteristically umbonate with undulate to coralloid margins ("fried egg") at 3–6 d.

The chrysobactin-mediated iron uptake is essential in enabling the bacterium to systematically attack plants (Expert et al., 1996). Chrysobactin (*N*-(N^2-(2,3-dihydroxybenzoyl)-D-lysyl)-L-serine) is a compound with siderophore activity (Persmark et al., 1989). The iron status is involved in *pel* regulation. Iron acquisition involves an inductive process resulting in differential expression of two siderophore-mediated pathways in relation to external accessibility (Mahe et al., 1995).

The general protein secretory pathway was studied by mutagenesis of cellulase EGZ (Py et al., 1993). *P. chrysanthemi* produces four proteases encoded by *prtA*, *prtB*, *prtC*, and *prtG*, and they are secreted by a type I secretion system encoded by *prtD*, *prtE* (inner membrane), and *prtF* (outer membrane) (Barras et al., 1994). PrtG is an extracellular metalloprotease secreted through a signal peptide-independent secretion pathway. The COOH-terminal exposition of the last four amino acids in the secretion of PrtG plays a key role in the protease secretion pathway (Ghigo and Wandersman, 1994). These metalloproteases are secreted independently of the general export pathway encoded by the *sec* genes. They are secreted via a C-terminal secretion signal and by a secretion apparatus composed of the two inner membrane proteins, PrtD and PrtE, and the outer membrane protein PrtF. PrtD exhibits a secretion signal-regulated ATPase activity (Delepelaire, 1994). PrtD is the ATP-binding cassette (ABC) integral membrane component from the metalloprotease secretion system. PrtA and prtB are two tandem metalloprotease-encoding structural genes (Boyd and Keen, 1993). Further, *P. chrysanthemi* produces two cellulases, encoded by *celZ* (the majority) and *celY* (5% of the total activity), and four types of pectinases. The importance of these various isoenzymes in pathogenicity depends on the plant species infected (Barras et al., 1994). The pectinases are subjected to multiple regulations—KdgR, PecT, PecS, PecM—and products of pectic catabolism encoded by *ogl*, *kduI*, *kduD*, *kdgK*, and *kdgA*. Mutants were isolated, containing genetic fusions of the *kdgK*, encoding 2-keto-3-deoxygluconate (KDG) kinase (Hugouvieux-Cotte-Pattat et al., 1994) or *kdgA* genes to the *lacZ* gene of *Escherichia coli* by infection of a *lacZ* mutant of *E. chrysanthemi* with the phage Mu d(Ap lac) (Hugouvieux-Cotte-Pattat and Robert-Baudouy, 1985). A second set of secondary pectate lyases are preferentially expressed in plants (Barras et al., 1994). The *out* genes are required for the translocation across the outer membrane during secretion of pectate lyases, pectin methyl esterases, exopolygalacturonases, and CelZ. An open reading frame *outT*, located between *outB* and *outC*, has no homology with the *pul* cluster but is involved in secretion. *OutC*, *outD*, and *outE* form an operon, while *outS*, *outB*, and *outT* constitute independent transcription units. *OutT* and the *outCDE* operon are regulated by *kdgRa*, encoding a repressor that negatively regulates the expression of genes involved in pectinolysis and in pectinase secretion. *OutB* and *outS* seem to be expressed constitutively (Ji et al., 1989; Condemine et al., 1992; Nasser et al., 1994).

Mutants defective in secretion of pectinase and cellulase were obtained by chemical and insertion mutagenesis (Andro et al., 1984).

The regulation of pectinolysis was reviewed by Hugouvieux-Cotte-Pattat et al. (1996). Four types of pectinases have been identified: two pectin methyl esterases (PemA, PemB), a polygalacturonase (PehX), nine pectate lyases (PelA, PelB, PelC, PelD, PelE, PelI, PelL, PelZ, PelX), and a pectin acetyl esterase (PaeY) (Shevchik et al., 1997). PecT, encoded by *pecT*, represses the expression of pectate lyase genes *pelC, pelD, pelE, pelL,* and *kdgC*, activates *pelB*, and has no effect on the expression of *pelA* or the pectin methylesterase genes *pemA* and *pemB*. *PecT* activates its own expression (Surgey et al., 1996). *PecS* encodes a repressor that negatively regulates the expression of virulence factors such as pectinases or cellulases (Reverchon et al., 1994; Praillet et al., 1996, 1997). The oligogalacturonate lyase (*ogl*) gene is involved in oligogalacturonides degradation (Reverchon and Robert-Baudouy, 1987) and the *pem* gene encodes the pectin methylesterase (PME) (Laurent et al., 1993). *kduD* mutants altered in pectin degradation were isolated by chemical and Mu d(Ap lac) insertion mutagenesis (Condemine et al., 1986).

Harpins are synthesized in a nutrient-deprived medium and induce plant response, including alkalinization of the apoplastic fluid. Harpin from *P. chrysanthemi* contributes to soft-rot pathogenesis (Bauer et al., 1995). Harpins are encoded by the *hrp* genes, which have at least three biochemical functions: gene regulation, protein secretion, and production of HR elicitor proteins.

P. chrysanthemi strains can be genotypically characterized by RFLP of PCR-amplified fragments of *pel* genes (Nassar et al., 1996a) and ribotyping, which correlates well with the established pathovars (Nassar et al., 1994).

A transducing phage Phi EC2 was described by Resibois et al. (1984) and Phi EC2-resistant mutants, lipopolysaccharide-defective, were isolated by Schoonejans et al. (1987).
